It has to be noted that what is usually defined is the gain of the whole antenna system, not just the gain of the aperture antenna in isolation. Therefore, all other losses such as mismatch and ohmic losses have to be taken into consideration. A well-designed aperture antenna fed by a poorly designed feed system results in poor performance.

Polarization

The radiated far-field of a horn antenna can be decomposed into two components: The one in the direction of the desired polarization is called co-polarization, and the orthogonal component is called cross-polarization. Polarization performance measurement can determine, in general, how much power is radiated in the undesired polarization which cannot be received by receiving antennas. The most common measurement is the peak cross-polarization level for linear polarization and the axial ratio for circular polarization. The measurement of the cross-polarization can be achieved in different ways. For linearly polarized horns, the co-polar pattern is measured by aligning the test antenna with the

polarization of the distant source antenna, and the cross-polar pattern is obtained by rotating the source antenna by 90° and repeating the radiation pattern measurement.

Functioning environment

Consideration of the working environment in which the antenna is likely to operate is important in design process as well. In many cases this too will dictate the choice of materials and the mechanical aspects of the system. One consideration is the potential effects of surrounding objects on the horn's performance. A horn antenna may work perfectly well in isolation but give poor performance when surrounded by nearby scatterers. A typical effect is

caused by conductive surrounding objects which are fitted afterward in forms of blockage or radome effect. Other considerations are any special needs for horn antennas such as pressurization, high-power handling, low passive intermodulation level, robustness, and low-loss requirements.

Conventional horn antennas

Rectangular horn

Rectangular horns are constructed by gradually flaring a rectangular waveguide to provide a smooth transition from the input to free space. If the flare angle is small enough so that the higher-order modes can be

Microwave Horn Antennas, Figure 6 Gain characteristics of pyramidal horns of optimum-gain design.

Microwave Horn Antennas, Figure 7 Universal patterns of pyramidal horns of optimum-gain design.

neglected, the transverse electric field of the dominant mode of the waveguide is a good first approximation to the aperture field at the horn mouth. For reference, some important characteristics of the open-ended rectangular waveguide (Figure 3) are shown in Figure 4.

Depending on to what plane its opening tapers rectangular horns may be classified as E-plane sectoral, H-plane sectoral, or pyramidal horns (Figure 5). The type, direction, and amount of taper can have a significant effect on the overall performance of the horn. The radiation characteristics can be determined using the aperture field

Microwave Horn Antennas, Figure 8 Gain characteristics of conical horns of optimum-gain design.

Microwave Horn Antennas, Figure 10 Profiled conical corrugated horn.

method or GTD construction (Jull, 1973; Huang et al., 1983). The latter is also capable of predicting the near field and back-radiated field. Considerable amounts of design data are available on rectangular horns, and the reader is referred to the just-mentioned references (Balanis, 1988, 1996; Bird and Love, 2007).

For pyramidal horns, the geometrical parameters may be chosen to achieve the so-called optimum-gain design (Balanis, 1988). Figure 6 shows the relationship between the parameters to design an optimum-gain horn for a specified gain (the overall efficiency of these horns is typically about 50 %). Figure 7 is the plot of the E- and H-plane patterns of such horns.

Conical horns

The geometry of a circular horn is shown in Figure 8. In contrast to pyramidal horns which are typically fed by rectangular waveguides, the circular horn is usually fed by circular waveguides. The aperture field of these horns can be constructed in a fashion similar to that of pyramidal horns by simply multiplying the aperture field of the circular waveguide by a quadratic phase term (Balanis, 1988). The resulting integral for the computation of the radiated field can then be evaluated numerically. Figure 8 gives the proper horn dimensions for constructing an optimum-gain horn for a specified gain. These horns typically possess more symmetric E- and H-plane patterns than do their pyramidal horn counterparts. They can also be used more effectively to create circularly polarized fields.

Multimode, corrugated, matched horns, and others

The requirements for designing more advanced remote sensing systems have resulted in the generation of a new class of feeds. These feeds in particular are used in large reflectors for radio astronomy and remote sensing reflectors. Among them one may refer to multimode (Potter, 1963; Thomas, 1970;

Bhattacharyya and Goyette, 2004), corrugated (hybrid mode) (Clarricoats and Olver, 1984; James, 1984; Thomas et al., 1986; Olver et al., 1994), and matched horns (Rudge and Adatia, 1975; Bahadori and Rahmat-Samii, 2006).

Multimode horns were invented to equalize the pattern asymmetry of single-mode horns. For instance, in the Potter horn (Potter, 1963) the TM_{11} mode is generated along with the dominant TE_{11} mode of a circular horn. Although this new TM_{11} mode does not have any appreciable effect on the H-plane radiation pattern, when it is properly phased and combined with the TE_{11} mode, it can effectively alter the E-plane aperture distribution, which results in a symmetric radiation pattern. All these favorable features, however, cannot be properly realized until the feed aperture diameter exceeds about 1.3λ . For example, Figure 9 shows the radiation pattern of a dual-mode Potter horn as reported in Potter (1963). A partial conversion of the TE_{11} mode energy to a TM_{11} mode happens in the flared section of the horn, while the straight section enforces the condition that both modes have the proper phase relation at the aperture which can be maintained over a bandwidth of less than 10 %. There are also available other types of multimode horns, which result from a combination of modes such as TE_{10} , TE_{12} , and TM_{12} in a square-aperture pyramidal horn.

Corrugated horns have become the main choice of antenna feeds in recent advanced communications, radar, and remote sensing applications where demanding performance is required. First introduced in the 1960s (Minnett and Thomas, 1966; Simmons and Kay, 1966), they can provide superior radiation performances such as symmetric patterns and low cross-polarization levels compared with conical horns.

Corrugated horns are capable of creating similar boundary conditions at all polarizations which result in similar tapers in the aperture field distribution in all planes. Due to these boundary conditions, symmetric radiation

Microwave Horn Antennas, Figure 11 20 dB half beamwidths of corrugated horns.

patterns can be obtained at levels as low as -25 dB in both the E- and H-planes. A corrugated horn can be realized by grooving the E-plane of a pyramidal horn or the entire wall of a circular horn with, typically, six or more slots (corrugations) per wavelength (Figure 10). For circular corrugated horns, Figure 11 shows the plots of the pattern widths at 20 dB level as a function of the opening angle.

The existence of the corrugations, especially near the waveguide-horn junction, affects the VSWR of the horn. The usual practice is to begin the corrugations at a small distance from the junction. These horns are also classified as hybrid-mode horns because they support modes in which both longitudinal E- and H-field components are present. In a circular corrugated horn, a natural mixture of TE_{11} and TM_{11} results in the generation of a hybrid-mode HE_{11} . In contrast to dual-mode horns there is no need of a mode converter, and therefore, the

hybrid-mode horns have typically wider bandwidths. In particular, one version of these hybrid horns (scalar horns), which has a large flare angle with a relatively short horn, has radiation characteristics with little dependence on frequency. There now exists advanced computational and optimization methods (Sinton et al., 2002) to tailor corrugated horn antennas for various applications including profiled corrugated horns with shorter lengths than the standard straight corrugated horns.

There are other horn feeds which are properly tailored to specifically overcome some undesirable characteristics of reflectors. For example, matched horn feeds (Rudge and Adatia, 1975; Bahadori and Rahmat-Samii, 2006) are used to significantly reduce the generation of unwanted cross-polarized fields in an offset parabolic reflector illuminated with a tilted horn feed. The basic concept behind these designs is to match the horn

aperture field distribution with the receiving focal plane distribution of the reflector.

There also exists a class of dielectric horns with some unique properties, as described in Oh et al. (1970), Baldwin and McInnes (1973), and Jha et al. (1975), and other configurations (Love, 1962; Vokurka, 1979).

Summary

Microwave horn antennas are widely used as standard gain antennas for antenna testing or evaluation or feeds for other antennas due to their simple and solid geometries and excellent performances. Among many different types of horns, rectangular pyramidal horns and conical horns, multimode and corrugated horns are the most popular and practical configurations, and a selection of a specific type is made based on the design specifications such as bandwidth, gain and aperture efficiency, polarization, and some other unique radiation characteristics. With the advances in computational and optimization methods, more sophisticated designs such as profiled corrugated horns and matched horns are developed for demanding applications in radars, satellite communications, remote sensing, deep-space telemetry, and radio astronomy.

Passive microwave radiometer (PMR)

Definition

The microwave radiometer is a calibrated receiver that measures properties of the natural emission from the environment as picked up by an antenna system.

Introduction: what is radiometry about?

All bodies at a temperature above the absolute zero ($0\text{ K} = -273\text{ }^{\circ}\text{C}$) radiate power, according to Planck's law. At microwave frequencies the Rayleigh-Jeans approximation holds, and the radiation is proportional to physical temperature. Actually, this is only true for the

so-called blackbodies, which are perfect emitters. Natural bodies radiate less, and we introduce the term emissivity (ϵ) which is a number between 0 and 1 describing how well the body radiates relative to a blackbody. Within radiometry the radiated power is expressed as the so-called brightness temperature, T_B , so that $T_B = \epsilon \cdot T_{\text{phys}}$. The brightness temperature of a blackbody is thus equal to its physical temperature, while all natural bodies will have brightness temperatures lower than that. The brightness temperature of a natural body can also be understood as that physical temperature a blackbody would have to have in order to emit the power in question. Typical values related to planet Earth range from almost 0 K (looking up toward free space) to about 300 K.

The radiated energy can be picked up by an antenna in order to be measured by a radiometer. Unfortunately antennas are not perfect: a perfect antenna would have a sharply defined main lobe so that when this is pointed toward the target, only this contributes to the received power. But the main lobe is not with sharp cutoff, so some power is received from the surroundings of the target. Furthermore, antennas have side lobes far from the main lobe meaning that some power is also received from other directions. The process can be expressed by the following equation:

$$T_A = \frac{1}{4\pi} \cdot \int_{4\pi} T_B(\theta, \phi) \cdot G(\theta, \phi) d\Omega. \quad (1)$$

This convolution integral, where $G(\theta, \phi)$ is the antenna radiation pattern, shows how the received power, denoted as the so-called antenna temperature T_A , is a gain-weighted summation of the brightness temperatures $T_B(\theta, \phi)$ from each direction (see Ulaby et al., 1981).

Sensitivity

As stated above, the task of the radiometer is to measure the power picked up by the antenna. So in fact the radiometer is basically a calibrated microwave receiver. The basic and simplest radiometer, the total power radiometer, is illustrated in Figure 1a.

The received power is amplified with a gain G , a certain bandwidth B around the center frequency is selected by the filter, the microwave signal is detected by a square law detector, and since we are handling noise-like signals, a certain integration time τ is required. Finally, it is indicated that we cannot make a receiver without introducing an additional noise T_N .

The output will represent a power measure expressed as $P = k \cdot B \cdot G \cdot (T_A + T_N)$ where k is Boltzmann's constant: $1.38 \cdot 10^{-23}$ J/K. As already stated the signals are noise-like, so the output fluctuates, but the fluctuations are smoothed by the integration. The level of fluctuations, the standard deviation of the output to be specific, is expressed as the radiometer sensitivity, ΔT , and it is calculated from Eq. 2:

$$\Delta T = \frac{T_A + T_N}{\sqrt{B \cdot \tau}}. \quad (2)$$

Stability and accuracy

A fundamental problem with this simple and direct implementation of the radiometer is that the output, $P = k \cdot B \cdot G \cdot (T_A + T_N)$, is dependent on stability of the gain G and the receiver noise temperature T_N . Hence, stability may be problematic, and frequent calibration is required, or a more developed radiometer principle must be employed (Skou and LeVine *cpoo*).

If k , B , G , and T_N are not only constants but known constants, we have no absolute accuracy problems: a given T_A results in a given P that can be calculated. Such knowledge of the constants is rarely available, leading to the necessity for calibration. This illustrates the fundamental difference between stability and accuracy: stability is a highly appreciated virtue of an instrument, but a stable instrument need not be accurate. The steps toward accuracy include the calibration process.

In the following we will describe a slightly different aspect of absolute accuracy, which stresses the care that must be exercised when designing or working with radiometers. Consider losses in a signal path – it could be the waveguide connecting the antenna with the radiometer input or a passive component in the radiometer front end. Let ℓ denote the fractional loss (or the absorption coefficient) and T_0 the physical temperature. T_1 is the input temperature and the output temperature is then given by $T_2 = T_1 (1 - \ell) + \ell \cdot T_0$.

The difference between output and input is $T_D = T_2 - T_1 = \ell (T_0 - T_1)$. If T_1 is 100 K and T_0 is 300 K, a loss as small as 0.01 dB ($\ell = 0.0023$) results in a difference, T_D , of 0.5 K. Bearing in mind that the losses of a real signal path are much greater than 0.01 dB, the physical temperature of the path must be measured and used for correction of the measured brightness temperature. The corresponding losses must be known to an accuracy of better than 0.01 dB and must remain stable within the same limits.

Consider a mismatch, for example, at the input of a radiometer; with a reflection coefficient ρ , we similarly find $T_D = \rho (T_{\text{RAD}} - T_1)$ where T_{RAD} is the microwave temperature as seen from the point of reflection into the radiometer. T_{RAD} is typically 300 K and if T_1 again is assumed to be 100 K, a reflection coefficient of -26 dB will give an error (T_D) of 0.5 K. Care must be exercised to obtain reflection coefficients better than -26 dB.

Radiometer types

The conventional radiometers are illustrated to the left in Figure 1, while the more advanced types are illustrated by the correlation radiometer to the right.

The total power radiometer has already been discussed. It is the simplest and basic radiometer that has the optimum sensitivity but may have problems with stability.

Microwave Radiometers, Figure 1 Two conventional radiometer types: (a) total power and (b) Dicke and (c) the correlation radiometer.

The classical way of alleviating stability problems is to employ switching as done in the Dicke radiometer (Figure 1b). The idea here is that the radiometer in fact measures the difference between the unknown antenna temperature and an internal, known reference. The Dicke radiometer has proven very good behavior and has been widely used. An enhanced version of the Dicke radiometer is the noise injection radiometer (NIR) in which a null-balancing technique is employed resulting in total independence of gains and receiver noise temperatures. A price has to be paid for the enhanced stability of Dicke type switching radiometers: the sensitivity is degraded by a factor of 2 compared with that of the total power radiometer.

More advanced radiometers are very often based on the correlation radiometer shown in Figure 1c. It basically consists of two total power radiometers, but in addition to the usual detected outputs, the signals before detection in the two channels are cross correlated to produce two additional outputs: the real and imaginary part of the correlation. The correlation radiometer is the building block of interferometric, synthetic aperture radiometer systems and often also of polarimetric radiometer systems.

Radiometer antennas

An important part of any radiometer system is its antenna. The purpose of the antenna is to collect the emitted energy from a target and present it to the radiometer input. Thus, the antenna radiation pattern determines the spatial resolution of the radiometer system. Important antenna parameters are main beam efficiency and side lobe level. A good beam efficiency and low side lobes ensure that the radiometer system primarily measures what the antenna points toward and not so much the surroundings. Of paramount importance for a radiometer antenna is low loss following the previous accuracy discussion.

Hence, the most popular antenna types are the microwave horn and reflector antennas.

Horns are bulky, low-gain devices and as such normally not used as primary spaceborne antennas, but they play an important role in ground-based and airborne systems and as feeds for reflector antennas. Especially Potter horns and dual-mode horns are favored due to excellent radiation patterns.

Reflector antennas – typically based on offset parabolic reflectors – have been used extensively in spaceborne systems. They feature low loss and good radiation patterns, and, very importantly, they can serve a wide range of frequencies (e.g., 5–90 GHz) through the use of clusters of feed horns.

For the antennas discussed here, where the electrical aperture is roughly equal to the physical aperture, it is very simple to estimate the width of the main beam. The 3 dB beamwidth is slightly larger than the reciprocal of the aperture measured in wavelengths of the operating frequency:

$$\theta = 1.4 \cdot \frac{\lambda}{D}. \quad (3)$$

The factor 1.4 reflects the need for high beam efficiency. A 1 m reflector antenna used at 30 GHz (1 cm wavelength) will thus have a 0.014 ($= 0.8^\circ$) beamwidth. Looking straight down from a satellite in an 800 km orbit, the footprint on Earth will be 11.2 km. Spaceborne radiometer systems are not high-resolution devices like optical scanners or synthetic aperture radars, but they do supply unique data for geophysical interpretation with frequent coverage of the globe.

Calibration

The purpose of calibration is to establish the relation between the input brightness temperature and the

Microwave Radiometers, Figure 2 Antenna target calibrator, principle, and practical layout.

radiometer output – usually digital numbers following analog to digital conversion of the radiometer output voltage. Assuming that the radiometer transfer is linear, two calibration points are required, typically one hot around 300 K and one cold in the 0–77 K range. The most obvious solution is a cooled microwave termination. A well-matched load will generate a noise temperature equal to its physical temperature – and the physical temperature is easily measured. If the load is left at room temperature, it provides a hot calibration point, and if it is submerged into liquid nitrogen, it will be a cold load at around 77 K. However, the latter is not quite as easy as it sounds: heat flow into the load must be prevented, and the loss in the input transmission line must be corrected for.

An alternative solution is a cooled target viewed by a suitable antenna connected to the radiometer (see Figure 2). A microwave absorber (normally used to cover the inside walls of radio anechoic chambers) will emit a brightness temperature equal to its physical temperature T_O . Under ideal conditions, the antenna will sense nothing but the brightness temperature from the absorber and $T_A = T_B = T_O$. Figure 2 also shows a practical layout of this concept. The radiometer is connected to an antenna horn through a short waveguide (very low losses!). The horn views a microwave absorber soaked with liquid nitrogen. The absorber and the liquid nitrogen are contained in an insulated metal bucket, and the excess opening of the bucket is covered by aluminum foil. In this way the antenna is only able to pick up energy from the absorber, which is cooled to 77 K by the nitrogen. There is generally no problem with losses and heat flow in the antenna and the waveguide, liquid nitrogen is readily available, and the setup is cheap and simple. Overall this is a very useful radiometer calibrator – and before liquid nitrogen is applied it provides also the hot calibration point.

Finally, it shall be noted that pointing an antenna toward free space will provide a cold calibration point of only a few K. The problem is that the atmosphere will give

a significant contribution to the temperature, and it must be carefully accounted for. However, this is not the case for satellite-borne systems, and here such a sky view is often used for the cold calibration point.

Going to the more advanced correlation radiometers, also shown in Figure 1, calibration is somewhat more complicated. First, a basic calibration of the two channels is carried out as just described, but in addition to this, the calibration of the correlation channels requires generation of a pair of known signals with a known amount of correlation between them. This issue is outside the scope of the present text.

Conclusion

Microwave radiometers are sensitive receivers requiring special attention to stability and accuracy. Several types have been developed over the years each with its special virtue. The antenna is an important part of the radiometer system determining what is actually measured by the radiometer. Any radiometer must be carefully calibrated – not only after its development but also a frequent check of calibration must be carried out at proper intervals when the radiometer is in use. More information can be found in (Skou and LeVine, 2006).

Passive microwave radiometer (PMR)

Definition

The conventional microwave radiometer is a calibrated receiver that measures the power from the environment as picked up by an antenna system.

Introduction

The emission from the environment is received by the antenna. This can typically be horizontally or vertically polarized. The conventional radiometer measures the power corresponding to one of these polarizations, and it is basically a single channel receiver. If both polarizations must be measured, two independent radiometer receivers are employed. In-depth treatment of conventional radiometers is found in Ulaby et al. (1981) and in Skou and LeVine (2006).

Total power radiometer

The simplest and most direct implementation of a radiometer is found in the total power radiometer (TPR) as illustrated in Figure 1a. The gain in the radiometer has been symbolized by an amplifier with a gain G and the frequency selectivity by a filter with a bandwidth B (centered around some given frequency). We cannot make a receiver without introducing an additional noise T_N . The microwave power has to be detected to find some measure of its mean. In the present case, it is very attractive to use a square-law detector: then the output *voltage* will be proportional to the input *power* and hence the input temperature. Finally, we indicate where the integration takes place: the signal from the detector is smoothed by the integrator to reduce fluctuations in the output, and the longer is the integration time, the more smoothing.

The output can be expressed as

$$V_{\text{OUT}} = c \cdot (T_A + T_N) \cdot G \quad (1)$$

where c is a constant. V_{OUT} is totally dependent on T_N and G . These can for some applications not be regarded as stable enough to satisfy reasonable requirements to stability and accuracy. In other cases, however, the total power radiometer is very useful, namely, where frequent calibration, for example, once every few seconds, is possible.

The sensitivity (standard deviation of the output signal) of the total power radiometer is given by

$$\Delta T_{\text{TPR}} = \frac{T_A + T_N}{\sqrt{B \cdot \tau}} \quad (2)$$

Dicke radiometer

In 1946, R. H. Dicke found a way of alleviating the stability problems in radiometers (Dicke, 1946). By using the radiometer not to measure directly the antenna temperature T_A but rather the difference between this and some known reference temperature T_R , the sensitivity of the measurement to gain and noise temperature instabilities is greatly reduced (see Figure 1b).

The input of the radiometer is rapidly switched between the antenna temperature and the reference temperature. The switch frequency F_S could be 1,000 Hz. The output of the square-law detector is multiplied by +1 or -1, depending on the position of the Dicke switch, before integration. The input to the integrator is then $V_1 = c \cdot (T_A + T_N) \cdot G$ in one half period of F_S and $V_2 = -c \cdot (T_R + T_N) \cdot G$ in the second half period.

Provided that the switch frequency F_S is so rapid that T_A , T_N , and G can be regarded as constants over the period and that the period is much shorter than the integration time, the output of the radiometer is found as

$$V_{\text{OUT}} = c \cdot (T_A - T_R) \cdot G \quad (3)$$

It is seen that T_N has been eliminated, while G is still present, although with less weight. Now G multiplies the difference between T_A and T_R , where T_R is reasonably chosen to be in the same range as T_A , while in the total power case, G multiplied the sum of T_A and the rather large T_N .

The Dicke principle has proven to be very useful, and Dicke radiometers (DR) have been used extensively over the years.

A price has to be paid, however, for the better immunity to instabilities. Since only half of the measurement time is spent on the antenna signal (the other half is spent on the reference temperature), the sensitivity is degraded by a factor of 2 compared with the total power radiometer:

$$\Delta T_{\text{DR}} = 2 \cdot \frac{T_A + T_N}{\sqrt{B \cdot \tau}} \quad (4)$$

Noise injection radiometer

The noise injection radiometer (NIR) represents the final step toward stability; that is, the output is independent of gain and noise temperature fluctuations (Goggins, 1967; Hardy et al., 1974).

From Equation 3 it is seen that the output from a Dicke radiometer is zero (independent of G and T_N) if the reference temperature and the antenna temperature are equal. The noise injection radiometer is a specialization of a Dicke radiometer in which this condition is continuously fulfilled by a servo loop.

In almost any case encountered in Earth remote sensing, the antenna temperature is below some 300 K (emissivities between 0 and 1 are multiplied by the physical temperature). The reference temperature in a Dicke radiometer is conveniently equal to the physical

Microwave Radiometers, Conventional, Figure 1 (a) Total power radiometer, (b) Dicke radiometer, (c) noise injection radiometer, and (d) hybrid radiometer.

temperature in the microwave front end, that is, 300–320 K. In [Figure 1c](#) we show how the output T_I of a variable noise generator is added to the antenna signal T_A , so that the resultant input (T_A') to the Dicke radiometer is equal to the reference temperature (T_R) and a zero output results. A servo loop adjusts T_I to maintain the zero output condition or rather the near-zero output condition: the loop gain can be made large but not infinite.

From [Equation 3](#) we have

$$V_{OUT} = c \cdot (T_A' - T_R) \cdot G = 0$$

and as $T_A' = T_A + T_I$, we find $T_A = T_R - T_I$. T_R is a known constant, and knowledge of T_I is required to find T_A . The accuracies of the Dicke radiometer part of the NIR and of the loop gain are (given large loop gain) completely insignificant for the accuracy with which we determine T_A . This is solely dependent on the accuracy of T_I . Accurate and stable noise sources with variable output can be made and are used for “injecting” the required signal T_I into the input line, so that T_I and T_A are added.

The sensitivity of the noise injection radiometer is very close to that of the Dicke radiometer:

$$\Delta T_{NIR} = 2 \cdot \frac{T_R + T_N}{\sqrt{B \cdot \tau}} \quad (5)$$

Hybrid radiometer

The radiometers as described hitherto in this entry are the classical receiver types, and their implementation is indicated in the classical way using, for example, analog integration after detection and analog subtraction of antenna and reference signals (in the Dicke radiometer). And indeed many radiometers are still implemented this way. But with the advent of analog to digital converters and digital processing, other implementation forms are possible and often used. This is illustrated in [Figure 1d](#).

As soon as possible following detection, the signal is A to D converted – only a low-pass filter is indicated to condition the signal bandwidth to the sampling frequency of the converter. The signal from the converter is led to some kind of digital processor, typically a PC or an FPGA (field-programmable gate array), where suitable data handling takes place. This can typically be digital integration to the required integration time τ , as well as subtraction of the antenna signal and the reference signal. Since these processes are under computer control, flexibility becomes a key word, and the distinction between total power and Dicke radiometer vanishes to some extent: if the processor operates the input switch rapidly and regularly, we can regard it as a Dicke case, while if the measurement situation is such that the antenna signal can be measured (with interruptions when the switch points to the reference signal) without loss of data, then we have a total power case with frequent calibration.

A classical Dicke radiometer spends half of its time measuring the well-known reference temperature and thus only half of its time doing its real job, namely, measure the unknown antenna temperature. Thus over the years researchers have considered a better duty cycle for the antenna measurements (in turn potentially leading to improved sensitivity). However, having analog subtraction of the signals, the 50 % duty cycle is instrumental to having simple and stable circuitry. But with the subtraction done digitally this is no longer a limitation, and optimized duty cycles can be found on a case-by-case basis. A word of warning should, however, be stated: the naive notion that spending more time on the unknown antenna signal will lead to improved sensitivity is not necessarily true! When more time is spent on the antenna, less time is left for the reference and this in turn leads to an increased standard deviation for that measurement. Thus, the final standard deviation after subtraction might not decrease.

However, there are possible improvement schemes: since the reference temperature and the receiver noise temperature are assumed relatively stable while the antenna temperature may change rapidly, averaging over several reference temperature measurements will reduce the standard deviation of this measurement and thus allow a non-50 % duty cycle to be employed. Initial instrument fluctuations and averaging times must of course be considered carefully. See further discussion in Tanner et al. (2003) and Racette and Lang (2005).

Implementation

The radiometer is merely a very sensitive microwave receiver, and like any receiver, it can be implemented as a direct receiver or, by use of a mixer and a local oscillator, as a superheterodyne receiver. In the direct receiver, all amplification takes place at the input RF frequency, and all selectivity is determined by filters in the same frequency range. In the superheterodyne receiver most of the amplification takes place at the much lower intermediate frequency (IF), and selectivity is determined by a combination of filters at RF and IF levels.

Microwave FET amplifiers with excellent noise figures and square-law detectors covering the frequencies well beyond 40 GHz are available. Hence, the general trend is that conventional radiometers be implemented as direct receivers at frequencies below some 40 GHz, while higher-frequency implementations seem to favor the superheterodyne receiver – due to unavailability of amplifiers or very expensive amplifiers.

Another very important issue when implementing microwave radiometers is the concept of thermal stabilization. The best and simplest way to achieve a stable

radiometer is to carefully temperature-stabilize all important components of the receiver – first and foremost the microwave front end.

Imaging considerations

A microwave radiometer is often mounted on an aircraft or a satellite in order to cover large areas.

If a radiometer with its antenna is mounted on a satellite and the antenna points straight down, the forward movement of the satellite will facilitate measurements on the ground along a straight line (the nadir path of the satellite). Coverage of the entire Earth by such “profiles” will require an enormous number of orbits! A dramatic increase in mapping efficiency results from scanning the antenna (see Figure 2a). The antenna rotates about a vertical axis, and the footprint will cover a wide swath on the Earth dependent on satellite altitude and incidence angle. Other scanning methods are possible, but the rotating scan is attractive due to constant incidence angle on the ground and the lack of accelerations associated with reciprocating scans.

In a scanning system it is obvious that there is only a limited time for the radiometer to carry out its measurement before the footprint moves to another position within the swath. The so-called dwell time per footprint is short. The users in general want small footprints (or high spatial resolution, to put it differently). As technology evolves, high-resolution systems become possible, but a small footprint results in rapid rotation (mechanical problems) and in a very small dwell time per footprint, hence in a short integration time, which, through our radiometer sensitivity formula, directly translate into poor sensitivity! The solution to this fundamental problem is offered by the so-called push-broom concept illustrated in Figure 2b.

Microwave Radiometers, Conventional, Figure 2 (a) Conical scan and (b) push broom.

In the push-broom radiometer system a multiple-beam antenna covers the swath while the satellite moves forward. A host of radiometer receivers are connected to an equal number of antenna feeds, producing individual beams to sense the Earth simultaneously.

The obvious advantages of the push-broom system compared to a scanning system are no moving antenna to cause problems in the satellite design and much larger dwell time per footprint, hence better sensitivity.

For the scanning radiometer systems, the requirement for receiver sensitivity is severe. At the same time, frequent calibration is easily achieved: once per scan, while the antenna is anyway looking away from the swath, the receiver is calibrated. Hence, the total power radiometer is an obvious candidate for such systems, due to its optimal sensitivity and since potential instabilities are taken care of by frequent calibration.

For the push-broom system, requirements for receiver sensitivity are greatly relaxed due to the much larger dwell time per footprint as compared to the scanner situation. At the same time, frequent calibration is not attractive, as all receivers are always busy sensing the Earth. Hence, the push-broom situation favors a trading of sensitivity for stability, and in conclusion, a Dicke type of switching radiometer is preferred – maybe the NIR.

Conclusion

Microwave radiometers are sensitive receivers requiring special attention to stability and accuracy. Several types have been developed over the years, and in general stability comes at a price: degraded sensitivity. So, when designing a satellite-borne imaging system, an important trade-off between sensitivity, stability, and imaging properties must be carried out.

MICROWAVE RADIOMETERS, CORRELATION

Christopher Ruf

Department of Atmospheric, Oceanic and Space Sciences,
 University of Michigan, Ann Arbor, MI, USA

Definition and overview

A microwave radiometer measures statistical properties of the electrical field incident on its antenna. A total power radiometer, for example, measures the variance of the field strength, which is proportional to the brightness temperature of the source of the electric field. A correlation radiometer measures the statistical covariance between two incident electric fields. The most common types of correlation radiometers are autocorrelation spectrometers (Ruf and Swift, 1988), spatial interferometers (Kerr et al., 2000), and coherent detection polarimeters (Piepmeier and Gasiewski, 2001). Autocorrelation spectrometers measure the correlation between one electric field and a time-delayed version of itself. Spatial interferometers measure the correlation between the electric field at two locations. Polarimeters measure the correlation between two polarization components of an electric field. Since variance is defined as the statistical correlation of a signal with itself, a total power radiometer can be thought of as a special case of all three correlation radiometers – a spectrometer with zero time delay, an interferometer with no spatial separation, or a polarimeter with a common polarization component.

Autocorrelation spectrometer

The autocorrelation of a time-varying electric field is given by

$$R(\tau) = \langle E^*(t, \vec{r}) E(t - \tau, \vec{r}) \rangle \quad (1)$$

where $E(t, \vec{r})$ is the electric field at time t and position $\vec{r}$, $*$ denotes complex conjugation, τ is the time delay between the two versions of the electric field being correlated, and $\langle \bullet \rangle$ denotes a statistical expectation operator. In practice, the expectation operation is approximated by a time average because, in most cases, second-order statistics of the electric field associated with microwave thermal emission can be considered to be stationary over short time intervals. The autocorrelation is typically sampled over a suitable range of time delays, τ . The Fourier transform of the autocorrelation with respect to the time delay is its power spectrum. For this reason, the autocorrelation of a radiometric signal is often measured in order to determine the spectral dependence of its brightness temperature. The Fourier transform that recovers the power

spectrum from the autocorrelation is performed in software as part of data post-processing. Autocorrelators are used to determine the Tb spectrum when the spectrum is to be resolved with sufficiently fine resolution that a bank of narrow band filters is impractical.

Spatial interferometer

The correlation between the electric field at two positions is given by

$$V(\vec{s}) = \langle A_1 \{E(\vec{r}, \Omega)\}^* A_2 \{E(\vec{r} - \vec{s}, \Omega)\} \rangle \quad (2)$$

where $E(\vec{r}, \Omega)$ is the electric field at position $\vec{r}$ arriving from angular direction Ω , $A_n\{\bullet\}$ denotes the angular reception sensitivity of antenna n ($n = 1, 2$) to the incident electric field, and $\vec{s}$ is the separation between the two versions of the electric field being correlated. This correlation statistic is referred to as the visibility of the brightness temperature distribution. The visibility is sampled over a suitable range of separations between antenna pairs. If the two antennas have overlapping angular reception sensitivities, then the Fourier transform of the visibility with respect to the separation, $\vec{s}$, is related to the angular dependence of the power density of the incident electric field received by the antennas. The power density is, in turn, proportional to the brightness temperature of the source of the electric field. Spatial interferometers (also called Fourier synthesis imagers) are used to determine the angular dependence of the brightness temperature, $T_b(\Omega)$. The Fourier transform required to convert measured visibilities to a Tb image is performed in software as part of the data post-processing. Interferometers are used to image the Tb when its angular variation is to be resolved with sufficiently fine resolution that a large antenna, capable of comparable spatial resolution, is impractical.

Coherent detection polarimeter

The correlation between two linearly polarized components of the electric field is given by

$$C_{pg} = \langle E_p(t, \vec{r})^* E_q(t, \vec{r}) \rangle \quad (3)$$

where the subscripts p and q denote the two polarization components being correlated. A common polarization component was assumed in [Equations 1 and 2](#) for the two versions of the electric field being correlated. If p and q are the same, then C_{pg} is proportional to that polarization component of the brightness temperature of the source of the electric field. If p and q are orthogonal, then the real and imaginary components of C_{pg} are proportional to the third and fourth Stokes parameters in brightness temperature. This type of correlation radiometer differs from the other two in that the correlation measurement itself, and not a Fourier transform of it, is typically the measurement of fundamental interest.

Conclusions

Correlation microwave radiometers measure the statistical covariance between different components (in time, space, or polarization) of the electric field radiated by a source of thermal emission. Certain properties of the brightness temperature associated with that source (its spectrum, its angular distribution, or its polarization state) can be determined from the correlation measurements. Correlation radiometers are typically used when determination of those properties would be otherwise difficult or impossible.

Synonyms

Aperture synthesis radiometers; Synthetic, interferometric radiometers

Definition

Interferometry. Technique of using the mean product of two random signals to infer some characteristics of the source that generated them.

Aperture synthesis. Application of interferometry to an array of antennas to form an image of the signal source equivalent to one that would be observed by an antenna the size of the whole array.

Introduction

Microwave interferometric radiometers are a particular class of microwave radiometers, which work on the same principles as radio telescopes (Krauss, 1996; Thompson et al., 1988): interferometry and aperture synthesis. In turn, the development of the first aperture synthesis radiometers for space applications has led to a fundamental review of the very principles of radio astronomy

exemplified in the *Corbella equation*. Instead of being pointed to the sky, these radiometers observed the Earth surface from ground-based, airborne, and spaceborne platforms. However, interferometric radiometers present very different features by comparison with radio telescopes, namely, the small size of the antenna elements and the short spacing at which they are clustered together, both of the order of the wavelength. Aperture synthesis radiometers have been developed to achieve fine spatial resolution in those applications where a single scanning antenna is mechanically too complex to realize. Since an interferometric radiometer does not need to scan to make an image, this has been the preferred solution in those cases. The original driving scientific applications have been the mapping of soil moisture and ocean salinity from space (Swift, 1993) and, more recently, atmospheric observations from geostationary orbit.

Historical development of aperture synthesis in remote sensing

While the origin of radio astronomy dates back to 1950 (Ryle et al., 1950), its application to Earth observation was only considered in the late 1970s by the University of Berne (Schanda, 1979) and the beginning of the 1980s by engineers at NASA Goddard Space Flight Center in collaboration with the University of Massachusetts at Amherst (LeVine and Good 1983; Ruf et al., 1988; Tanner, 1990; Swift et al., 1991). The objective behind was to map the Earth's soil moisture and ocean salinity, two important geophysical parameters never measured before at global scale.

The first interferometric radiometer that was built had a synthetic beam in only one dimension, using the real aperture antenna pattern in the other. This was NASA's ESTAR (electronically steered thinned array radiometer), an aircraft demonstrator of such a hybrid instrument; see Figure 1 (LeVine et al., 1992; Swift, 1993). Subsequent developments followed elsewhere with different variations as that using the motion of the platform to save in the required number of receivers (Komiya, 1990), this being equivalent to the use of Earth rotation in radio astronomy.

Aperture synthesis in two dimensions was developed in Europe during the 1990s. The Technical University of Denmark constructed a laboratory demonstrator (Laursen et al., 1994; Skou, 2004), and the European Space Agency (ESA) started the research of an L-band spaceborne MIRAS (Microwave Imaging Radiometer with Aperture Synthesis) (Martin-Neira, 1993; Goutoule et al., 1994; Bayle et al., 2002). ESA's study involved French scientists at the Centre d'Etudes Spatiales de la Biosphère (CESBIO) (Kerr et al., 2000) and benefited with the participation of radio astronomers from the Observatoire du Midi Pyrenees (Lannes and Anterrieu 1994; Anterrieu et al., 2002). The Polytechnic University of Catalonia (UPC) in Barcelona played an important role in defining the requirements and calibration strategy for MIRAS

Microwave Radiometers, Interferometers, Figure 1 NASA's electronically steered thinned array radiometer: the first one-dimensional airborne radiometer (Courtesy David LeVine, NASA).

Microwave Radiometers, Interferometers, Figure 2 Helsinki University of Technology's two-dimensional airborne interferometer (HUT-2D) (Courtesy Martti Hallikainen, TKK).

(Camps, 1996; Torre et al., 1996). Even more crucial was UPC's research on the completed ESA's MIRAS demonstrator, which led to the *Corbella equation* (Corbella et al., 2004), a fundamental correction to the formulation used by radio astronomers. The Helsinki University of Technology embarked in the manufacturing of an airborne two-dimensional microwave interferometer, the HUT-2D (see Figure 2) (Rautiainen et al., 1999), the first airborne two-dimensional aperture synthesis radiometer that provided good quality images of the Earth surface (Kainulainen et al., 2007). The calibration strategy of SMOS was first tested on HUT-2D (Colliander et al., 2007).

Microwave Radiometers, Interferometers, Figure 3 ESA's soil moisture and ocean salinity (SMOS) mission (Courtesy Yann Kerr, CESBIO).

In 1999, the SMOS (soil moisture and ocean salinity) mission was selected by ESA as second Earth Explorer Opportunity Mission, carrying MIRAS as only payload (McMullan et al., 2008). SMOS was launched 2 November 2009 being the first aperture synthesis radiometer flown in space; see Figure 3. It has successfully demonstrated the technique paving the way for its application in other areas. In fact, aperture synthesis has been proposed from geostationary orbit (Ruf, 1990), and higher frequency interferometers are now considered viable for Earth observation satellites flying in low Earth orbit.

In the 2000s, several other ground-based and airborne microwave interferometric radiometers have been developed by different groups around the world, as NASA Goddard's ESTAR-2D, JPL's and ESA's geostationary sounder demonstrators (Christensen et al., 2007), the C- and X-band one-dimensional interferometers of the Chinese Center of Space Science and Application Research's (Wu et al., 2005; Yan et al., 2005), or ESA's Airborne MIRAS in Europe.

Basic principles in remote sensing aperture synthesis

A microwave aperture synthesis radiometer consists of a collection of N antennas arranged in an adequate geometry for optimum imaging. Every antenna is connected to a microwave receiver, which filters out all frequencies of the incoming radiation except for a narrow band, in such a way that the output signal is quasi-monochromatic, with slowly varying but random amplitude and phase. The receiver output signal is then a random process with *Gaussian statistics* and is best represented by its complex *analytic signal*.

Each of the $N \times (N - 1)/2$ possible pairs that can be formed with all the antennas of the collection is called a *baseline*. The two elements of a baseline receive the radiation from a distant target with some delay with respect to each other depending on the angle of arrival of the signal relative to the baseline. The average product of the two receiver output signals of every baseline, named *correlation* or visibility, is then computed. The visibility presents maxima and minima (null value), depending on whether the corresponding spatial delay is or not an integer number of the central wavelength. This means that some directions yield peak visibility values, while others do not contribute to it at all, what is equivalent to a spatial filtering. Every baseline acts then as a spatial filter: the longer the baseline, the shorter the spatial wavelength of the filter. Baselines oriented in different directions provide spatial filtering along those same directions. Thus, the set of all visibilities provides the spatial frequency content of the scene inside a frequency domain limited by the physical extent and location of the antenna elements. The image can then be recovered by a Fourier Transform of the visibilities. This is the formulation of the Van Cittert–Zernike theorem. Nonetheless, as explained later, this theorem would not suffice to describe the operation of an aperture synthesis radiometer, which obeys the Corbella equation instead.

Spatial resolution and windowing

By the properties of the Fourier Transform, the angular resolution of the interferometric radiometer is determined by the extension of the spatial frequency domain. Since a given baseline can be taken in one direction as well as in its opposite direction, the spatial frequency support has a size twice the maximum baseline length, this fixing the angular resolution.

The angular resolution of an aperture synthesis radiometer can now be compared with that of a real aperture instrument. An antenna of the same physical size as the synthetic radiometer would produce a far-field distribution equal to the Fourier Transform of the aperture illumination, following standard antenna theory. The square of the far field gives the radiated power that, when inverse Fourier Transformed, yields the spatial convolution of the original field illumination with itself. For a uniformly illuminated square aperture, the self-spatial convolution becomes a square pyramid with a side twice the physical length of the aperture. This is equivalent to applying a pyramidal weighting function to the visibilities collected by the synthetic radiometer.

In summary, the same spatial resolution of a real aperture with a given illumination can be achieved by an interferometric radiometer of the same physical size and a proper weighting of its visibility function. This is the principle of *aperture synthesis* or *aperture thinning*.

Real aperture radiometers never use uniform illumination as the side lobes become too high. Instead strong tapering is applied to increase the amount of energy collected through the main beam. Similarly, the visibility

samples of an aperture synthesis radiometer are multiplied by weighting functions, or *windows*, that achieve a better beam efficiency than when using a pyramidal weighting. As an example, SMOS weighs the visibility function with a *Blackman window*.

Field of view

The signal received by each element of an interferometer is affected by its antenna pattern. As the gain of the element decreases substantially outside its main beam, the radiometer becomes quite insensitive away from boresight. Imaging is therefore only feasible within the main beam of the element, which defines the field of view of the interferometric radiometer. Small antenna elements are preferred because of their wide beam, which avoids the need for mechanical scanning, a major advantage of interferometric radiometers. This is an important difference with respect to radio astronomy, where mechanically scanned large dish antennas are used. The field of view of an aperture synthesis radiometer is hence very wide and constrained by the element pattern, but not only, as explained below.

Spatial frequency sampling and aliases

The element pattern of a microwave interferometer is chosen to fit the size of the area to be imaged, or *swath*, in each particular application. For instance, an interferometer flying in a low Earth orbit at 800 km altitude will map the complete Earth in less than 3 days if its field of view is 60° wide (900 km on ground), while from geostationary orbit 18° suffices to cover the Earth disk. In matching the element pattern to the area of interest, the physical size of the element becomes defined, which in turn determines the pitch or minimum *spacing* possible between a pair of adjacent antenna elements. The resulting element spacing is usually larger than the maximum sampling period of the spatial frequency domain that guarantees the absence of grating lobes, and *aliases* appear in the image surrounding the alias-free area. The alias borders, like the element pattern, limit the field of view in aperture synthesis radiometry.

The extension of the alias zones depends on the physical arrangement of the antenna elements. For any given spacing, the alias is minimized when the antennas are placed on a hexagonal grid with a pitch the same as the spacing. Examples of such hexagonal geometries are the triangle, the hexagon, the Y (three lines at 120°), and, in general, any snowflake configuration, which lead to visibility domains with the same shapes (triangle, hexagon, a six-point star). An alternative geometry is the rectangular one, like a square, a rectangle, a cross, a U, or a T, all leading to a square or rectangular coverage in the spatial frequency domain. The maximum distances between elements (normalized to the wavelength) before aliases appear are 0.577 and 0.5 for the hexagonal and rectangular geometries, respectively, which shows the benefit of the former.

Radiometric sensitivity

The sensitivity of an aperture synthesis radiometer is comparable to that of a real aperture radiometer. As an example, consider a U-shape interferometer with N elements per arm. On the one hand, the sensitivity is proportional to the collecting area, given by the area of each antenna element a times the number of them $3N$, that is, $3Na$. On the other, the sensitivity is proportional to the square root of the integration time, or, what is equivalent, proportional to the square root of the number of resolution cells inside the field of view. In alias-free conditions, this number equals $2N$. Finally, the sensitivity is also proportional to the volume of the weighting window, normalized by the area of its base, which for a pyramidal window gives $1/3$. The final sensitivity of the interferometer is thus determined by $2N^2a$. A uniformly illuminated real aperture radiometer of collecting area A has 4 resolution cells in its field of view, and its sensitivity is thus proportional to $2A$. If both instruments have the same physical size, $A = N^2a$, the sensitivity of the real aperture radiometer becomes $2N^2a$, the same as that of the aperture synthesis radiometer.

The Corbella equation

The Van Cittert–Zernike theorem, basis of radio astronomy, is not compatible with the Bosma theorem (Wedge and Rutledge 1991). This became apparent for the first time within ESA's MIRAS Demonstrator Pilot Project in 2002. A two-dimensional aperture synthesis radiometer was placed inside an anechoic chamber, and all measured visibilities were zero, as expected from the Bosma theorem. This theorem states that for any passive network (as an array of antennas inside an anechoic chamber) in thermal equilibrium with its terminations (as the isolators following the antennas), the cross-correlation of the outgoing noise waves must be null. But according to the Van Cittert–Zernike theorem, the measured correlations should have been equal to the Fourier Transform of the element antenna pattern. The theoretical foundations of aperture synthesis were revised and a new equation established, compatible with the Bosma theorem, which correctly explains aperture synthesis, and by extension, radio astronomy: the *Corbella equation*. According to this equation, the visibility function is proportional to the difference or *contrast* in physical temperature between the target and the instrument. High correlations are expected when looking to the cold sky, and very small correlations when inside an anechoic chamber at similar physical temperature as the instrument. The Corbella equation has been verified from ground, airborne and space.

The flat target transformation

According to the Corbella equation, any uncertainty in the knowledge of the antenna pattern is amplified by the instrument–target temperature contrast. Thus, it is desirable to minimize such contrast. This is possible if the *flat target response* (FTR) of the interferometer is acquired

first. The FTR is the visibility function measured when imaging an unpolarized uniform brightness temperature distribution, which is stable over time. In practice, the cold sky near the galactic poles of the Milky Way is a good approximation of such a target, and the FTR can be measured by pointing the aperture synthesis radiometer to the galactic poles. The FTR is like a mask formed by ripples due to system imperfections, mainly antenna errors. When this mask is scaled down to the temperature contrast between the instrument and an Earth scene, and is subtracted from the measured visibilities, the instrument errors are cancelled to a large extent. Mathematically, the Corbella equation is transformed by this linear combination with the result that the instrument physical temperature is replaced by the average temperature of the scene. The final temperature contrast is then reduced to that between each pixel of the scene and the average of all the pixels. The transformation of the Corbella equation using the FTR is known as the *flat target transformation* (FTT) and is an essential step in aperture synthesis imaging (Martín-Neira et al., 2008).

Polarimetry in aperture synthesis

An aperture synthesis radiometer is inherently a polarimetric type of instrument because of its very wide field of view. Horizontal H and vertical V polarizations on the target are transformed into v and h polarizations on the element antenna according to a different rotation matrix depending on the direction. Since the H and V fields appear mixed together in the v and h fields in the instrument polarization frame, a nonzero vh cross brightness temperature is measured even from a target with no correlation between H and V . Reversely, to recover the horizontal and vertical brightness temperatures of the target, it is necessary to measure the vh cross brightness temperatures. When these are not available, a singularity along the image diagonals appears, and pixels in those areas have to be discarded. They can be recovered though when, due to the platform motion, they move to directions outside the singularities.

Calibration

An aperture synthesis radiometer is a complex instrument and requires several calibration steps. The first one is the flat target transformation, explained above, for which a cold sky view to acquire the flat target response must have been performed before hand. The second step is the correction of any comparator offset in the digital circuits and quadrature error of the demodulator. Then comes the phase correction, achieved by injecting correlated noise to all receivers internally, and the amplitude calibration, based on two standard temperatures, as the cold sky and an internal matched load at a well-monitored physical temperature. Finally, an uncorrelated load is used to remove any correlation offsets due to residual internal interference. In addition, to form an image, the antenna patterns must have been characterized a priori, and the

fringe-washing function has to be determined during operation. The fringe-washing function takes into account the decorrelation of the signal with time delay across the array and is estimated from early, punctual, and late correlations.

Summary and conclusions

Aperture synthesis radiometry has developed starting in the early 1980s mainly driven by the need to map soil moisture and ocean salinity from space. During this development, the theoretical fundamentals had to be revised, and a new formulation, the Corbella equation, was found, which describes correctly the operation of this type of instruments, and, in fact, of radio telescopes as well. A consequence of the new formulation is the flat target transformation, a powerful method to calibrate out antenna errors in aperture synthesis.

The spatial resolution and sensitivity of an aperture synthesis radiometer are comparable to those of a real aperture radiometer. Field of view, collecting area, and integration time take different values in each case, but balance each other, yielding the same net result at the end.

ESA's SMOS mission carrying the first aperture synthesis radiometer into space was launched 2 November 2009. Scientists have been able to assess the ultimate benefits of this new remote sensing technique. Following SMOS success, a next generation of interferometric radiometers might follow not only from low Earth orbit but also from geostationary orbit, already under study.

Synonyms

Microwave polarimeter; Polarimetric radiometer

Definition

Microwave Polarimetric Radiometer. Microwave radiometer capable of measuring at least three of the four modified Stokes' parameters of the incident field.
Polarimetry. Measurement of the polarization characteristics of incident electromagnetic radiation.

Introduction

Polarimetric microwave radiometers are capable of measuring at least three Stokes' parameters of the incident microwave radiation or radiometric scene. Traditional dual-polarized radiometers measure vertically and horizontally polarized brightness temperatures or, equivalently, the first two Stokes' parameters of the input scene. In order to completely characterize the spatially averaged input scene, measurements of third and fourth Stokes' parameters are required (Jackson, 1975), and these measurements can be performed utilizing coherent (direct) or incoherent techniques. Direct measurements are performed by polarization-correlating radiometers to measure the third and/or fourth Stokes' parameters. Indirect methods include a combination of linearly polarized brightness temperatures typically oriented at 45° and –45° with respect to the principle directions in order to derive the third Stokes' parameter and by combining left-and right-hand circular polarized brightness temperatures to derive the fourth

Stokes' parameter. Several airborne microwave polarimeters have been part of airborne experiments conducted between 1993 and 2003 in order to investigate application of microwave polarimetry to retrieval of sea surface wind direction (Yueh et al., 1995). The satellite-based wind direction system (WindSat), developed by the US Naval Research Laboratory (NRL) and launched in January 2003, performed the first space-based polarimetric measurements (Gaiser et al., 2004).

Background

Airborne and space-based polarimetric radiometers measure the intensity of the Earth's naturally occurring upwelling thermal emission. This arbitrarily polarized, non-or partially coherent thermal radiation is completely characterized by the four parameter-modified Stokes' vector:

$$\bar{I} = \begin{pmatrix} I_v \\ I_h \\ U \\ V \end{pmatrix} \frac{W}{(m^2 \cdot sr \cdot Hz)}$$

where I_v and I_h are the spectral intensities of the vertically and horizontally polarized field components and U and V are the in-phase and quadrature correlations, respectively, between the orthogonally polarized field components $\hat{v}$ and $\hat{h}$. The spectral intensity of this emission can be described by the brightness temperature vector, $\bar{T}_B$:

$$\bar{T}_B \equiv \frac{\lambda^2}{k} \bar{I} = \begin{pmatrix} T_v \\ T_h \\ T_U \\ T_V \end{pmatrix} = \begin{pmatrix} \langle |E_v|^2 \rangle \\ \langle |E_h|^2 \rangle \\ 2\text{Re}\{\langle E_v E_h^* \rangle\} \\ 2\text{Im}\{\langle E_v E_h^* \rangle\} \end{pmatrix}$$

where E_v and E_h represent the vertically and horizontally polarized electric fields, respectively, $\langle \cdot \rangle$ represents a time-averaged quantity. Microwave polarimeters measure at least three of the four parameters. There are two general methods in passive microwave remote sensing in order to measure the third and fourth Stokes' parameter: (1) cross-correlation between two orthogonally polarized measurements (polarization-correlating radiometer) and (2) measurements of polarized brightness temperature measurements using multiple polarizations. For example, using linearly polarized brightness temperatures at orientations of $\pm 45^\circ$ with respect to the orientation of the vertical polarization vector, the third Stokes' parameter can be found simply by differencing the two measurements: $T_U = T_{45} - T_{-45}$. Similar approaches can be used to measure T_V . One of the first reports on radiometer designs for sea surface microwave emission polarimetry was provided by Dzura (1992).

Polarization-correlating radiometer (direct method)

An example of an analog polarization-correlating radiometer is given below. Figure 1 shows the block diagram of a three-channel polarization-correlating radiometer.

Microwave Radiometers, Polarimeters, Figure 1 Block diagram of a three-channel polarization-correlating radiometer (Gasiowski and Kunkee, 1993).

The measurement sensitivity for v_U (and therefore T_U) is proportional to the geometric mean of the characteristics of v_A and v_B ; hence, if channels A and B are identical, channel U will have the same sensitivity (ΔT_{RMS}) as channels A and B. Phase adjustments are made by adjusting the relative oscillator phase ($\Delta\phi$) and/or relative line length (Δl) before the combiner. The phase can be adjusted to provide response to in-phase (U) or phase quadrature (V) components; however, in order to measure V (fourth Stokes' parameter), a single-side band configuration must be used in order to avoid cancelation of the signal from the contributions of the high and low side bands.

The post-detection analog signal summation in the scheme shown in Figure 1 is typically performed by using digital electronic circuitry (Piepmeier and Gasiewski, 2001).

Polarization combining radiometer (indirect method)

An alternate method is to combine brightness temperature measurements at multiple polarizations to derive U or V indirectly. This method is also called the incoherent method and is typically applied through measurements of linearly polarized brightness temperatures offset $\pm 45^\circ$ from the original basis to derive the third Stokes' parameter T_U and using left- and right-hand-polarized brightness temperatures to derive the fourth Stokes' parameter, T_V . Using a unitary rotational transform, the relationship between linearly polarized brightness temperatures rotated ϕ degrees is expressed by

$$\begin{aligned} \overline{T}' &= \begin{pmatrix} T_{\nu'} \\ T_{h'} \\ T_{U'} \\ T_{V'} \end{pmatrix} \\ &= \begin{bmatrix} \cos^2 \phi & \sin^2 \phi & 0.5 \sin^2 \phi & 0 \\ \sin^2 \phi & \cos^2 \phi & -0.5 \sin^2 \phi & 0 \\ -\sin^2 2\phi & \sin^2 2\phi & \cos 2\phi & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{pmatrix} T_{\nu} \\ T_h \\ T_U \\ T_V \end{pmatrix} \\ &= \overline{U}(\phi) \overline{T} \end{aligned}$$

where $\overline{T}'$ is the measurement made with the rotated polarization basis. Therefore, by using $T_{\pm 45} = T_{U'}(\phi = \pm 45^\circ)$, the third Stokes' parameter, $T_U = T_{45} - T_{-45}$. A popular way of deriving brightness temperature measurements at $\pm 45^\circ$ is through the use of polarization combining networks (Yueh et al., 1995). Note that in the above equation, the fourth Stokes' parameter, T_V , is rotationally invariant; however, it can be shown that $T_V = T_R - T_L$ where T_R and T_L are the right- and left-hand circularly polarized brightness temperatures of the incident wave, respectively (Tsang et al., 1985).

Ocean surface wind measurements

One of the primary applications of microwave polarimetry is to improve ocean surface wind (OSW) retrievals

performed with dual-polarized, T_{ν} and T_h , brightness temperatures at 18 and 37 GHz. Dual-polarized radiometric measurements from space-based radiometers are currently and routinely used to accurately observe ocean surface wind speed to better than 1 m/s accuracy, Wentz (1997). The relationship between wind-roughened ocean surfaces and upwelling brightness temperature is well understood and was first explored by Hollinger (1971). Ocean surface wind speed measurements have been performed from operational microwave radiometers since the first special sensor microwave/imager (SSM/I) radiometer was launched and began operating in 1987 (Goodberlet et al., 1990; see also "*Ocean, Measurements and Applications*").

The first measurements showing a variation of brightness temperature as a function of the relative angle between the surface wind direction and the polarization plane were reported by Bepalova et al. (1979) as part of an airborne radiometry experiment conducted by the Space Research Institute at Moscow. A study by Wentz (1992) showed that there was a systematic bias in wind speed retrievals from SSM/I compared to ocean buoys that was dependent on the angle of observation with respect to the surface wind direction. The directional dependence was used to demonstrate that wind direction could also be retrieved using microwave brightness temperatures. However, the presence of multiple solutions, or directional ambiguities, limits the utility of wind direction derived using dual-polarized microwave brightness temperatures.

Building upon theoretical modeling and laboratory measurements of polarized microwave emission from wave-covered surfaces (Yueh et al., 1994; Gasiewski and Kunkee, 1994), the utility of the third Stokes' parameter for ocean surface wind direction retrieval was demonstrated through airborne experiments that measured polarimetric brightness temperatures over the ocean (Yueh et al., 1995). In order to demonstrate wind direction retrievals from space, the WindSat microwave polarimetric radiometer was developed by the US Naval Research Laboratory and launched in 2003 (Gaiser et al., 2004). Wind vector (speed and direction) retrievals using WindSat data (Bettenhausen et al., 2006) are now assimilated into numerical weather forecasting (NWP) models and used to improve forecasts (Candy et al., 2009).

Other applications

Measurements of the third and fourth Stokes' parameters by WindSat over the Greenland ice sheet have shown responses related to the asymmetrical features of polar ice sheets and potentially the microphysical structure of snow crystals (Li et al., 2008). Over desert, polarimetric measurements are also sensitive to the asymmetrical features of the surface such as the structure of sand dunes (Narvekar et al., 2007). Investigations have also shown the WindSat polarimetric measurements to be highly sensitive to RFI signals, and in some cases, showing responses before contamination is apparent in the vertically or horizontally polarized channels (Ellingson and Johnson, 2006; see also "*RFT*").

Summary

Microwave polarimetry involves the measurement of the third and fourth Stokes' parameter of the input radiometric "scene." Traditional dual-polarized radiometers measure only the first two parameters of the Stokes' vector and miss some characteristics of the brightness temperature scene. Microwave polarimeters can be designed for direct (coherent) polarimetric measurements or indirect (incoherent) measurements that are derived through post-detection combination of polarized measurements. Motivation to develop airborne and space-based microwave polarimeters is provided by improvements to passive ocean surface wind vector measurements. The WindSat radiometer was the first space-based microwave polarimeter, providing global measurements of all four Stokes' parameters. These measurements are used to retrieve ocean surface wind vectors and improve weather forecast quality of NWP models. Other potential applications of microwave polarimetry are under development and include snow and ice characterization, land monitoring, and RFI detection and characterization.

MICROWAVE SUBSURFACE PROPAGATION AND SCATTERING

Alexander Yarovoy

Delft University of Technology, Delft, The Netherlands

Definitions

Subsurface. Natural materials (soils, rock, snow, ice) below air–ground interface.

Ground-penetrating radar. Radar for subsurface sensing. It locates, images, and characterizes changes in electrical and magnetic properties of subsurface materials.

Introduction

The first description of microwaves use for subsurface sensing is attributed to a German patent by Leimbach and Löwy from 1910 (Daniels, 2004). In this patent, propagation of microwaves between pairs of vertically buried dipole antennas has been used to detect any subsurface objects with higher conductivity than the surrounding medium. Only monochromatic electromagnetic waves have been considered in this patent. The first use of electromagnetic pulses with a broad spectrum to determine the structure of buried objects is attributed to Hülsenbeck (Hülsenbeck et al., 1926). It was noted that any dielectric variation, not necessarily involving conductivity, would also produce reflections. The first ever experiments with subsurface microwave propagation to sound the depth of a glacier were performed in Austria in 1929 (Stern, 1929, 1930). These experiments were largely forgotten

until the late 1950s when US Air Force radars were seeing through ice as planes tried to land in Greenland but misread the altitude and crashed into the ice. This accident together with lunar soil investigations within Apollo program (Simmons et al., 1972) triggered research on microwave penetration into subsurface, including not only ice sounding but also mapping soil properties and the water table. This fundamental research and simultaneous development of ultra-wideband microwave technology resulted, in the early 1970s, in wide use of microwave subsurface propagation and scattering for characterization and mapping of subsurface. Since then, the range of applications has been expanding steadily.

Dielectric properties of soil, rock, ice, and snow

Propagation velocity and attenuation of microwaves is controlled by the electrical and magnetic properties of subsurface. Regarding the subsurface, three different types of natural earth materials should be distinguished: rocks, soils, and ice/packed snow. At microwave frequencies, electrical properties (which in most cases are more important than the magnetic properties) are dominantly controlled by density and by the chemistry, fine structure (composition of liquid/gas/solid components), and content of water. Below we concentrate mainly on rock and soil properties.

Following Heimovaara et al. (1994), soils can be considered as a four-component system: irregularly shaped solid particles, air, free water, and bound water. The bound water refers to the first few (up to 10) molecular layers of water near solid surfaces that are rotationally hindered by surface forces. The frequency-dependent complex dielectric permittivity of soils can be described then with a four-component complex dielectric mixing model based on the volumetric mixing of the refractive indices of the soil components. It should be noted that free water and bound water have different dielectric permittivities and thus different impact of the electrical properties of the material. Similarly to this approach, Wobschall (1977) has considered rocks as a three-phase system: irregularly shaped particles, air-or water-filled voids (pores), and crevices. In both cases, presence of moisture strongly influences electrical properties of material.

Solid particles of soils and rocks have different physical properties depending on their material. In the most simple and frequently used approach (Wang and Schmugge, 1980; Dobson, et al., 1985), the soil solid particles are considered to be a mixture of sand particles of diameter $d > 0.005$ cm; silt, 0.0002 cm $< d < 0.005$ cm; and clay, $d < 0.0002$ cm, weight content of which is expressed in percentage of total weight of soil. Dielectric permittivities of dry sand, clay, and silt are slightly different (see Table 1). More important is that clay, silt, and sand have different abilities to bind the water. It is shown in Wang and Schmugge (1980) that the quantity of bound water in soil depends on the volume of clay fraction in it and

Microwave Subsurface Propagation and Scattering,
Table 1 Typical values of relative dielectric permittivity of some dry soils and rocks at microwave frequencies (Daniels, 2004)

Material	Relative dielectric permittivity
Sand	2.4–6
Loam	4–10
Clay	2–6
Granite	5
Limestone	7
Sandstone	2–5
Silt	3–10

the quantity of bound water increases with the volume of clay. This is explained by a large specific area of clay surface compared to other soil fractions. Sand and silt particles are also covered with bound water films; however, the amount of bound water on sand and silt particles is less than 0.1 % (Bojarskii et al., 2002). Further discussions on dielectric properties of soils and rocks can be found in Hoekstra and Delaney (1974), Hipp (1974), De Loor (1983), and Hallikainen et al. (1985).

Providing a deep insight in the interaction of microwaves with rocks and soils, the abovementioned approaches require detailed knowledge of many physical parameters of soils, which are often not known during the field work. Thus, a large number of approximate equations have been proposed to compute dielectric permittivity of soil as a mixture of different components (Shutko and Reutov, 1982; Dobson et al., 1985; Sen et al., 1981). Among them, the so-called Bruggeman–Hanai–Sen (BHS) mixing model (Sen et al., 1981) is widely used nowadays:

$$p = \frac{(\epsilon_m - \epsilon_r) \left(\frac{\epsilon_w}{\epsilon_r} \right)^C}{\epsilon_m - \epsilon_w}$$

where ϵ_r is bulk soil relative dielectric permittivity, ϵ_m is the dielectric permittivity of dry soil, ϵ_w is the dielectric permittivity of water, p is fractional porosity (volume of voids/total volume), and C is a shape factor (1/3 for spherical grains). When the water content is large, wet rock or soil can be considered simply as dry solid/water mixture and simply empirically stated Topp equation (Topp et al., 1980) is frequently used:

$$\epsilon_r = 3.03 + 9.3 \cdot \theta + 146.0 \cdot \theta^2 - 76.3 \cdot \theta^3$$

where ϵ_r is bulk soil relative dielectric permittivity and θ is volumetric water content. Increase of the water content in general is responsible for increase of relative dielectric permittivity of the material.

In order to use different dielectric mixture formulas, knowledge of dielectric permittivity of water and dry soils is required. The complex-valued dielectric permittivity of bulk water at microwave frequencies can be described by

the Debye theory and the Cole–Cole model (Cole and Cole, 1941; Heimovaara, 1994) is frequently used:

$$\varepsilon(\omega) = \varepsilon' - j\varepsilon'' = \varepsilon_\infty + \frac{\varepsilon_s - \varepsilon_\infty}{1 + j(\omega\tau)^{1-\beta}} - j\frac{\sigma_{dc}}{\omega\varepsilon_0}$$

where ε_s is the low-frequency (static) dielectric permittivity of water (which is of about 88 at a temperature of 0 °C), ε_∞ is the high (infinite)-frequency dielectric permittivity and equals 4.25 for the 0 °C, τ is the relaxation time of water and $\beta = 0.0125$ and is a factor that accounts for the possible spread in relaxation frequencies, σ_{dc} is the DC conductivity at a given temperature, and ε_0 is the permittivity of free space, which is $8.854 \cdot 10^{-12}$ F/m. The relaxation time of water molecules, which equals $7.7 \cdot 10^{-12}$ s at 27 °C, drastically increases due to surface forces, and in monomolecular layers of water covering, the soil particles can reach the value of $5.0 \cdot 10^{-10}$ s at 27 °C (Bojarskii et al., 2002). As a result, the bound water exhibits relaxation at frequencies below 300 MHz and has, at microwave frequencies, considerably lower values for the dielectric permittivity than free water. The permittivity of bound water is temperature dependent, resulting in a substantial increase in bulk dielectric permittivity with temperature at microwave frequencies for soils with high surface area (Or and Wraith, 1999).

In an idealized representation, the water relative permittivity remains constant at high (roughly above 10 GHz) and low (below 100 MHz) frequencies. In a transition region over a frequency band, the real part of complex dielectric permittivity considerably decreases, while imaginary part exhibits a maximum.

Solid parts of most soils and rocks have, when dry, a relative permittivity in the range 2–9 (see Table 1) (Daniels, 2004). Very often, it is assumed that the relative permittivity of dry soils and rock is frequency independent at microwave frequencies.

Total losses in natural rocks and soils are mainly due to conductivity and polarization losses. According to Olhoeft (see, e.g., Olhoeft, 1987), water plays the dominant role in rock and soil conductivity through ionic charge transport through water-filled pore spaces in rocks and soils. Furthermore, conductivity might be due to presence of metals and other good conductors. Conductivity results in dissipation of microwave energy into heat.

Similarly to soils, dielectric properties of snow and seawater ice depend on texture and volumetric amount of water and ice crystal (Bogorodskii et al., 1983; Boyarskii and Tikhonov, 1994; Kovacs et al., 1995). Relaxation frequencies of water molecule in ice crystals lie in kHz region. Thus at microwave frequencies, pure ice has almost constant with frequency dielectric permittivity of about 3.17 and very low losses. Dry snow can be considered as a mixture of ice crystals and air. Depending on density of snow, its relative dielectric permittivity varies from 1.2 to 2. Dielectric permittivity of wet snow depends largely on amount of water in it.

Seawater ice has different properties than freshwater ice, because seawater ice consists of pure ice, air, brine, and possibly solid salts. Furthermore, the sea ice has a multilayer structure, which depends on periodic processes of growth, deformation, and melting. Depending on its age and internal structure, several types of sea ice are distinguished. Relative dielectric permittivity of ice may vary from 3 till 18–30. Losses of coherent energy of microwaves in ice are determined by ice conductivity and noncoherent scattering on spatial heterogeneities.

Attenuation and dispersion of microwaves in subsurface

To simplify the mathematical description of microwave propagation in natural subsurface, a complex-valued apparent dielectric permittivity is used:

$$\varepsilon = \varepsilon' - j\varepsilon''$$

where ε' is a bulk dielectric permittivity of the subsurface and ε'' stands for losses associated with both conductivity and polarization (dipolar) losses:

$$\varepsilon'' = \frac{\sigma}{j\omega} + \varepsilon''_{relaxation}$$

The polarization losses are caused mainly by dielectric relaxation of water and are due to the polarity of the two hydrogen atoms of the water molecule.

The plane electromagnetic wave propagating in such medium can be presented as a function of distance z and time t :

$$E(z, t) = E_0 \cdot e^{-\alpha z} \cdot e^{j(\omega t - \beta z)}$$

where E stands for the electric field component of the field, α is the attenuation factor, and β is the phase constant. Both parameters are determined by the complex-valued apparent dielectric permittivity of the medium:

$$\alpha = \omega \left[\frac{\mu\varepsilon'}{2} \left(\sqrt{1 + \left(\frac{\varepsilon''}{\varepsilon'} \right)^2} - 1 \right) \right]^{\frac{1}{2}}$$

$$\beta = \omega \left[\frac{\mu\varepsilon'}{2} \left(\sqrt{1 + \left(\frac{\varepsilon''}{\varepsilon'} \right)^2} + 1 \right) \right]^{\frac{1}{2}}$$

The distance d at which the electric field is attenuated in e times is called the skin depth and is equaled to $1/\alpha$. The skin depth is widely used in practice to estimate penetration depth of microwaves into subsurface or thickness of the top subsurface layer which determines microwave emission from the subsurface. It can be seen that the attenuation factor α by ignoring frequency dependence of complex-valued apparent dielectric permittivity is linearly related to frequency. Thus, the skin depth in the very first approximation also linearly decreases with frequency.

Attenuation of microwaves in dry subsurface at 100 MHz varies from typically less than 1 dB/m for snow and sand up to 10 dB/m for some clay, limestone, and sandstone (Daniels, 2004). The attenuation factor slowly increases with frequency in the range from 100 MHz till 1 GHz, while at the frequencies above 1 GHz, it sharply increases due to dielectric relaxation of water. At, for example, 3 GHz, microwave attenuation in subsurface varies typically between several dozens and several hundreds dB/m.

The phase constant β determines the phase velocity of microwave propagation in subsurface:

$$v = \frac{\omega}{\beta} = \left[\frac{\mu\epsilon'}{2} \left(\sqrt{1 + \left(\frac{\epsilon''}{\epsilon'} \right)^2} + 1 \right) \right]^{-\frac{1}{2}}$$

In the case of small losses and far away from relaxation frequencies, the microwave propagates with the phase velocity:

$$u = \frac{c}{\sqrt{\epsilon_r}} = \frac{1}{\sqrt{\mu_0\epsilon_0\epsilon_r}}$$

which is frequency independent. In the general case, finite conductivity of subsurface and the dielectric relaxation of water are responsible for dependence of phase velocity on frequency. This dependence is called dispersion. For microwaves, the dispersion is typically observed at the frequencies above 1 GHz.

By propagation of wideband microwave pulses in subsurface, the dispersion and attenuation cause not only decrease of the pulse magnitude but also distortion of the pulse waveform.

Subsurface scattering

Subsurface is heterogeneous not only on microscopic but also on macroscopic scale. On top of regular geological structure created by multiple strata of different soils/rocks, there is a finer irregular structure created by local spatial inhomogeneities. These are created by spatial variations of moisture, all kind of inclusions (e.g., stones or man-made objects), and animal burrows. While propagating in subsurface, microwaves scatter on interfaces between different strata as well as on local inhomogeneities. Fields scattered from large-scale heterogeneities are used in subsurface remote sensing for geological structure reconstruction and minerals prospecting (Fung, 1994; Daniels, 2004). It has been shown by Yarovoy et al. (2000) that the presence of a low-loss (e.g., sand) layer above rock at certain angles and polarizations of the incident field will enhance microwave backscattering from either internal interface (rock surface) or from air-ground interface.

Field scattered on small-scale (local) inhomogeneities is called subsurface clutter. At medium and/or high microwave frequencies, typical size of many abovementioned local inhomogeneities becomes

comparable with the wavelength of electromagnetic field. As a consequence, strength of clutter at these frequencies might become comparable to useful (searched) reflections, resulting in masking these reflections. It is widely believed that at frequencies above 1 GHz, the subsurface clutter becomes the major limiting factor for subsurface sensing.

Subsurface sensing

Subsurface propagation and scattering of microwaves makes a basis for subsurface sensing. Nowadays, three major approaches are used: ground-penetrating radar (GPR) and airborne and spaceborne remote sensing.

GPR

GPR is a surface-based active radar system (Daniels, 2004). In order to achieve reasonable penetration depth, frequencies below 1 GHz are typically used in GPR. At a frequency of 1 GHz, penetration depth varies from about 1–2 m (for dry sandy soil or dry rock) to about 10 cm in water-saturated clay. At a frequency of 100 MHz, penetration depth might reach several 100 m (Cook, 1975). Due to its short-range operation, GPR has to radiate very short (of an order of a few ns) microwave pulses into subsurface, which requires ultra-wide operational bandwidth of the system. Commercial GPR systems have typically octave bandwidth (ratio between the highest and lowest operational frequency equals 2), while some experimental systems have this ratio above 10.

While ultra-wide operational bandwidth is one key feature of GPR, another one is ground-coupled antennas. The latter is needed to avoid, as much as possible, reflection of microwaves from air-ground interface and maximize transmitted into the ground microwave power.

GPR nowadays are widely used for a wide scope of applications starting from geological prospecting and ending with landmine detection and classification.

Airborne sensing (CARABAS, radiometers)

Airborne subsurface sensing has been performed both by active (radars) and passive (radiometers) systems. First active systems have been used for polar ice profiling and mapping of central areas of Kalimantan. Furthermore, CARABAS (airborne radar developed by FOA in Sweden and operating at the frequency band 25–85 MHz) has demonstrated capabilities to image buried pipelines in desert conditions (Hellsten et al., 1996), while FOLPEN (radar developed by SRI International and operating at the frequency band 200–400 MHz) has produced images of buried metal-cased antitank landmines in the Yuma Desert (Grosch et al., 1995).

While performance of active radar systems is limited by maximal allowed transmitted power and field breakdown in the antennas, passive systems are free from these limitations. Airborne microwave radiometers have been successfully used in arid regions for search of subsurface

water, water leakage from irrigation channels, and other purposes. Achieving probably similar to active systems penetration depth, passive systems however cannot provide 3D subsurface images as well as comparable to active systems cross-range resolution.

Spaceborne sensing

Similar to airborne systems, satellite-based systems use both radar and radiometer for subsurface sensing. In particular, SIR-A and SIR-C results demonstrated that the L-band radar has penetration capabilities up to 2 m in rigid areas, revealing details of buried rock structures (Elachi et al., 1984).

Conclusion

Having almost 100 years of history, subsurface remote sensing became recently a fast-growing area of science and engineering with steadily expanding range of applications. This subject lies in a border area of three disciplines: microwave interaction with subsurface materials at microscopic level is studied by geophysics; microwave propagation and scattering in lossy, dispersive, and heterogeneous media is studied by electromagnetics; and extraction of information from microwaves radiated or emitted from the subsurface is studied by remote sensing (including GPR). The main research focus in this area remains on interaction of microwaves with heterogeneities of soils and rocks at microscale in order to determine effective dielectric permittivity of matter and development of statistical models for microwave field scattered from subsurface heterogeneities at macroscale.

MICROWAVE SURFACE SCATTERING AND EMISSION

David R. Lyzenga

College of Engineering, Naval Architecture and Marine Engineering, University of Michigan, Ann Arbor, MI, USA

Definition

Surface scattering. The process by which microwave radiation incident upon a solid or liquid surface is wholly or partially redirected away from that surface.

Microwave emission. The process by which microwave radiation originates from a solid or liquid surface due to the rotational or vibrational motions of molecules near the surface.

Introduction

This topic deals with the processes through which a solid or liquid surface influences the electromagnetic field (at microwave frequencies) in the vicinity of that surface and the manner in which these processes are determined by the physical and chemical properties of the surface. The processes of surface scattering and emission, though distinctly different, are related by *Kirchhoff's law* and can both be described by means of a single function, the *bidirectional reflectance*. The bidirectional reflectance function is defined in the following section, and the dependence of this function on the physical and chemical properties of the surface is discussed in the subsequent section. For active microwave (radar and scatterometry) purposes, the scattering properties of surfaces are more commonly described in terms of the normalized radar cross section, or cross section per unit area, which is related to the bidirectional reflectance as discussed near the end of this section.

Bidirectional reflectance

The bidirectional reflectance of a given surface, denoted here by the symbol $\rho(\mu, \phi; \mu', \phi')$, may be loosely described as the proportion of the radiance incident upon the surface from the direction (μ', ϕ') which is scattered or reflected from the surface into the direction (μ, ϕ) . Here μ refers to the cosine of the angle between the direction of the reflected radiation and the surface normal, and ϕ refers to the azimuthal angle of the reflected radiation about the surface normal. The symbols μ' and ϕ' similarly refer to the direction from which the incident radiation arrives at the surface. If we denote the surface normal direction by the unit vector $\mathbf{n}$ and the direction of propagation of the reflected and incident radiation by the unit vectors $\mathbf{k}$ and $\mathbf{k}'$, respectively, then $\mu = \mathbf{k} \cdot \mathbf{n}$ and $\mu' = -\mathbf{k}' \cdot \mathbf{n}$. For a specular surface, all of the incident radiation is reflected into the direction $\mu = \mu'$ and $\phi = \phi' + \pi$, whereas for a diffusely reflecting surface, the radiation incident from a given direction is scattered into a range of angles.

The bidirectional reflectance may be defined more rigorously, albeit implicitly, by the equation

$$L(\mu, \phi) = \int_0^1 \int_0^{2\pi} \rho(\mu, \phi; \mu', \phi') L(\mu', \phi') \mu' d\mu' d\phi' \quad (1)$$

where $L(\mu, \phi)$ is the reflected radiance and $L(\mu', \phi')$ is the incident radiance (Nicodemus, 1965). For a system in thermal equilibrium, the incident radiance is isotropic and is equal to $B_\nu(T_s) = \frac{2}{\lambda^2} \frac{h\nu}{e^{h\nu/kT_s} - 1}$ where $\nu = c/\lambda$ is the frequency, h is Planck's constant, k is Boltzmann's constant, and T_s is the surface temperature. In this case, the sum of the reflected and emitted radiation is also equal to $B_\nu(T_s)$. The emitted radiance in the direction (μ, ϕ) is then equal to $\varepsilon(\mu, \phi) B_\nu(T_s)$, where

$$\varepsilon(\mu, \phi) = 1 - \int_0^1 \int_0^{2\pi} \rho(\mu, \phi; \mu', \phi') \mu' d\mu' d\phi' \quad (2)$$

is the surface emissivity. This relationship is known as Kirchhoff's law for unpolarized radiation. At microwave frequencies, $h\nu \ll kT_s$ for temperatures typical of the Earth's surface, and $B_\nu(T_s) \approx 2kT_s/\lambda^2$ (Rayleigh-Jeans law). Thus, the emitted radiance is proportional to the product of the surface temperature and the emissivity and is often converted into units of temperature (K) and referred to as the *brightness temperature*, this being defined as the temperature of a blackbody that emits the same radiance as the actual surface, i.e., $T_B = \varepsilon T_s$.

Thus far, we have only considered the case of unpolarized radiation. However, the quantities defined above can be extended to the case of polarized radiation as well. There are various definitions of the state of polarization, but for microwave radiation, the most common definition is in terms of the modified *Stokes parameters* T_h, T_v, U , and V (see entry on "*Radiation, Polarization, and Coherence*"). A complete description of the reflectivity would require 16 components, corresponding to each possible combination of incident and reflected polarization states. However, for most remote-sensing applications, we are primarily interested in the reflection of atmospheric (and cosmic) radiation which is virtually unpolarized, and we can combine these into four components corresponding to the reflection of unpolarized radiation into each of the four polarization states. For notational purposes, we indicate that the bidirectional reflectance is polarization dependent by using the bold-faced symbol $\boldsymbol{\rho}(\mu, \phi; \mu', \phi')$, to be understood as a vector with components corresponding to the four modified Stokes parameters. Since the blackbody radiation is unpolarized, the blackbody emissivity vector can be written as $\boldsymbol{\varepsilon}_b = [1, 1, 0, 0]$, and Kirchhoff's law for polarized radiation becomes

$$\boldsymbol{\varepsilon}(\mu, \phi) = \boldsymbol{\varepsilon}_b - \int_0^1 \int_0^{2\pi} \boldsymbol{\rho}(\mu, \phi; \mu', \phi') d\mu' d\phi'. \quad (3)$$

Just above the surface of the Earth, the upwelling radiation field includes contributions from both the downwelling (atmospheric and cosmic) radiation that is reflected from the surface and the radiation that is emitted from the surface. The reflected contribution can be written in terms of the brightness temperature as

$$T_r(\mu, \phi) = \int_0^1 \int_0^{2\pi} \rho(\mu, \phi; \mu', \phi') T_d(\mu', \phi') d\mu' d\phi' \quad (4)$$

where $T_d(\mu', \phi')$ represents the (unpolarized) downwelling radiation at the surface, and the surface-emitted component can be written as

$$\begin{aligned} T_e(\mu, \phi) &= T_S \epsilon(\mu, \phi) \\ &= T_S \epsilon_b - T_S \int_0^1 \int_0^{2\pi} \rho(\mu, \phi; \mu', \phi') d\mu' d\phi'. \end{aligned} \quad (5)$$

Combining these expressions, the total upwelling brightness temperature just above the surface can be written as

$$\begin{aligned} T(\mu, \phi) &= T_e + T_r \\ &= T_S \epsilon_b + \int_0^1 \int_0^{2\pi} \rho(\mu, \phi; \mu', \phi') \\ &\quad [T_d(\mu', \phi') - T_S] d\mu' d\phi'. \end{aligned} \quad (6)$$

Measured at spacecraft altitudes, the observed brightness temperature would of course be reduced by attenuation in the atmosphere and augmented by the upwelling radiation emitted from the atmosphere.

Dependence of bidirectional reflectance on surface properties

The interest in making measurements of the microwave radiation field above the surface of the Earth is to obtain information on geophysical or biological processes occurring at the surface or in the atmosphere or on the physical or chemical state of the surface and/or atmosphere. The types of information and the methods used to extract this information are discussed in other entries (see, e.g., *Land-Atmosphere Interactions*, *Evapotranspiration*; *Ocean-Atmosphere Water Flux and Evaporation*; *Ocean, Measurements and Applications*; *Cryosphere, Measurements and Applications*). In this section, we discuss some of the relationships that underlie these applications.

As discussed in the previous section, the effects of the surface on the radiation field above the surface can be described in principle by the surface temperature and the bidirectional reflectance vector $\rho(\mu, \phi; \mu', \phi')$. This quantity can be defined for a specific surface but more often refers to a statistical ensemble of surfaces with similar properties. It could in principle be measured, but as can

be imagined, this is a difficult and time-consuming process since it involves many different combinations of incidence and reflection angles and must be repeated for many surfaces to obtain a stable statistical mean. Thus it is desirable to model the bidirectional reflectivity when possible, although measurements are necessary for model validation and can sometimes be used directly if some assumptions are made about the directional dependence.

Models have been developed, even for complex surfaces such as vegetation canopies, as discussed in the *Measurements and Applications* entries referenced above. A review of these models is beyond the scope of this entry, but in general the reflectivity depends on the surface roughness, or the geometrical shapes of the elements comprising the surface or canopy, as well as the *dielectric constant* of the component materials. Since the dielectric constant is influenced by such factors as the water content of soils and vegetation, the salinity and phase (liquid or ice) of the ocean surface, and possibly other chemical constituents, the radiation field potentially contains information about these factors. In addition, the roughness of the ocean surface is a function of the wind speed and direction (as well as, possibly, other factors such as the presence of surface slicks, converging or diverging surface currents, and atmospheric stability conditions). As a result, radiometric measurements from aircraft and satellite platforms have been shown to be very useful for measuring surface winds over the ocean on regional and global scales and for observing some of the other features mentioned above on smaller scales. Polarimetric measurements such as those provided by WINDRAD (Yueh et al., 1999) and WindSat (Gaiser et al., 2004) are particularly useful for separating atmospheric from surface effects and for inferring the wind direction as well as wind speed.

For the ocean surface, the bidirectional reflectance is most commonly modeled using a two-scale model (Wentz, 1975; Yueh, 1997) although other models such as the small-slope approximation (Irisov, 1997; Johnson and Zhang, 1999) have also been used. Such modeling also requires a representation of the ocean wave spectrum and its dependence on the wind speed. The spectral model of Durden and Vesecky (1985) has been widely used for this purpose, but some modifications have also been suggested (Lyzenga, 2006) in order to improve comparisons with satellite data. The shortwave (centimeter-scale) portion of the ocean wave spectrum has a strong influence on the microwave surface reflectivity, and there are large uncertainties in this portion of the spectrum due to the difficulty of measuring the surface on these scales. The effects of wave breaking and surface foam on the reflectivity are also incompletely understood, although considerable work has been done in this area.

In the radar literature, the scattering properties of objects are most often described in terms of the radar cross section σ , which is defined as 4π times the reflected power per unit solid angle divided by the power density (power per unit area) incident on the object. It can be defined for any scattering angle but is most commonly used for

backscatter, i.e., for the case in which the source of radiation and the receiver are collocated. This definition applies to discrete objects but was later extended to the case of scattering surfaces by dividing the reflected power by the surface area illuminated or resolved by the radar. This dimensionless quantity is denoted by the symbol σ^o and referred to as the normalized radar cross section, or the cross section per unit area.

The relationship between the radar cross section and the bidirectional reflectance can be found by considering the radiation scattered from a unit surface area. For the case of a distant source, the incident radiance can be written as

$$L(\mu', \phi') = E_o \delta(\mu' - \mu_o) \delta(\phi' - \phi_o) \quad (7)$$

where E_o is the incident power per unit area normal to the direction of the incident radiation (as in the definition of the radar cross section). The scattered radiance for this case is given by Equation 1 as

$$L(\mu, \phi) = \mu_o E_o \rho(\mu, \phi; \mu_o, \phi_o). \quad (8)$$

Following from the definition of the radiance, the reflected power per unit solid angle is equal to $\mu L(\mu, \phi)$. Applying the definition of the radar cross section, we then have

$$\sigma^o = 4\pi \frac{\mu L(\mu, \phi)}{E_o} = 4\pi \mu \mu_o \rho(\mu, \phi; \mu_o, \phi_o) \quad (9)$$

in agreement with Tomiyasu (1988). For the backscatter case, of course, $\mu = \mu_o$.

Conclusion

The effect of the Earth's surface on the naturally occurring microwave radiation field above the surface can be described in terms of the surface temperature and the bidirectional reflectance of the surface. The bidirectional reflectance is a function of the geometry and composition of the surface. For land surfaces, the reflectance is strongly dependent on the water content of the soil and/or vegetation. For water surfaces, the reflectance depends on the salinity, the phase (liquid or solid), and the surface roughness. For the liquid ocean, the surface roughness is primarily dependent on the wind speed but may also be influenced by surface slicks, currents, and atmospheric stability effects.

MISSION COSTS OF EARTH-OBSERVING SATELLITES

Randall Friedl and Stacey Boland
 Jet Propulsion Laboratory, California Institute of
 Technology, Pasadena, CA, USA

Synonyms

Earth-observing mission costs; Spaceborne mission costs

Definition

Earth-observing satellite mission. An instrumented spacecraft deployed in space that is designed to observe select geophysical parameters of the Earth for purposes of environmental science or monitoring. A satellite mission requires a launch vehicle, observing instruments, and a spacecraft bus which houses the instruments as well as systems for guidance, navigation, control, communications, command and data, power, thermal control, propulsion, and structures.

Satellite mission cost. The total cost of implementing a satellite mission. The cost includes all of the component

costs as well as costs for design, system engineering, operating and data analysis software, and mission operations. The cost does not typically include scientific analysis of the data collected by the mission.

Introduction

Observing the Earth from the vantage point of space has transformed our understanding of the Earth as an integrated system of physical and biological components. The number of Earth-observing satellites has steadily increased with time, with more than 100 satellite missions currently operating. The desire for new satellite missions remains high, especially since many of the geophysical parameters of interest to scientists (e.g., 44 essential climate variables as defined by the Global Climate Observing System Program) are still not observed from space and other key parameters need to be sustained over many satellite lifetimes to enable investigations of long-term climate trends. The need for new missions is tempered by the relatively high cost, currently ranging from \$100 M to \$3 B, to deploy and operate a satellite mission. Understanding the factors that determine the costs of satellite missions is critical to developing and sustaining an effective system of Earth-observing satellites.

Cost factors

Transporting instrumented science payloads to space requires powerful launch vehicles. The relatively small number (i.e., ~30 total, ~12 USA) of available launch vehicles is divided into four classes, as defined by the US Federal Aviation Administration Office of Commercial Space Transportation, that reflect lift capability as follows: small ($\leq 5,000$ lb to Low Earth Orbit or LEO), medium (5,001–12,000 lb to LEO), intermediate (12,001–25,000 lb to LEO), and heavy ($\geq 25,000$ lb to LEO). Examples of launch vehicles across the four classes are Pegasus (small), Delta II (medium), Atlas IIAS (intermediate), and Atlas V (heavy). While the cost of a launch vehicle increases with each step-up in class, the per pound payload cost is roughly the same across classes when the launch vehicle lift capability is fully utilized. There is thus a substantial cost incentive to either design a payload to fit into the smallest possible launch vehicle or to combine payloads to take advantage of the full capability of a larger-class vehicle. Most of the past and current Earth science missions range between 1,000 and 10,000 lb (instruments plus spacecraft) and were launched on small- and medium-class launch vehicles.

While launch vehicle costs can be directly correlated to performance requirements in terms of a “price per pound” metric, this is not the case for estimating the cost of the satellite instruments. Science instrument payloads typically represent the most unique and challenging components of Earth-observing missions. Payload designs are generally mission unique, resulting from a careful optimization of science requirements against physical and programmatic constraints (e.g., cost, schedule, risk). Instrument

costs can thus be driven by a variety of factors. Increasingly stringent requirements on temporal and spatial resolution, for example, might necessitate larger signal collection optics and/or antennas as well as highly sensitive detectors and precision signal processing electronics, driving payload mass, volume, and component costs higher. Attempts to reduce payload mass and volume might necessitate incorporation of new, yet expensive, lightweight technologies.

Spacecraft costs, like launch vehicle costs, are generally performance driven. Instrument accommodation requirements, particularly mass, power, data rate, and configuration constraints, greatly dictate requirements for the platform, or spacecraft bus, that houses the instrument. While many standardized platforms are now available, most missions have the need for some degree of spacecraft customization (e.g., tighter thermal control, improved pointing accuracy or knowledge, larger onboard data storage capacity, additional power allocations). The cost of customization is to a large extent dependent on whether new technology development is required.

Mission operations costs are driven, to a large extent, by mission data volume and latency requirements which can drive ground network, data processing, and archival costs. The spacecraft’s onboard data storage capacity (i.e., solid-state recorder size) is also a determining factor in the required frequency of data downlinks and/or number of ground stations.

Cost estimation methods

Three methodologies are generally used to estimate mission costs, namely, analogy, parametric, and “grass roots.”

An analogy-based estimate represents the simplest approach to cost estimation. It relies on direct comparisons to analogous ongoing or previous missions. Provided there is little deviation from the chosen analog, rapid and accurate mission cost estimates can be obtained using this method. However, since very few missions share identical subsystems or components, analogy-based estimates are not widely applicable without including cost adjustments based on analysis of differences between the target mission and the analog. Such adjustments typically employ parametric analyses in order to enable quantitative extrapolations between systems with varying degrees of differences. Analogy-based estimates best apply to mission lines which involve launching a series of similar (or near-identical) satellites (e.g., the NOAA POES series of weather satellites) and those which incorporate incremental performance improvements between generations (e.g., the NASA TOPEX-Poseidon, Jason, OSTM-sustained research satellite series).

Parametric cost estimates are based on cost driver relationships derived from analyses of historical data. The primary cost drivers used for parametric studies typically include mass, power, and subsystem complexity. For example, experience shows that mission costs increase roughly linearly with mass within a given launch vehicle

class, allowing derivation of the “price per pound” metric cited above. Once developed, parametric relationships are particularly useful for performing rapid trade studies during the initial scoping of mission concepts, particularly for concepts without direct historical analogy.

Grassroots cost estimates involve detailed consideration of each element of a mission or component of an instrument. For each element or component, a cost estimate is generated and basis of estimate is documented, describing the technique used to derive the estimate. For a true grassroots estimate to be performed, the mission or instrument design must be specified to a fairly high degree to enable rigorous quantitative cost estimates based on material and labor costs allocated over a defined implementation schedule. Consequently, grassroots estimates find their greatest utility during later stages of mission development. During concept development, a “quasi-grassroots” mechanism can be employed in which the grassroots cost estimating structure is preserved, including documentation of a basis of estimate, while leveraging analogy or parametric cost estimates for the individual components for which detailed requirements, designs, and/or schedules are not well known.

Cost estimation accuracy

The ability to conceive, plan, and implement an effective and affordable multi-satellite observing system rests in large part on understanding the costs of individual missions. In particular, decisions regarding mission priorities and sequencing are intimately tied to considerations of cost to benefit.

Because there are relatively small numbers of satellite missions and most of them are partially, or wholly, unique in design, the ability to accurately estimate cost is limited in the beginning phases of a mission. Analysis of historical mission cost data reveals a tendency for substantial increases (10–50 %) in estimates for lower-cost Earth missions when going from initial to later mission phases. These increases have been traced primarily to initial underestimations of instrument and spacecraft components. In many cases, the cost increases reflect more stringent measurement requirements stemming from refinement of the mission science goals, rather than inherent inaccuracies in the estimation methodology.

MISSION OPERATIONS, SCIENCE APPLICATIONS/REQUIREMENTS

David L. Glackin
 Los Angeles, CA, USA

Synonyms

Environmental data record (EDR) requirements

Definition

Science applications. Environmental phenomena to be measured in the Earth’s atmosphere, oceans, land surface, solid Earth, ice cover, and near-Earth space environment. *Science requirements.* A numerical specification of the phenomena that must be measured and a corresponding set of attributes including spatial resolution, spatial reporting interval, spatial coverage, measurement uncertainty (accuracy/precision), long-term measurement stability, mapping uncertainty, reporting frequency, and timeliness of data delivery.

Introduction

The science applications are described thoroughly elsewhere in this volume (see *Atmospheric General Circulation Models*; *Ocean, Measurements and Applications*; *Cryosphere, Measurements and Applications*; *Land-Atmosphere Interactions, Evapotranspiration*; *Trace Gases, Troposphere - Detection from Space*). The thrust of this entry is the science requirements and how they are motivated, established, codified, analyzed, and iterated.

David L. Glackin: deceased.

Motivation for and establishment of requirements

In an ideal world, science requirements should be motivated by a problem in need of a remote sensing instrument (or set of instruments), not vice versa. Reality is sometimes different, but environmental remote sensing missions, especially large ones, typically have a large user constituency behind them that provides the rationale for the mission. Mission requirements may be driven by the need for new types of data, improvements in the quality of old types of data, or continuity of data for studies of long-term trends.

Ideally, the requirements flow should be from the top down. The science requirements should drive the instrument concepts. Those concepts in turn should drive the instrument designs, which should in turn drive the platform (satellite, aircraft, etc.) concept and design. Examples of important aspects of the platform design that the science requirements drive are pointing accuracy and stability and the choice of satellite orbit (see *Observational Systems, Satellite*).

As an adjunct to the science requirements, the postlaunch data reduction, analysis, and research activities should be considered up front. Too often, the tendency is to focus on building the instruments and the platform to meet the requirements and to delay consideration of the analysis and research. The latter approach can have large systems impacts, and it is best to consider these issues up front while setting requirements. For example, the calibration/validation phase of a mission is a major postlaunch activity and is the one in which the instrument calibration is established and in which the quality of the science data products is validated (see *Calibration and Validation*). If the science requirements lead to data products that are exceedingly difficult to validate, unexpected amounts of postlaunch resources may be required (see *Mission Costs of Earth-Observing Satellites*).

Science requirements are usually established by user working groups, which are organized by scientific discipline. It is important to involve the instrument systems engineers early in this process. They understand the hardware in an end-to-end systems sense and can help the user communities to understand the cost and risk implications of their requirements. Often, scientific “desires” must be tempered with technological reality. Sometimes, it may be possible to achieve half of what is desired at one-tenth the cost. Science requirements are typically iterated between these two groups of people until a realistic set of requirements is established.

Science requirements are often couched in terms of “thresholds” and “objectives.” The thresholds are the minimum set of requirements that must be met. The objectives represent the performance that the users would like to meet, if meeting them does not inordinately drive the hardware design. Remote sensing missions may in the end deliver data products that fall between these two benchmarks.

Codification of requirements

The science requirements must be established carefully. Clarity is of the utmost importance. If the requirements

are not clear up front, much time will be wasted later in clarifying the requirements to the instrument and platform vendors and then in rewriting the requirements. Definitions must be clear and comprehensive. Units must be consistent and understandable. Requirements must be consistent with basic physics. There should be no conflicting requirements. Very significant is the establishment of requirements for measurement quality. It is possible to generate major confusion over items as seemingly simple as measurement accuracy, precision, and uncertainty. The latter can be a major stumbling block in the process of requirements establishment and should be treated thoughtfully.

Requirements analysis and iteration

Science requirements should be thoroughly analyzed after they are initially established, for clarity, consistency, comprehensiveness, lack of conflict, and impact on the end-to-end mission. This is the point at which the design engineers, the hardware vendors, and the operators should engage with the system engineers to ensure that the set of requirements is sound. At this stage, iterations of the requirements are usually made, in consultation with the user community.

It is paramount that experienced people think through these issues up front. Otherwise, problems can crop up during the course of the program that can be very wasteful of resources.

It is particularly important to define the “driving requirements” (Wertz and Larson, 1991). These are the ones that dictate some of the major hardware characteristics.

“Requirements creep” is almost always a problem in any large remote sensing mission. Once the user communities start to see what the system can do, they usually think of more things that it might do. One solution for that is to define these items as “Pre-Planned Product Improvements” (P3I) that might be addressed later, given sufficient resources.

Conclusion

An intelligent process of establishing the science requirements for a mission can make the difference between mission success and failure or between delivering the hardware on time and under budget and delivering it late and far over budget. Getting the science requirements right at the beginning and thinking things through thoroughly up front is key to mission success.

O

OBSERVATIONAL PLATFORMS, AIRCRAFT, AND UAVS

Jeffrey Myers
NASA/Ames Research Center, Airborne Science and
Technology Laboratory, University of California,
Santa Cruz, Moffett Field, CA, USA

Synonyms

Airborne platforms; Remote sensing aircraft; Suborbital platforms

Definition

Airborne observational platforms are any aircraft, manned or unmanned, which is equipped to obtain remotely sensed data or in situ atmospheric samples above the surface of the Earth.

Introduction

Airborne platforms are typically used to obtain observations of high spatial or temporal resolution that cannot be practically achieved with satellite- or ground-based systems. These include remote sensing observations of dynamically evolving events (e.g., volcanic eruptions or convective weather systems) which could not be made by satellites due to their fixed revisit schedules or in situ air sampling of atmospheric constituents at varying altitudes. Because they can selectively operate during clear-sky conditions, they are also often used for remote sensing in areas which have persistent cloud cover. Imagery in some tropical, mountainous, and arctic regions, for example, cannot be obtained from polar-orbiting satellites on any regular basis.

The spatial resolution of imagery obtained from an airborne platform can be precisely controlled by varying the altitude of the aircraft above the ground. Pixel sizes

produced from a sensor with a 2.5 mrad instantaneous field of view (IFOV), for example, can thus be varied between 3 and 50 m with the same instrument, when operated at altitudes of 1,200 and 19,800 m, respectively. This variability allows the imagery to be tailored to the requirements of the specific phenomenon being studied. Most satellite systems, especially those with the infrared spectral bands of interest to earth scientists, are designed for broadscale global observations at fixed spatial resolutions, which may be too coarse for many detailed geophysical process studies. Spatial resolutions of airborne infrared imaging systems can exceed 3 m and can be as high as 1 cm in the visible and near-infrared wavelengths, depending on platform altitude.

Airborne platforms are also used as test beds for new instrument development. They provide an economical method of testing prototype satellite sensors prior to launch and also for collecting the empirical data needed to develop the associated retrieval algorithms for new orbital systems. Once a satellite system is placed in orbit, airborne sensors are often used to conduct simultaneous, high-resolution observations for data validation and instrument calibration purposes.

Overview of platform types

Manned aircraft

A wide variety of airborne platforms are used for Earth observations, ranging from small single-engine propeller planes with minimal modifications to large specially adapted multiengine commercial and military reconnaissance aircraft. Unmanned Aerial Vehicles (UAVs), airships, and balloons also fill unique observational niches. These platforms are modified to varying degrees to accommodate either remote sensing or air sampling payloads. The particular measurement requirements, together with budget constraints, indicate the most appropriate platform for a given application. Fundamental aircraft

variables to be considered include operating range and altitude, payload capacity, flight endurance, and cost of operation. There is typically a trade-off with most aircraft between the weight of the payload and the amount of fuel to be carried, which in turn affects the operating range.

If the instruments to be flown are relatively lightweight and the projected operating area is small and close to an airfield, a light one- or two-engine private plane is by far the most economical. Typically unpressurized, they usually operate at altitudes below 7,500 m with ranges under 600 km. As the size of the instrument payload and/or the extent of the study area increases, larger and more capable platforms are required. Turbine or turbo-charged twin engine propeller aircraft offers the next level of performance with a significant increase in payload and range, pressurized cabins, and operating altitudes up to 10,000 m. These often offer the best compromise between performance and cost-effectiveness for many applications. Corporate jets or larger commercial transport aircraft, which can fly above 12,000 m and at much higher speeds, can carry heavy payloads and cover even larger areas in a single flight but are relatively expensive to operate. Special-purpose high-altitude platforms, such as the NASA ER-2 (a Lockheed U-2 reconnaissance aircraft derivative) or the Russian M-55 Geophysica, can fly into the lower stratosphere and operate over very large geographical areas. These aircraft are often used for atmospheric research but are still more expensive and require specialized ground support equipment. For remote sensing missions, the very long atmospheric path length below these aircraft makes the atmospheric correction task more problematic. Imaging through a nearly full atmospheric column can be an advantage for the validation of satellite data, however. Flying at 20,000 m altitude, these aircraft are above 95 % of the Earth's atmosphere, allowing for very accurate at-sensor response comparisons between airborne and orbital systems.

UAVs: unmanned aerial vehicles

Also known as Unmanned Aerial Systems (UAS), these include a full range of size classes from very small hand-launched aircraft resembling model airplanes to the large high-altitude observational systems used by military services and some science agencies. The complexities of operation, together with payload and range capabilities, also vary conversely. Most UAVs are remotely piloted by a person on the ground, using a radio link to send commands to the flight control system on the aircraft. However, some are configured to operate autonomously, using an onboard computer with a preprogrammed flight plan, together with a satellite Global Positioning System (GPS) and an inertial guidance system. UAVs offer several significant advantages over manned platforms. For example, they can operate in hazardous environments (e.g., near volcanic activity or in toxic plumes) without endangering a human pilot. Some UAVs also have endurance in excess of 20 h, which enables sustained observations of

an evolving phenomenon. Airships, both rigid dirigibles and nonrigid types, also have this capability.

Apart from vehicles designed for completely autonomous operation, some form of communication link is generally required to operate a UAV. This can consist of a simple line-of-sight radio link as used on small model airplanes, which limits the range of operation, or a larger satellite communication ("satcom") system, which extends the operating range over the horizon. The most elementary satellite communications systems use mobile satellite telephone technology with small omnidirectional antennas and conventional low-speed data modems. The higher data-rate satcom systems found on larger UAVs require large directional antennas and are significantly heavier and more expensive to operate.

The smaller UAVs can be very economical overall to operate, while the larger military-type platforms, which use high-speed satellite communications links and complex ground stations with professional pilots, can be considerably more expensive. Regardless of size, however, almost all UAVs are subject to some form of government air traffic control regulations, which can make flight operations – especially over urban areas – highly problematic. In the USA, even the smallest model airplane types are subject to federal airspace restrictions when used for any purpose other than recreation. Access to the local airspace for a UAV should never be assumed and indeed has been a major obstacle to their wider proliferation in the private and scientific sectors.

Payload accommodations

Airborne observation platforms require varying degrees of mechanical modification to suit their intended purpose. These can range from simple external instrument mounting fixtures on an otherwise unmodified light aircraft to permanent airframe modifications that may include optical windows, air sampling probes, or external attachment points for sensor pods.

Remote sensing aircraft

These aircraft are usually fitted with optical camera windows at various angles for nadir, side, or zenith viewing or external pods with similar accommodation. If the windows are fitted in an aircraft with a pressurized cabin, they must be specially engineered with adequate safety margins. Windows in an unpressurized aircraft (typically operating at altitudes less than 3,000 m) are less problematic to install. Commercially available aircraft optical windows typically have wavelength transmissions between 180 nm and 2.5 μm . Infrared windows are also available, although generally in smaller sizes, and are much more expensive. Many infrared instruments instead are designed to view through an open aperture in the aircraft fuselage to avoid window cost and/or spectral transmission issues. In the case of a pressurized aircraft, this open observation port, together with the instrument itself, is enclosed beneath a sealed housing which preserves the

aircraft cabin pressurization. These installations often include an external sliding door that covers the open aperture to protect the instrument when not in use.

Airborne radar platforms

Airborne radar or passive microwave systems require various forms of antennas, which are either integral to the airframe or carried in external pods. Flat-panel phased-array antennas which have no moving parts can be affixed directly to the outside of the aircraft. Mechanically pointed antennas are typically mounted under domes or in external pods made of a material that is transparent to the relevant frequencies. Depending on the particular system, these antennas can be quite large and may require extensive modifications to the platform. They may also have large electrical power requirements, which can require special modifications to the aircraft power system.

Air sampling platforms

These platforms are equipped with inlets to bring the external ambient air into measurement devices mounted either inside the cabin or in externally mounted pods. These usually consist of external probes or booms on the aircraft nose, fuselage, or wings, which extend the inlets into the free airstream. The inlet probes must extend beyond the boundary layer of the platform and be otherwise free of any turbulence or aerodynamic effects from the aircraft itself, to ensure unbiased sampling of free air at ambient pressure. The location of the probes on the aircraft is usually determined by modeling the airflow around the particular fuselage, under the airspeed and attitude parameters (pitch, roll, yaw) expected during sampling operations.

Data systems

Observation platforms are also often fitted with ancillary data systems to augment the primary instrument measurements. These may include the basic recording of aircraft state parameters, such as time, navigational position and attitude, altitude, and heading, as well as external air temperatures and pressures. These data are usually provided by some combination of satellite GPS and the aircraft's own Inertial Navigation System (INS) or Air Data Computer. For applications requiring very precise knowledge of platform attitude and location, such as the precision geo-location of image data, or for quantitative air sampling, stand-alone Inertial Measurement Unit (IMU) and differential GPS units may be used. In the air sampling case, this may be coupled with external pressure transducers, which allows for the derivation of external winds around the platform.

Other considerations

The operating environment for instruments onboard an aircraft is typically demanding and may impose stresses on the equipment that are not always conducive to good

scientific measurement. Outside air temperatures vary radically with altitude, often causing instruments to cool considerably unless mounted inside a pressurized cabin. Those with thermal infrared channels viewing through an open port are particularly subject to severe environmental stresses, including temperature cycling, water condensation, and optical contamination. The use of heaters to maintain the temperature of critical electrical and optical components above the local dew point, and hermetic sealing of optics and spectrometers wherever possible, has been proven to increase data quality as well as the longevity of the systems themselves. The deposition of contaminants onto glass surfaces (lenses, windows, etc.) can also compromise measurement quality, so regular cleaning of these surfaces is necessary. The electrical power found on many commercial aircraft, usually 28 V Direct Current, together with the associated electrical grounding circuitry, can be highly variable in quality. Instruments should incorporate internal electrical power conditioning whenever possible to mitigate adverse effects.

Mechanical vibration is another potential problem source for delicate instrumentation and each platform has its own vibration frequency spectrum which changes with engine power and control surface settings. Excessive vibration can affect the optical alignment of spectrometers, induce microphonic noise in infrared detectors, and cause the failure of electrical connections. The G-forces associated with landings and in-flight turbulence can also be substantial. Some form of vibration isolation between instrument and airframe, tailored to the weight of the instrument and the specific vibration regime of the platform, is often indicated. In general, instrumentation should be ruggedized to obtain consistent results in the airborne environment.

Summary

Airborne observational platforms consist of a variety of types, including conventional and unmanned aircraft, and have a broad range of technical capabilities and operating costs. Aircraft used for Earth observing require varying degrees of modification, depending on their intended applications. This entry provides a brief overview of platform types, mission-specific modifications, and their relevant operating envelopes.

Definition

Satellite Observational System. A system for the study of the Earth and its environment (atmosphere, oceans, ice, land surface, solid Earth, and near-Earth space environment) from space. The end-to-end system includes (1) the spacecraft (the platform that hosts the remote sensing instruments and provides them with pointing, power, commands, data storage, etc.), (2) the remote sensing instruments (often called “sensors”) that observe and measure the characteristics of the Earth’s environment, and (3) the ground-based mission operations. The term “satellite” is usually used for the combination of the spacecraft and instruments, but in some communities, the term “spacecraft” is used for that combination, with the term “satellite” indicating the platform.

Introduction to satellite observational systems

Although the first weather satellite, TIROS I, was launched in 1960, the field of satellite-based remote sensing of Earth really began to take form in the 1970s (see *Remote Sensing, Historical Perspective*). The launches of Landsat-1 in 1972, Skylab in 1973, Nimbus-7 in 1978, and Seasat in 1978 set the stage for modern environmental remote sensing (Glackin, 2004).

Since the pioneering work of the 1970s, the field of satellite environmental remote sensing has steadily evolved. Before 1990, only six nations owned environmental satellites (China, France, India, Japan, the USA, and the former USSR), but since then, the number has quintupled. The new nations (Glackin and Peltzer, 1999; Kramer, 2002; eoPortal, 2008) include the ones in Africa (Algeria, Morocco, and Nigeria), Asia (Indonesia, Malaysia, South Korea, Taiwan, Thailand, and Ukraine), Europe (Belgium, Germany, Italy, Portugal, and the UK), the Middle East (Egypt, Iran, Israel, Pakistan, and Turkey), North America (Canada), Scandinavia (Sweden), and South America

(Argentina, Brazil, and Chile), as well as the country of Australia. Many of these nations have procured their satellites from other nations, as described below.

Pre-1990 programs primarily involved systems of high cost and complexity, but post-1990 the focus shifted to include missions involving smaller satellites of lower complexity and cost and greater commercial involvement, including hybrid government/commercial systems (see *Public-Private Partnerships*) and fully commercial systems (see *Commercial Remote Sensing*). Examples of hybrid government/commercial systems are the US Landsat, the French SPOT (Système Pour l'Observation de la Terre), and the Canadian RADARSAT satellites. In such hybrid programs, industry is expected to share a portion of the development costs and to recoup their investment by developing a commercial market for the data products (see *Cost Benefit Assessment*).

Fully commercial systems have met with some success, although many efforts have been canceled. These include an Australian hyperspectral (see *Remote Sensing, Physics and Techniques*) mining satellite called ARIES, satellites for precision agriculture called GEROS from Geophysical and Environmental Research Corp. (GER) and Resource21 from Boeing/GDE Systems, the "One-Meter System" from GDE Systems, the Radar-1 SAR (Synthetic Aperture Radar) system from Research and Development Laboratory (RDL), and AVStar, a system from AstroVision to provide color imagery of the Earth from GEO (Geostationary Earth Orbit) (see Glackin and Peltzer, 1999.) The five latter systems were all from the USA.

UoSAT-5, launched by the British company Surrey Satellite Technology Ltd (SSTL; SSTL, 2008) in 1991, was the first commercial microsat. OrbView-1, launched by the US company ORBIMAGE (now part of GeoEye) in 1995, was the first commercial weather satellite (Glackin and Peltzer, 1999). In the 1990s, governments also pioneered the concept of buying end-user data products rather than satellites. The first example involved a NASA (the National Aeronautics and Space Administration) data buy of data from OrbView-2/SeaStar, the first satellite launched to provide commercial ocean color imagery in 1997 (GeoEye, 2008).

Commercial high-resolution remote sensing imagery (see *Commercial Remote Sensing*) became a reality when the former USSR began selling 5 m resolution panchromatic (see *Remote Sensing, Physics and Techniques*) imagery in 1987, followed by Russian sales of 2 m resolution panchromatic imagery in 1992 under the Kosmos/SPIN-2 (Space Information-2) program. Both were digitized from returned film. The US industry felt that SPIN-2 could be the harbinger of a lucrative market that might expand internationally, from which they would be excluded because of existing restrictions on imagery resolution (NASA, 2007). As a result of intense lobbying by industry, in 1994, the first licenses were granted allowing commercial US systems with a resolution of 1 m to be built and flown. Still, in 1998, the highest-resolution satellite imagery commercially

available was from SPIN-2 and from India's IRS-1C and -1D (IRS = Indian Remote Sensing) satellites with 5.8 m panchromatic resolution (Jacobsen, 2008). The first commercial high-resolution remote sensing satellite with 1 m resolution, IKONOS, was launched by the US company Space Imaging (now part of GeoEye; GeoEye, 2008) in 1999, followed by others of similar resolution from several countries (India, Israel, Russia, and South Korea). Those in turn were followed in 2007 by high-resolution SAR systems from Canada (RADARSAT-2 with 3 m resolution) and Germany (TerraSAR-X with 1 m resolution). The commercial high-resolution satellites will be discussed further below. Much of their success has relied on the existence of governments as "anchor-tenants," i.e., principal customers. Sales to the commercial sector have not proven to be as viable as many practitioners envisioned in the 1990s.

Beginning in 1991, remote sensing satellites in the microsatellite (microsat) category (10–100 kg) were launched, followed in 1997 by satellites in the minisatellite (minisat) category (100–500 kg). The first such minisat was NASA's TOMS/Earth Probe carrying the Total Ozone Mapping Spectrometer (TOMS/EP, 2008). These microsats and minisats have enabled much of the international proliferation in this field. Many of the newer countries involved in this field have used the technological know-how of other countries to build much of the space-based hardware. They have used foreign-partnership programs for technology transfer to build up an indigenous capability for constructing the hardware, usually to complement their existing capability in analyzing remote sensing data. A leader in the technology transfer field for nearly 20 years has been the very successful British company SSTL (SSTL, 2008). They have provided microsats to countries including Algeria (Alsat-1/DMC), Chile (FASat-Alfa and Bravo), China (Beijing-1/DMC), Nigeria (NigeriaSat-1/DMC), Portugal (PoSat-1), South Korea (KITSAT-1 and -2), Thailand (TMSat), and Turkey (BilSat-1/DMC). DMC stands for Disaster Monitoring Constellation, an effort in international collaboration established by SSTL for the monitoring of disasters from space using simple multispectral cameras. The former TRW in the USA provided minisats to South Korea (for KOMPSAT-1; Korea Multi-Purpose Satellite-1; KOMPSAT, 2008) and Taiwan (for ROCSAT-1/Formosat-1; Republic of China Satellite-1), used principally for ocean color monitoring (ROCSAT, 2008).

Coupled with the trend toward more small satellites, especially in the minisat class, has been a desire for downsized but highly capable remote sensing instrumentation. Smaller, lighter instruments mean smaller, lighter spacecraft to support them, which means smaller launch vehicles, all equating to lower cost (see *Mission Costs of Earth-Observing Satellites*).

The international proliferation of small satellites has certainly not meant that large satellites have gone out of fashion. In 2002 alone, three high-mass satellites

(eoPortal, 2008) were launched [SPOT-5 from France at 3,000 kg, ADEOS-2 (Advanced Earth Observing Satellite-2) from Japan at 3,700 kg, and Envisat from ESA at 8,000 kg]. Many more medium-to-large (>500 kg) satellites have been launched and are planned.

While many systems hosting multispectral instruments have been launched and are operating successfully, relatively few hyperspectral instruments have been launched. Following some failures and cancelations, the first success was NASA's NMP (New Millennium Program) EO-1 (Earth Observer-1) satellite in 2000, carrying the Hyperspectral instrument with 220 spectral bands (EO-1, 2008). This was followed by the PROBA (Project for On-Board Autonomy) technology demonstration satellite from the UK and Belgium in 2001, carrying the CHRIS (Compact High-Resolution Imaging Spectrometer) hyperspectral imager (CHRIS, 2008). CHRIS data have received broad application. In 2004, NASA's Earth Observing System (EOS) Aura satellite hosted the hyperspectral Ozone Monitoring Instrument (OMI) from the Netherlands and Finland (Aura, 2008). It observes ozone in the ultraviolet (UV) from 0.27 to 0.38 μm (see *Remote Sensing, Physics and Techniques*). Future hyperspectral instruments have been announced by Argentina/Brazil (HSI, 2007), Germany (EnMAP, 2008), India (IMS-1, 2008), Italy (Hypseo, 2007), and South Africa (ZASat-2, 2008). Hyperspectral imagers can quickly generate gigabytes of data and provide a particular challenge for satellite data handling and transmission systems (see *Mission Operations, Science Applications/Requirements and Mission Costs of Earth-Observing Satellites*).

The application of lidar (see *Remote Sensing, Physics and Techniques*) to spaceborne remote sensing remains a fledgling field. The first lidar to fly in space designed to perform remote sensing of the Earth's atmosphere was NASA's LITE (Lidar In-space Technology Experiment) that flew on the shuttle in 1994 (Kramer, 2002). The Russian Balkan-1 lidar was launched on the Mir-Spektr module in 1995 (Kramer, 2002), while the French ALISSA lidar was launched on the Mir-Priroda module in 1996 (Kramer, 2002) to study clouds, aerosols, and the Earth's surface (ALISSA = l'Atmosphere par Lidar Sur SAlout). Currently operating lidars are on the US/French CALIPSO (Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation) satellite, launched in 2006, with 100 m laser spot size at the Earth's surface and NASA's EOS ICESat (Ice, Cloud, and land Elevation Satellite), launched in 2003, with 70 m spot size. Planned spaceborne lidars are ESA's in 2008, to measure the tropospheric wind profile for the first time; the European/Japanese EarthCARE (Earth Clouds, Aerosols and Radiation Explorer) satellite, to fly in 2013, with <100 m spot size; and NASA's ICESat-2, to fly in 2015 (Table 1).

Observational platforms

Remote sensing of the Earth may be carried out from towers, balloons, uninhabited airborne vehicles (UAVs),

Observational Systems, Satellite, Table 1 Lidar instruments flying as of 2008 or planned by 2015

Technique	Satellite	Country/organization	Launch date
Backscatter	ICESat	USA	2003
	CALIPSO	USA/France	2006
	EarthCARE	ESA/Japan	2013
Doppler	ADM	ESA	2008

manned aircraft, satellites, and space stations. Because it is impractical to instrument the entire globe with ocean buoys, ground-based sensors, and weather balloons, remote sensing from platforms that can efficiently cover large areas is employed. This is especially true for large remote areas such as the South Pacific. For applications requiring global coverage or large-area synoptic coverage, remote sensing platforms tend to be spaceborne (see *Observational Systems, Satellite and Observational Platforms, Aircraft, and UAVs*). It is physically and financially impractical to provide global coverage with aircraft due to their limited range, limited geographical coverage, weather restrictions, etc. (see *Observational Platforms, Aircraft, and UAVs*).

Platforms that Earth remote sensing has been carried out from include the space shuttle (see *Observational Platforms, Aircraft, and UAVs*). It provided the platform (Kramer, 2002) for the SIR-A, SIR-B, and SIR-C/X-SAR series of SAR instruments (SIR = Shuttle Imaging Radar), as well as the Shuttle Radar Topography Mission (SRTM), a pioneering US/German/Italian Interferometric SAR system (see *Microwave Radiometers, Interferometers*). It was also the platform for LITE, which was used to study clouds and aerosols with lidar (see *Lidar Systems*). The US Skylab space station and the Russian Mir space station both provided platforms for pioneering Earth remote sensing instruments (see *Observational Platforms, Aircraft, and UAVs*). Skylab hosted a microwave imager, scatterometer, and altimeter, among other instruments. The Mir contained approximately 30 remote sensing instruments, housed in five different modules (Kramer, 2002). The International Space Station (ISS) now has the potential to serve as a platform for Earth observation and instrument technology demonstrations.

Satellite orbits: coverage and sampling

Most Earth remote sensing satellites are placed into circular, near-polar, sun-synchronous orbits at altitudes of approximately 600–900 km above the Earth's surface. A satellite in a sun-synchronous orbit passes over a given region on the ground at approximately the same local time every day. This means that the solar illumination angle changes relatively slowly for that area from day to day, which simplifies data interpretation. Some sun-synchronous satellites are in exact repeat orbits, meaning that they fly over the same region at exactly the same local time every day. A single sun-synchronous

LEO satellite carrying a low-resolution instrument with a wide swath providing single-pass coverage over a 3,000 km-wide strip, such as a weather imager, can cover the entire globe in 12 h if the instrument can operate both day and night. Three such satellites in orbits that are spaced 60° apart in longitude can cover the entire globe in approximately 4 h.

A large part of the science community requires frequent imaging revisits of the same area on the Earth. Revisit time is defined here as the average elapsed time between imagery of a given location at the Earth's equator (because for polar sun-synchronous orbits the equator represents the most stressing case). Revisit times are measured for a single instrument onboard the satellite, and they are lower (better) in cases where the instrument can gimbal transverse to the direction of travel of the satellite. An instrument that cannot gimbal is the Thematic Mapper onboard the current US Landsat satellites, in which case 16 days are required for the instrument swath width of 185 km to "paint" the Earth and begin to repeat coverage. The French SPOT system, on the other hand, can gimbal, resulting in revisit times of 3 days. Such a capability is becoming much more commonplace.

Stereo imaging instruments, in which a fore-and-aft image (and an image looking directly down at nadir) of the same region is acquired along the direction of satellite motion (along-track) as the satellite flies over that region, were pioneered in the 1990s by Germany. The MOMS-02/D2 (Modular Optoelectronic Multispectral Scanner) flew on the shuttle and the MOMS-02P instrument flew on the Russian Mir-Priroda space station (Kramer, 2002). These instruments paved the way for the higher-resolution systems with stereo capability that are now flying, many of which acquire stereo imagery by gimbaling a single imager to acquire imagery from different look angles. (Examples are pointed out in the text below.) This capability is useful in mapping, road route selection, communications equipment siting, disaster response, 3-D news "flythroughs," visualization of pieces of real estate, etc.

Some satellites in LEO fly in formation (see *Satellites, Constellations and Formation Flying*). The A-Train is a series of five satellites following one another along the same orbit like "beads on a string" (NASA, 2003). Currently, the NASA EOS Aqua satellite is leading the A-Train, followed by CloudSat, CALIPSO, France's PARASOL (Polarization and Anisotropy of Reflectances for Atmospheric Sciences coupled with Observations from a Lidar), and the NASA EOS Aura satellite (see [International Collaboration](#)). (CloudSat uses radar to study clouds and precipitation, CALIPSO uses lidar to study clouds and aerosols, and PARASOL uses polarization to study clouds and aerosols (PARASOL, 2008). Aqua is a multidisciplinary mission that includes the study of atmospheric water, while Aura studies atmospheric chemistry, trace gases, and pollution.) The temporal gap from Aqua to Aura is 8 min. The last satellite to join the A-Train will be NASA's Orbiting Carbon Observatory (OCO), when it

flies in late 2008 (OCO, 2008). The values of formation flying lie in (1) not investing in a single very large satellite, for which a single problem could result in failure of the entire mission; (2) the ability to acquire synergistic measurements of the same part of the Earth's environment over a very short period of time and combine them to result in an improved understanding of the physics of the Earth's environment, weather, and climate; and (3) sharing of mission cost among agencies (see [Mission Costs of Earth-Observing Satellites](#)).

Some satellites fly as part of a constellation, in which satellites in different orbits, typically carrying the same or similar instruments, operate together to collect data. Flying constellations of satellites allow for more frequent revisit time of the same region, thus faster global coverage. One example is the Disaster Monitoring Constellation described above (see section "[Introduction to Satellite Observational Systems](#)"). More information is available (see [Observational Systems, Satellite](#)).

Many remote sensing weather satellites occupy geosynchronous orbits. Positioned at 36,000 km above the equator, their orbital periods of 24 h make them appear to hang over one spot on the Earth. With broad-area imagers on five "GEO birds," it is possible to cover the globe up to approximately 60° latitude, with spatial resolutions of up to approximately 1 km. Such coverage is provided today from the US Geostationary Operational Environmental Satellites (GOES-East and GOES-West; GOES, 2008) series of metsats (meteorological satellites), the European Meteosat Second Generation (MSG) metsats (MSG, 2008), the Indian InSAT-3 series and their METSAT-1/Kalpana-1 (India, 2008), China's Feng Yun-2 (FY-2) series (FY-2, 2008), and Japan's MTSat (MTSat, 2008) series (the follow-on to their GMS series). South Korea plans to launch a GEO metsat called COMS (Communications, Oceans and Meteorology Satellite) in 2009 (COMS, 2008), while Russia plans to launch GOMS/Elektro-L (Geostationary Orbit Meteorological Satellite) in 2010, replacing GOMS/Elektro-1 that lasted from 1994 to 2000 (GOMS, 2008). This is, in fact, a complete list of environmental remote sensing satellites in, and soon planned for, GEO orbits.

No particular use has been made of medium Earth orbits for remote sensing of the Earth's atmosphere/ocean/land/ice system. MEO has been studied as a possibility for part of a future merged LEO/GEO US weather satellite constellation, but plans have not progressed beyond the study phase.

The Molniya orbit is a type of highly elliptical orbit that allows a satellite to pass slowly over one of the Earth's poles (usually the north pole) and observe the arctic regions for approximately 8 h out of 24 h. A constellation of three such suitably spaced orbits can provide 24 h coverage of the arctic regions. Such orbits are used more for Russian communications satellites than for remote sensing. The upcoming Russian/Finnish Arktika mission for studying the arctic environment plans to fly some of its satellites in Molniya orbits (Arktika, 2008). There are

currently no environmental remote sensing satellites in Molniya orbits.

The L1 libration point, a gravitationally stable point between the Earth and the Sun, has been discussed as a possible location for a satellite to study the Earth as a planet for climate research (the sunward-facing hemisphere of the Earth can be covered). To date, the L1 point has been used for solar-observing satellites. NASA's Triana/DSCOVR mission was envisioned as a climate satellite at L1 (Triana, 2008), but it was canceled as Triana, reinvigorated as DSCOVR, and canceled again. One day, a climate-monitoring satellite may well fly at L1.

Spacecraft subsystems

As outlined in the "Definition" section above, the portion of the satellite minus the instruments is usually called the "spacecraft." The spacecraft exists to support the instruments and provides them with the requisite pointing, commands and data storage, power, thermal conditions, and structural support. Pointing is typically the most difficult requirement to meet, especially for instruments that have very high spatial resolution.

Mission operations

The prime directive of mission operations is to ensure delivery of required data to the user communities of a quality that supports conversion into end products that meet the science requirements (see *Mission Operations, Science Applications/Requirements*). That conversion is typically performed outside of the mission operations environment. An important function of mission operations is to schedule the data the satellite collects in response to user community input and uplink (transmit) that schedule to the satellite. Limitations of onboard data storage or data transmission from the satellite to the ground (downlink) limit the amount of data that can be collected in a given time period. Another important function of mission operations is to monitor the health and status of the instruments and the spacecraft and to take appropriate corrective actions when problems arise. For typical environmental remote sensing satellites in sun-synchronous LEO orbits, the ground receiving stations tend to be in the polar regions, because those satellites can be seen from there on essentially every orbit.

Specific satellite observational systems

We will now examine satellite observational systems, organized by the environmental regime to which they contribute. Many satellites are multidisciplinary and will be so noted. There are several hundred past, present, and future systems that could be included here. The remainder of this entry is restricted to satellites that are actively gathering data in 2008, as well as to ones that appear to be reasonably firmly planned for launch through 2015. A representative sampling of the total number of satellites in each environmental discipline is included (Rao

et al., 1990; Glackin and Peltzer, 1999; Kramer, 2002; eoPortal, 2008; and references below).

Satellite observational systems for the atmosphere

Multidisciplinary

Envisat (Environmental Satellite) is a large European satellite from ESA that has been flying since 2002 (Envisat, 2008). It has application to the atmosphere (clouds, aerosols, ozone, greenhouse gases, and trace gases), the ocean (ocean color, sea surface temperature, sea state, and topography), the land surface (vegetation, snow, and topography), and ice (sea and land ice). Except for certain Russian satellites, this is the most massive satellite that has been flown (8,000 kg) for Earth environmental remote sensing.

EOS Terra, formerly known as EOS AM-1, is a large NASA satellite that has been flying since 1999 (Terra, 2008). It is part of a series of satellites flying in formation, like the A-Train described above, but in a different (morning) orbit. This series includes the Argentinean SAC-C (Satellite de Aplicaciones Cientificas-C; SAC-C, 2008) satellite and the US Landsat-7 and EO-1 (Earth Observer-1), which is a pathfinder for the next Landsat. Terra's name indicates that its applications are focused on the Earth's surface, but it is actually multidisciplinary. It has application to the atmosphere (clouds and aerosols, Earth radiation budget, and pollutants) and the ocean (ocean color) as well.

EOS Aqua, a NASA satellite formerly known as EOS-PM-1, was launched in 2002 and currently leads the A-Train (Aqua, 2008). Aqua's name indicates that its applications are focused on water, but it is actually multidisciplinary. It measures the atmospheric temperature and moisture profiles, precipitation, cloud water, and Earth radiation budget. It measures the ocean surface temperature, wind speed, and ice cover. Over land, it measures soil moisture and snow extent/snow water equivalent.

Megha-Tropiques ("Clouds-Tropics") is a joint mission between the Indian space agency ISRO (Indian Space Research Organization) and the French space agency CNES (Centre National d'Etudes Spatiales) (see Megha-Tropiques, 2008). It is a satellite for monitoring of the tropics that is scheduled for launch in 2009. It hosts the ScaRaB (Scanner for Radiation Budget) radiometer and the MADRAS conically scanning microwave radiometer (MADRAS = Microwave Analysis and Detection of Rain and Atmospheric Structures).

NPOESS (National Polar-orbiting Operational Environmental Satellite System) is a joint program between NOAA (National Oceanic and Atmospheric Administration), the US DoD (Department of Defense), and NASA (NPOESS, 2008). EUMETSAT (European Organisation for the Exploitation of Meteorological Satellites) is a partner and will provide the European MetOp (Meteorological Operational) satellite (MetOp, 2008) as part of the NPOESS constellation of three satellites. The NPOESS

program was established in 1994. The first satellite is currently scheduled to fly in 2013. Originally a joint NOAA-DoD program focused on operational weather and environmental data, NPOESS will now also host selected climate-monitoring instruments and will serve as a partial follow-on to NASA's EOS program. As presently planned, NPOESS will measure more than 35 different environmental parameters (atmosphere, ocean, land, and ice).

NASA's NPP (NPOESS Preparatory Project) satellite is intended to be a technology demonstrator for NPOESS, as well as a gap-filler between the projected end-of-life of NASA's EOS satellites and NPOESS (NPP, 2008). Launch is scheduled for 2010. NPP will provide a subset of the NPOESS environmental parameters.

Cloud characteristics and aerosols

AIM (Aeronomy of Ice in the Mesosphere) is a NASA satellite that was launched in 2007 to study polar mesospheric clouds, also known as noctilucent ("night shining") clouds (AIM, 2008). Occurring at altitudes around the mesopause (approximately 84 km above ground level), they remain a poorly understood phenomenon.

CloudSat is a NASA satellite that was launched in 2006 and is part of the A-Train (CloudSat, 2008). Its mission is to study the structure of clouds, which is very important in understanding climate change. It carries the first spaceborne cloud profiling radar, operating at 94 GHz, which is a frequency that can penetrate most clouds (see *Cloud properties*).

CALIPSO (Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation), a joint mission between NASA and CNES, was launched in 2006 and is part of the A-Train (CALIPSO, 2008). Its mission is to study clouds and aerosols, and its payload includes a backscatter lidar (see *Aerosols*).

EarthCARE (Earth Clouds, Aerosols and Radiation Explorer) is a joint mission between ESA and the Japanese space agency JAXA (Japanese Aerospace Exploration Agency), formerly known as NASDA. Currently scheduled for launch in 2013, its payload will include a cloud radar and a cloud-aerosol lidar (EarthCARE, 2008).

Stratospheric ozone, greenhouse gases, and trace gases
EOS Aura, a NASA satellite formerly known as EOS Chem, was launched in 2004 and is the last satellite in the A-Train (Aura, 2008). It has application to ozone and greenhouse gases, as well as a variety of trace gases and pollutants in the troposphere and stratosphere (see *Trace Gases, Troposphere - Detection from Space and Trace Gases, Stratosphere, and Mesosphere*).

Odin is a joint Swedish/Canadian satellite (Odin, 2008) from the Swedish National Space Board (SNSB) and the Canadian Space Agency (CSA). Launched in 2001, its purpose is to measure ozone and chlorine chemistry. Its payload includes a sub-mm radiometer (see *Remote Sensing, Physics and Techniques*).

SCISAT-1 is a CSA satellite launched in 2003 to study ozone chemistry (SCISAT, 2006). Its payload is a Fourier Transform Spectrometer (see *Remote Sensing, Physics and Techniques*).

OCO (Orbiting Carbon Observatory) is a NASA satellite to be launched in 2008 to study atmospheric carbon dioxide (OCO, 2008). It will be the last satellite to join the A-Train. The payload is comprised of a grating spectrometer (see *Remote Sensing, Physics and Techniques*).

Glory is a NASA satellite to be launched in 2009 to study atmospheric aerosols and black carbon (soot). (See Glory, 2008.) Its payload will consist of an imaging polarimeter (see *Remote Sensing, Physics and Techniques*).

GCOM-A1 (Global Change Observation Mission-A1) is a JAXA satellite to be launched in 2008 to study ozone and greenhouse gases (GCOM, 2008). Its payload will consist of a UV spectrometer and a solar occultation spectrometer (see *Remote Sensing, Physics and Techniques*).

Rainfall

TRMM (Tropical Rainfall Measuring Mission) is a joint JAXA/NASA satellite launched in 1997 (TRMM, 2008) to study tropical rainfall (see *Rainfall*). Its payload includes a precipitation radar.

GPM (Global Precipitation Measurement) mission consists of a "core" JAXA/NASA satellite to be launched in 2013 and a series of "constellation" satellites. The core satellite's payload will include a precipitation radar (GPM, 2008).

Earth radiation budget

No satellites have been dedicated to this application since NASA's ERBS (Earth Radiation Budget Satellite) that was launched in 1984 (Kramer, 2002). These types of measurements are typically carried out by individual instruments onboard multipurpose satellites. The instruments include NASA's CERES (Clouds and the Earth's Radiant Energy System) on Terra, Aqua, and NPOESS, the Russian ScaRaB on Megha-Tropiques, and ESA's GERB (Geostationary Earth Radiation Budget) on the geosynchronous weather satellite MSG (see *Earth Radiation Budget, Top-of-Atmosphere Radiation*).

Lightning

This is also detected using individual instruments onboard multipurpose satellites. NASA's LIS (Lightning Imaging Sensor) is flying on TRMM, and NASA's GLM (GEO Lightning Mapper) will fly on NOAA's future GOES-R (GOES-R, 2008) weather satellites (see *Lightning*).

Tropospheric winds

ESA's ADM (Atmospheric Dynamics Mission; ADM, 2008) will be the first satellite to host a Doppler wind lidar to measure the vertical wind profile in the troposphere (see *Remote Sensing, Physics and Techniques*). Scheduled for launch in 2008, this pioneering mission will host an instrument of a type that has been under study since 1978 (see *Tropospheric Winds*).

GPS occultation and reflectometry

ROCSAT-3/COSMIC (Republic of China Satellite-3/ Constellation Observing System for Meteorology, Ionosphere, and Climate; COSMIC, 2008) is a joint Taiwanese/US constellation of satellites from Taiwan's National Space Organization (NSPO) and the US University Corporation for Atmospheric Research (UCAR). Launched in 2006, this constellation of six microsatellites measures the ionospheric electron density profile, the atmospheric temperature profile (see *Land Surface Temperature*), and other parameters, using the GPS occultation technique (see *Remote Sensing, Physics and Techniques*).

FEDSAT-1 (Federation Satellite-1) is an Australian satellite from the Commonwealth Scientific and Industrial Research Organisation (CSIRO). Launched in 2002, it performs GPS occultation (Fedsat, 2002).

CHAMP (CHALLENGING Minisatellite Payload) is a joint German/US mission (CHAMP, 2008) from the German Space Agency (DARA), the German Aerospace Center (DLR), the German Research Centre for Geosciences (GFZ), and NASA's JPL (Jet Propulsion Laboratory). Launched in 2000, it was the first satellite to include a capability for GPS reflectometry as well as GPS occultation (see *Remote Sensing, Physics and Techniques*).

SAC-C is a joint mission between Argentina's National Commission for Space Activities (CONAE) and NASA (SAC-C, 2008). Launched in 2000, it was the second satellite to include a capability for GPS reflectometry as well as GPS occultation.

Weather prediction and severe storms

LEO satellites for weather prediction and a host of other environmental measurements (see *Weather Prediction*) include NPP and NPOESS, described above (see section on "Multidisciplinary"). The two programs that were originally merged to create NPOESS are the DMSP Block 6 (Defense Meteorological Satellite Program) system (not discussed here) and NOAA's POES O-P-Q (Polar-orbiting Operational Environmental Satellite). POES (POES, 2008) has application to the atmosphere, oceans, land, and ice. POES/NOAA-18 was launched in 2005, and the last satellite in the series (dubbed NOAA-N-prime before launch) is scheduled for launch in 2009. The ESA/EUMETSAT MetOp satellite program was described above. It is an international collaboration with NPOESS and POES. MetOp-1 was launched in 2006 into a midmorning orbit to complete the present POES constellation (IJP, 2008). MetOp-2 and MetOp-3 are planned for launch in 2010 and 2014, during the transition from POES and DMSP to NPOESS.

Russia has flown the Meteor series of LEO metsats since 1969, the most recent being Meteor-3 M-1 from Roskosmos/Roshydromet, launched in 2001 (Russia, 2003). Meteor-M-N1, the first of a new series, is scheduled for launch in 2009. China has flown the FY-1 (Feng Yun-1) series of LEO metsats since 1988, the most recent

being in 2002 (FY, 2008). FY-3A, the first of a new series, was launched in 2008.

Present and near-future (through 2010) GEO weather satellites for monitoring weather and severe storms (see *Severe Storms*) are enumerated above in the section "Satellite Orbits: Coverage and Sampling." Regarding the next generation, ESA and EUMETSAT plan to launch Meteosat Third Generation (MTG) satellites starting in 2015, China plans to launch Feng Yun-4 (FY-4) satellites starting possibly in 2012 (FY-4, 2008), and the USA plans to launch GOES-R in 2015 (GOES-R, 2008).

Satellite observational systems for the oceans

Multidisciplinary

Aqua, Envisat, NPOESS, NPP, and Terra are described above. Please see the section on "Multidisciplinary" under the section "Satellite Observational Systems for the Atmosphere."

ESA's ERS-2 (European Remote Sensing-2) is a large oceanographic satellite launched in 1995 (ERS, 2008). One instrument combines the functions of a SAR and a scatterometer (see *Remote Sensing, Physics and Techniques*). The rest of the payload includes a radar altimeter, a sea surface temperature imager, and an ozone monitor.

ESA's Sentinel-1 satellite is part of Europe's Global Monitoring for Environment and Security (GMES). Scheduled for launch in 2011, it will host a SAR, as a follow-on to ERS and Envisat (Sentinel, 2008). ESA's Sentinel-3 satellite is scheduled for launch in 2012. It will measure ocean color and surface temperature as well as land vegetation and surface temperature.

China's HY-2 (Hai Yang-2) from the Chinese Association for Science and Technology (CAST) is due to be launched in 2009 (HY, 2007). It will host two ocean color imagers, a microwave radiometer, an altimeter, and a scatterometer.

Table 2 summarizes passive microwave imagers, as well as polarimetric radiometers (see next section).

Sea surface wind vector

Historically, instruments that measure both sea surface wind speed and direction have been active scatterometers. More recently, a proof-of-concept mission has been flown to examine the viability of making this measurement with a passive polarimetric microwave radiometer (see *Reflected Solar Radiation Sensors, Polarimetric*). As of 2008, it appears that each technique has advantages, depending on the range of wind speeds.

ESA's ERS-2 AMI (Active Microwave Instrument) can operate as a SAR or a scatterometer, as noted above (ERS, 2008). It has been providing sea surface wind data part-time since 1995. The ESA/EUMETSAT MetOp-1 satellite hosts the ASCAT (Advanced Scatterometer), which is a follow-on to the AMI (see *Sea Surface Wind/Stress Vector*).

NASA's QuikSCAT satellite, launched in 1999, hosts the SeaWinds scatterometer (QuikSCAT, 2008). Its data

Observational Systems, Satellite, Table 2 Passive microwave imagers and wind polarimeters flying as of 2008 or planned by 2015

Technique	Satellite	Country/ organization	Launch date
Imager	Aqua	USA	2002
	FY-3A	China	2008
	Oceansat-1	India	1999

	Megha-Tropiques	India/France	2009
	NPOESS-C2	USA	2016
	Oceansat-2	India	2008
Wind polarimeter	SMAP	USA	2012
	Coriolis/ WindSat	USA	2003
	NPOESS-C2	USA	2016
Interferometer	SMOS	ESA	2009

have proven to be useful for a variety of oceanographic applications.

The Coriolis satellite from the US Naval Research Laboratory (NRL) was launched in 2003 to test the microwave passive polarimetric approach from space (Coriolis, 2008). The WindSat instrument on Coriolis continues to provide wind speed and direction data, as well as other environmental parameters. Coriolis is a risk reduction mission for the NPOESS MIS (Microwave Imager/Sounder), which may include a passive polarimetric capability for wind.

India's IRS-2B/Oceansat-2 from ISRO is due for launch in 2008 (India, 2008). It will carry a "pencil-beam" scatterometer (see *Radar, Scatterometers*) and an ocean color imager.

Other future scatterometers are planned by Argentina, China, and Japan.

Ocean color

OrbView-2, launched in 1997 by the US company ORBIMAGE (now GeoEye), has provided ocean color imagery from its SeaWiFS (Sea-viewing Wide-Field Sensor) instrument (OrbView-2, 2008). This imagery provides a measure of organic material (such as phytoplankton) and marine optical properties (see *Ocean Measurements and Applications, Ocean Color*).

ROCSAT-1/Formosat-1 (Republic of China Satellite-1) from Taiwan's NSPO was launched in 1999 (ROCSAT, 2008). This satellite, Taiwan's first remote sensing satellite, is dedicated to ocean color imagery.

China's HY-1B from CAST was launched in 2007 (HY, 2007). Its payload is dedicated to ocean color imagery. The follow-on will be the HY-2 series, scheduled for first launch in 2009.

India's IRS-P4/Oceansat-1 from ISRO was launched in 1999 with an ocean color imager (Oceansat, 2008). The follow-on Oceansat-2 will also host an ocean color imager.

Sea surface temperature

This parameter (see *Sea Surface Temperature*) is typically measured by instruments flying on multidisciplinary satellites. Examples, all described above, are Aqua, Envisat, ERS-2, MetOp, NPOESS, NPP, and Sentinel-3.

Sea surface topography

Jason-1/TPFO (TOPEX/Poseidon Follow-On), a joint mission between CNES, NASA, and NOAA, was launched in 2001 (Jason, 2008). It hosts an altimeter for measurement of sea surface topography (see *Ocean Surface Topography*) and a microwave radiometer for the measurement and removal of atmospheric water vapor effects.

Jason-2/OSTM (Ocean Surface Topography Mission) is scheduled to be launched in 2008 (Jason, 2008). It will carry the same payload and adds EUMETSAT as a partner.

Table 3 summarizes active microwave instruments.

Sea surface salinity

ESA's SMOS (Soil Moisture/Ocean Salinity) will be the first satellite to measure ocean salinity (see *Sea Surface Salinity*). It will also be the first interferometric microwave radiometer (using aperture synthesis) in space (see *Remote Sensing, Physics and Techniques*). Operating at 1.4 GHz, it will measure not only ocean salinity but also soil moisture, which is best measured at this relatively low frequency. SMOS is scheduled for launch in 2009 (SMOS, 2008).

Aquarius is a joint mission between the USA and Argentina (NASA and CONAE). It will host a large real-aperture 1.4 GHz microwave radiometer for the measurement of ocean salinity and is scheduled for launch in 2010 (Aquarius, 2008).

Satellite observational systems for the land surface

Aqua, Envisat, NPOESS, NPP, and Terra are described above. Please see the section on "Multidisciplinary" under the section "Satellite Observational Systems for the Atmosphere."

Earth resources and environmental monitoring

Landsat is the longest-lived series of environmental remote sensing satellites (Landsat, 2008). These and several others listed in this section fill a niche between the low-resolution land imagers on satellites, such as Envisat, Terra, Aqua, NPOESS, and MetOp, and the high-resolution land imagers on commercial high-resolution satellites. Landsat-5 and Landsat-7 from NASA and the

Observational Systems, Satellite, Table 3 Active microwave instruments flying as of 2008 or planned by 2015

USGS (United States Geological Survey) are medium-resolution Earth resources systems launched in 1984 and 1999 and still operating in 2008. The Enhanced Thematic Mapper-plus (ETM+) on Landsat-7 provides 15 m panchromatic, 30 m multispectral, and 60 m LWIR (long-wave infrared) imagery over a 185 km-wide swath. The Landsat Data Continuity Mission (LDCM), to be launched in 2011, is a follow-on with a more advanced instrument, the Operational Land Imager (LDCM, 2008).

Russia began flying the Resurs-O1 (Resurs = "Resource") series of Earth resources satellites in 1985 (Resurs 2008). It appears that none remain operational (Resurs History, 2008).

The French SPOT series of satellites has been flying since 1986. Up until SPOT-5, they provided 10 m panchromatic and 20 m multispectral imagery. SPOT-5 provides 5 m panchromatic imagery that can be double-sampled and processed to approximate about 3 m resolution imagery (Jacobsen, 2008). The instrument can acquire stereo imagery and can gimbal, unlike Landsat. The follow-on SPOT-6 is not yet firmly scheduled.

The Indian IRS series of Earth resources satellites from ISRO has been flying since 1988. IRS-1D, launched in 1997, has 5.8 m panchromatic, 23.5 m multispectral (vis-near IR), and 70.5 m short-wave IR resolution (India, 2008). Resourcesat-1, the first follow-on mission launched in 2003, has 5.8 m multispectral (vis-near IR) resolution among others, with gimbaling and stereo capability (Resourcesat, 2008). Resourcesat-2 is scheduled for launch in 2009.

Japan has been flying Earth resources satellites since 1996. Still operating in 2008 is ALOS (Advanced Land Observing Satellite) that was launched in 2006 (ALOS, 2008). It can acquire 2.5 m stereo imagery with one instrument and 10 m multispectral imagery with another instrument, which can also gimbal. GCOM-B1, to be launched in 2008, is the follow-on satellite (GCOM, 2008).

China and Brazil have jointly been flying Earth resources satellites since 1999, the CBERS/ZY1 series (CBERS = China-Brazil Earth Resources Satellite; ZY = Zi Yuan), from CAST and the Brazilian National Institute of Space Research (INPE). CBERS-2B, launched in 2007, has 2.7 m panchromatic and 20 m multispectral instruments (CBERS, 2008). The follow-on satellite, CBERS-3, is scheduled to launch in 2008 and will have 5 m panchromatic and 20 m multispectral capability. CBERS-4, -5, and -6 are planned for launch after 2010.

Six other nations plan to launch Earth resources satellites soon, five of them in 2008. X-Sat, from the Nanyang Technological University (NTU) in Singapore, will provide 10 m multispectral resolution (X-Sat, 2003). ZASat-1/Sumbandila, from the University of Stellenbosch in South Africa, will provide 6.5 m multispectral resolution (ZA = Zuid Afrika; Sumbandila = "Lead the Way"). Its follow-on, ZASat-2, planned for 2009, will provide 2.5 m panchromatic, 5 m multispectral, and 15 m hyperspectral imagery (ZASat, 2008). THEOS (Thailand Earth Observation System) from Thailand's GISTDA

(Geo-Informatics and Space Technology Development Agency) will provide 2 m panchromatic and 15 m multispectral imagery (THEOS, 2008). Razaksat, from ATSB (Astronautic Technology Sdn Bhd) in Malaysia, will provide 2.5 m panchromatic and 5 m multispectral imagery (Razaksat, 2005). RASAT, from TUBITAK (The Scientific and Technological Research Council of Turkey) in Turkey, will provide 7.5 m panchromatic and 15 m multispectral imagery (RASAT, 2006). Finally, the first of the SAOCOM (Satellites for Observation and Communication) series of satellites from CONAE in Argentina (SAOCOM-1A) is scheduled for launch in 2010, carrying a SAR with 7–100 m resolution (SAOCOM, 2008).

Disaster management

SSTL's Disaster Monitoring Constellation (DMC) satellite series was described above. (See section "[Introduction to Satellite Observational Systems](#).")

India's *RISAT* (Radar Imaging Satellite) is due to launch in 2008. It will carry a SAR with 3 to 50 m resolution (RISAT, 2008). Its stated applications are disaster monitoring and crop inventory.

China's *Remote Sensing Satellite* (YaoGan WeiXing) series consists of a constellation of three reportedly disaster-monitoring satellites hosting SARs with unknown spatial resolution. These were launched in 2006–2007 (YaoGan, 2008).

China's CEMD/Huanjing (*HJ-1* series) consists of a constellation of three reportedly disaster-monitoring satellites, two carrying multispectral imagers (HJ-1A and -1B) and one carrying a SAR (HJ-1C). HJ-1A is scheduled for launch in 2008 (CEMD, 2008).

Soil moisture and freeze/thaw state

ESA's *SMOS* was described above. See the section "[Sea Surface Salinity](#)."

NASA's *SMAP* (Soil Moisture Active/Passive) satellite will exploit the synergy between active and passive microwave remote sensing techniques for measuring soil moisture (see [Soil Moisture](#)) and surface freeze/thaw state by carrying a 1.4 GHz radar and a large real-aperture 1.4 GHz microwave radiometer (SMAP, 2008). SMAP is scheduled for launch in 2012.

Commercial and hybrid government/commercial high-resolution systems, electrooptical

The genesis of the commercial high-resolution remote sensing industry is discussed above (see section "[Introduction to Satellite Observational Systems](#)"). Today, these systems typically have the ability to gimbal to provide frequent imagery of a given region, the ability to cover large areas efficiently, and the ability to collect stereo imagery, which can be converted to topographic information. Potential commercial applications (see [Commercial Remote Sensing](#)) include mapping, precision farming, urban planning, forestry, oil and mineral exploration, emergency response, disaster assessment, route selection for roadways, communications siting, real estate, land

use, utility pipeline and long-distance power line monitoring, news reporting, commodities trading, and many aspects of the insurance industry.

We present these satellites in chronological order of successful launch. Note that most, if not all, of these systems may be classified as "dual-use" (commercial/military), since governmental military organizations typically act as anchor-tenants (primary customers) for these systems (Jacobsen, 2008).

IKONOS-1 from the US firm Space Imaging (now GeoEye; GeoEye, 2008) was launched in 1999 (Ikonos is Greek for "Image"). With 0.8 m panchromatic and 4 m multispectral resolution, it is still operating. *EROS-A* from the Israeli firm ImageSat International (EROS, 2008), with 1.8 m panchromatic imagery, was launched in 2000, while *EROS-B* with 0.7 m panchromatic imagery was launched in 2006 (EROS = Earth Resources Observation Satellite). *QuickBird* from the US firm Digital Globe, with 0.6 m panchromatic and 2.5 m multispectral imagery, was launched in 2001 (Quickbird, 2008). *Cartosat-1/IRS-P5* from ISRO, with 2.5 m panchromatic resolution, was launched in 2005 (Cartosat, 2008), followed by *Cartosat-2/IRS-2A* with 1 m resolution in 2005 (Cartosat-2, 2008). [Note that commercialization of Cartosat imagery may not come about (GeoInformatics, 2007)]. *Resurs-DK1*, from the Russian organization Rosaviakosmos, with 1 m panchromatic and 3 m multispectral resolution (Russia, 2003), and perhaps the first Russian digital downlink system (replacing film canisters), was launched in 2006. *KOMPSAT-2/Arirang-2*, from the Korea Aerospace Research Institute (KARI), with 1 m panchromatic and 4 m multispectral resolution, was also launched in 2006 (KOMPSAT, 2008). ("Arirang" is the most popular Korean folk song.) *ROCSAT-2/Formosat-2* from the NSPO in Taiwan, with 2 m panchromatic and 8 m multispectral resolution, was launched in 2004 (ROCSAT, 2008). *KOMPSAT-2* and *ROCSAT-2* images are available commercially from SPOT Image. Finally, *WorldView-1*, from the US firm Digital Globe, with 0.5 m panchromatic resolution, was launched in 2007 (Digital Globe, 2008).

Future missions include *GeoEye-1* with 0.4 m panchromatic resolution in 2008 and *GeoEye-2* with 0.25 m panchromatic resolution in 2011, from the US firm GeoEye (GeoEye, 2008). *WorldView-2* with 0.5 m panchromatic resolution is scheduled in 2008 (Digital Globe/WV-2, 2008). *EROS-C* with 0.7 m panchromatic resolution is scheduled for 2008. (All of these systems also have multispectral capability.) *Cartosat-3* may have 0.30 m panchromatic resolution and was launched in 2011 (Cartosat-3, 2008). *SPOT-6* from CNES, with 2.5 m panchromatic resolution, is not yet firmly scheduled.

These systems are summarized in [Table 4](#).

Commercial and hybrid government/commercial high-resolution systems, SAR

TerraSAR-X is a German SAR satellite from the DLR and the firm EADS Astrium GmbH (EADS = European

Observational Systems, Satellite, Table 4 High-resolution commercial systems flying as of 2008 or planned by 2015

Technique	Satellite	Country/ organization	Launch date
Electrooptical	Cartosat-1	India	2005
	Cartosat-2	India	2005
	Cartosat-3	India	2011
	EROS-A	Israel	2000
	EROS-B	Israel	2006

	SPOT-6	France	?
	WorldView-2	USA	2008
Radar (SAR)	RADARSAT-2	Canada	2007
	TerraSAR-X	Germany	2007
	TanDEM-X	Germany	2009

Aeronautic and Space Company). Launched in 2007, it has a spatial resolution of 1 m (TerraSAR-X, 2008). It is designed to fly in formation with the German SAR system TanDEM-X, from the same organizations, with an identical SAR instrument (TanDEM-X, 2008). Potential commercial applications include ship routing through sea ice and oil spill assessment (see *Commercial Remote Sensing*).

RADARSAT-2 is a Canadian SAR satellite from CSA and MDA (MacDonald, Dettwiler and Associates, Ltd.) with 3 m resolution and a capability to observe with horizontal and vertical polarization in all send-receive combinations (RADARSAT, 2008). This is a follow-on to the lower-resolution single-polarization RADARSAT-1 and was launched in 2007. RADARSAT-3 is still in the formulation stages.

Other high-resolution systems

There are other high-resolution electrooptical and SAR systems, some of which have been announced as dual-use (civil/military) systems.

The Italian COSMO/SkyMed (Constellation of small Satellites for Mediterranean basin Observation) hosts a 1 m resolution X-band SAR and has been announced as a dual-use system, to operate in conjunction with the French Pleiades system. The first two satellites of the planned four-satellite constellation were launched in 2007 (COSMO/SkyMed, 2008). The French Pleiades satellite hosts an instrument with a 0.7 m resolution panchromatic band and 2 m resolution multispectral capability (Pleiades, 2008). It has also been announced as a dual-use

system. Two satellites are scheduled for launch in 2008 and 2010.

The Spanish Paz satellite will host a high-resolution SAR, to be launched in 2012. The Spanish Ingenio satellite will host a 2.5 m panchromatic imager, also to be launched in 2012. Both systems have been announced as dual-use (Paz/Ingenio, 2008).

Pakistan is planning to launch two RSSS (Remote Sensing Satellite System) satellites with 4 m panchromatic and 10 m multispectral capability (RSSS, 2008). This has been announced as a dual-use system.

Egypt launched the high-resolution MisrSat-1 ("EgyptSat-1") in 2007, but few details are available (MisrSat, 2008). China launched a series of three satellites called China Resource-1/ZY2-1 through China Resource-3/ZY2-3 in 2000–2004 with 3 m panchromatic imaging, but few details are available (China Resource, 2008). (This series should not be confused with the CBERS/ZY1 series.)

Other satellites that may have potential as dual-use systems include India's Cartosat and RISAT, Malaysia's Razaksat, South Africa's ZASat-2, and Thailand's THEOS (all are described above).

Commercial agriculture

The RapidEye constellation of five satellites from the company RapidEye AG in Germany is scheduled to be launched in 2008 (RapidEye, 2008). Its instruments will produce 6 m resolution multispectral imagery for application to precision farming and crops (see *Precision Agriculture and Crop Stress*).

Hyperspectral systems

Hyperspectral systems are summarized above in the section "[Introduction to Satellite Observational Systems](#)."

Satellite observational systems for the solid Earth

These two satellites are examples of ones that are capable of addressing applications discussed in this volume (see also the volume *Solid Earth Geophysics, Measurements and Applications* and its sections *Geodesy, Crustal Deformation, Subsidence, Volcanism and Landslides*). The German TerraSAR-X and TanDEM-X satellites are described above (see section "[Commercial and Hybrid Government/Commercial High-Resolution Systems, SAR](#)"). Flying in formation, they will perform single-pass Interferometric SAR (InSAR) and will reportedly be able to map the entire Earth in 2.5 years.

Gravity field and water resources

The GRACE (Gravity Recovery and Climate Experiment) mission from NASA and the DLR was launched in 2002 (GRACE, 2008). Two satellites are flying in formation, and their detailed trajectories in space can be used to measure changes in the Earth's gravitational field (see *Gravity Field*). This in turn can be used to infer changes in the mass of arctic ice and in the distribution of fresh water (see *Water Resources*). ESA's GOCE (Gravity field and

steady-state Ocean Circulation Explorer) mission is comprised of a single satellite (GOCE, 2008). It is scheduled for launch in 2008.

Satellite observational systems for the cryosphere (Ice)

The following satellites address applications discussed in this volume (see *Cryosphere, Measurements and Applications* and its sections *Ice Sheets*, *Sea Ice Extent*, and *Concentration*, *Polar Ice Dynamics*, and *Polar Ocean Navigation*). ESA's Envisat is described above. Please see the section on "Multidisciplinary" under the section "Satellite Observational Systems for the Atmosphere" in this entry. ESA's Sentinel-1 is described above; see the section "Multidisciplinary" under the section "Satellite Observational Systems for the Ocean" in this entry.

NASA's EOS ICESat, discussed above (see section "Introduction to Satellite Observational Systems"), hosts a backscatter lidar for measuring ice, land, and cloud elevation (ICESat, 2008). The follow-on mission IceSat-2 is scheduled for launch in 2015. Canada's RADARSAT-1 and RADARSAT-2 are discussed above (see section "Commercial and Hybrid Government/Commercial High-Resolution Systems, SAR"). Their SAR systems are good for providing ice data day and night. The Russian/Finnish Arktika satellite constellation, scheduled for launch starting in 2010, is designed to provide full-time coverage of the Arctic (Arktika, 2008). CryoSat-2 from the UK, scheduled for launch in 2009, will carry an interferometric altimeter to determine the thickness of land and sea ice (CryoSat-2, 2008).

Conclusion

The field of remote sensing of the Earth's environment from space is one that continues to expand internationally and that has benefited from advancements in instrument, spacecraft, ground-based data handling, and conversion of data and images to information. The availability of trained scientists and engineers who can understand the data and bring an end-to-end systems perspective to the field is a continuing issue. Training in astronomy and astrophysics provides a nearly ideal background for working in Earth remote sensing (Wertz, 1986). It has become a very common career path and a natural transition from a field with relatively limited job opportunities to one with excellent career potential and intellectual challenge.

OCEAN APPLICATIONS OF INTERFEROMETRIC SAR

Roland Romeiser

Rosenstiel School of Marine and Atmospheric Science,
University of Miami, Miami, FL, USA

Definition

SAR. Synthetic aperture radar – a side-looking imaging radar on a moving platform that exploits the Doppler history of received signals to synthesize the effect of a very long antenna (aperture) with a corresponding high spatial resolution in flight (azimuth) direction.

Interferometry. In this context, the analysis of amplitude and phase differences between corresponding pixels of two complex SAR images of the same scene, acquired from slightly different antenna locations or at slightly different times.

Interferometric SAR (InSAR). A SAR with two (or more) antennas for interferometry.

Along-track interferometry (ATI). Interferometric analysis of SAR images acquired by two antennas with a distance (baseline) in flight direction, which scan the scene at slightly different times. Phase differences are proportional to Doppler shifts and, thus, line-of-sight velocities.

Cross-track interferometry (XTI). Interferometric analysis of SAR images acquired by two antennas with a distance (baseline) perpendicular to the flight direction. Phase differences associated with the cross-track baseline are related to target elevations from a reference plane.

Repeat-pass interferometry. Cross-track interferometry using a single antenna that passes over a test area twice, e.g., during two subsequent satellite repeat cycles. This technique can be used for measuring target elevations and target displacements, e.g., due to an earthquake.

Introduction

When SAR raw data are processed into a SAR image, an amplitude and phase of the backscattered signal can be assigned to each pixel, but the phases in a single image have a uniform distribution and are usually ignored in the data interpretation. However, when two SAR images of the same scene, acquired from slightly different antenna locations (for XTI) and/or at different times (for ATI), are combined, the phase differences between corresponding pixels can contain information on target elevations and/or line-of-sight velocities, respectively. XTI and repeat-pass InSAR techniques are mainly used for land applications and will not be discussed further in the following. In the case of ATI, the phase differences are proportional to the Doppler shift of the signal and thus to line-of-sight target velocities; therefore, an along-track InSAR can be used for high-resolution surface current measurements. This concept was first described by Goldstein and Zebker (1987). For InSARs with combined cross-track and along-track baselines, detected phase variations over water are very similar to those from a pure along-track InSAR, because the surface is basically flat, while phase variations

over land are identical to those from a pure cross-track InSAR as long as there are no moving targets. Siegmund et al. (2004) demonstrated current measurements with such a combined XTI/ATI system. Suchandt et al. (2010) demonstrated speed measurements for moving vehicles on land by spaceborne along-track InSAR.

History

Following the ideas formulated by Goldstein and Zebker (1987), the first experiment with an airborne along-track InSAR was carried out over ship-generated internal waves in Loch Linnhe, Scotland, in 1989. Thompson and Jensen (1993) presented results from this experiment and demonstrated that ATI phase signatures include contributions of surface wave motions, which may vary within an image due to hydrodynamic wave-current interaction. Corrections for these contributions could be computed using the theoretical model of Thompson (1989). Graber et al. (1996) showed that properly corrected ATI-derived surface currents from another experiment were in good agreement with HF radar data. Toporkov et al. (2005) demonstrated two-dimensional vector current measurements with an airborne dual-beam ATI system, using two pairs of antennas with different look directions. This technique had been proposed a few years earlier by Frasier and Camps (2001). A first demonstration of current measurements by ATI from space was given by Romeiser et al. (2005), using data from the Shuttle Radar Topography Mission (SRTM) in early 2000 (see Figure 1). The German satellite TerraSAR-X, launched in 2007, is the first civilian satellite with experimental along-track InSAR capabilities in its divided antenna modes; first example results from TerraSAR-X were published by Romeiser et al. (2010).

Data processing

A description of an ATI raw data processing procedure can be found, for example, in the paper by Suchandt et al. (2010). At full resolution, the ATI phases are usually too noisy to show clear signatures of current variations. The phase noise results from instrument noise (dominant at very short time lags), the temporal decorrelation of the backscattered signal (at longer time lags), and spatial fluctuations of the actual Doppler shifts of radar signals received from different patches of the moving water surface. Filters need to be applied to reduce the phase noise and, at the same time, the effective spatial resolution of the data. Examples can be found in the papers by Romeiser (2005) and Romeiser et al. (2005, 2007, 2010).

In the next step, the detected phases have to be corrected for contributions of wave motions. To do this correctly, the wind speed and direction must be known. The wind information can be determined from the radar intensity image itself (Horstmann et al., 2000) or obtained from other sources, such as satellite data, in-situ data, or models. Using the wind vector information and the known radar parameters, a theoretical model, such as the ones

Ocean Applications of Interferometric SAR, Figure 1 (a) Line-of-sight surface current field derived from an interferometric image of the Dutch Wadden Sea from SRTM, acquired on February 15, 2000, 12:34 UTC; area size = $70 \text{ km} \times 70 \text{ km}$; arrows indicate orientation and strength of the current component parallel to the radar look direction; (b) corresponding current field from the numerical circulation model KUSTWAD for the tidal phase 20 min before the SRTM overpass (from Romeiser et al., 2005).

described by Thompson (1989) or Romeiser and Thompson (2000), can be used to estimate the mean contribution of wave motions to the Doppler frequency. A constant correction of this kind was used, for example, by Romeiser et al. (2010). In regions of strong wave-current interaction, spatially varying corrections may need to be computed; a method for doing this has been demonstrated by Romeiser (2005).

If ATI phases are not absolutely calibrated, additional information must be exploited to find a calibration constant to be added or subtracted from the whole array. This was the case with the data from SRTM. Romeiser et al. (2005) determined the calibration constant for an SRTM image of the Dutch Wadden Sea by requiring the current across a dam in the image to become zero. Romeiser et al. (2007) adjusted the calibration constant for an SRTM image of the Elbe river (Germany) in such a way that a uniform flow was obtained for different portions of the river with different flow directions relative to the radar look direction.

Accuracy and spatial resolution

The sensitivity of ATI phases to line-of-sight velocities increases with the ATI time lag, which is determined by the along-track baseline and the platform speed (approx. 7,500 m/s for satellites). At small time lags, the sensitivity is low, and the phase image looks noisy due to instrument noise. At longer time lags, instrument noise becomes less

dominant, but the received signal begins to decorrelate. As shown theoretically by Romeiser and Runge (2007), the best signal-to-noise ratio at X band (the radar frequency band used by SRTM and TerraSAR-X, about 10 GHz, wavelength $\approx 3 \text{ cm}$) should be obtained at time lags of 3–6 ms, corresponding to an effective baseline of 20–45 m. (The actual antenna distance may be twice as long if only one of the two antennas is transmitting and both are receiving.) This optimal time lag or baseline depends on the wind speed (decreasing with increasing wind, since the backscattered signal decorrelates faster) and is roughly proportional to the radar wavelength, i.e., it is an order of magnitude larger for L band (about 1 GHz, wavelength $\approx 30 \text{ cm}$). Even at an optimal time lag, some averaging of detected phases is required to reduce noise, and the effective spatial resolution of noise-filtered data will depend on the time lag and the full-resolution pixel size, as well as the incidence angle and polarization, since the signal-to-noise ratio decreases with increasing incidence angle and it is worse for horizontal (HH) than for vertical (VV) polarization.

For SRTM as well as TerraSAR-X Stripmap/Aperture Switching Mode data, the effective spatial resolution has been found to be on the order of 1 km at an accuracy of 0.1 m/s for measured horizontal currents. This is consistent with the theoretical findings of Romeiser and Runge (2007). With optimized system parameters (longer baseline, reduced instrument noise), the effective resolution could be improved by a factor of about 10. One should

note in this context that there is always a trade-off between the best possible accuracy and spatial resolution, i.e., a better spatial resolution can be obtained at the cost of a reduced accuracy (with less spatial averaging).

Applications

The ATI technique is attractive for all applications that require high-resolution surface current measurements in large areas or at many different locations, where the use of in-situ instruments or ground-based remote sensing techniques (HF radar, nautical radar) is not feasible for technical, economical, or political reasons. Examples are the monitoring of coastal bathymetry (see Calkoen et al., 2001 for a method based on conventional SAR imagery), the siting of turbines for electric power generation from tidal currents, and other coastal and offshore engineering applications. Furthermore, spaceborne along-track InSARs can be useful for a worldwide monitoring of river runoff. Bjerklie et al. (2005) have demonstrated the usefulness of surface current measurements for river runoff estimates with airborne ATI data. Romeiser et al. (2007, 2010) have demonstrated current measurements in rivers by spaceborne ATI. Over the open ocean, satellite-based ATI can be used to monitor oceanic internal waves and current features that cannot be resolved by altimeters, such as small eddies. Airborne ATI systems are useful for applications that require high-resolution current measurements for a limited time, at a higher spatial resolution than an HF radar (or existing satellites) can provide and a better temporal coverage than a satellite can provide (e.g., dedicated flights at certain tidal phases).

Summary

Out of various SAR interferometry techniques, ATI is the most attractive one for applications over coastal area, rivers, or the open ocean. ATI permits direct surface current measurements at spatial resolutions of 1 km and better from a satellite (a factor 10 improvement is possible for future instruments). Since the full-resolution images are noisy and include contributions of wave motions, some filtering and corrections for the wave motions need to be applied; techniques for these processing tasks are readily available. Promising applications are the ones that require high-resolution current measurements in areas where in-situ measurements or the use of other remote sensing techniques is not feasible.

OCEAN DATA TELEMETRY

Michael R. Prior-Jones
British Antarctic Survey, Cambridge, UK

Definitions

Airtime cost. The cost of using a particular communications system. Often charged per minute or per unit of data, but sometimes offered as a flat rate.

Constellation. Collective noun for a group of satellites which function together as a single system.

Data rate. The speed with which data may be transmitted over a communications link. Communications engineers quote this rate in bits/s (or kilobits/s, megabits/s, etc.), whereas many computer systems show data rate in kilobytes/s. One byte is eight bits, so converting from kilobytes to kilobits requires multiplying by eight.

Footprint. The area on the Earth's surface covered by a particular satellite.

Geostationary, geosynchronous, GEO. A satellite with an orbital period equal to the period of the Earth's rotation (the sidereal day, roughly 24 h and 56 min), such that it appears stationary from the Earth's surface. Geostationary orbit is around 35,000 km above the Earth.

ISDN. Integrated Services Digital Network, a telecommunications industry standard for digital communications over telephone lines.

Low Earth Orbit, LEO. A satellite orbiting close to the Earth – usually considered to be between 160 km and 2000 km above the Earth.

Terminal. Equipment used to communicate with a satellite, including the antenna.

Terrestrial radio. Radio systems not involving the use of satellites.

Introduction

Studies of the oceans are increasingly making use of automated instrumentation. These instruments take many forms – such as buoys, moorings, drifting floats, gliders, and autonomous undersea vehicles – but most rely on some form of telemetry to bring their data back for analysis. These data sets are often used in conjunction with remotely sensed measurements, for example, in refining algorithms and assessing the accuracy of the derived variables. A variety of communications systems are available to environmental scientists, many of which are described here. Systems vary in their cost, coverage, data rate, robustness, and power consumption, and so choosing which communications system to use is an important decision in the design of any new autonomous instrument.

Terrestrial radio

Terrestrial radio signals at frequencies of 30 MHz or higher (VHF and up) can be considered as travelling in straight lines. This line-of-sight restriction means that such systems are only suitable for use in coastal observations. A wide range of commercial radio modems are on

the market, typically offering up to 20 km range at up to 10 kbit/s. In many countries terrestrial radio modems may be operated without a radio license, although the law restricts the output power and frequencies that may be used. Licensed operation permits higher output powers and hence longer ranges and/or higher data rates.

Cellular phone systems may also be used. The GSM system used in most countries worldwide has a maximum range of 35 km and can provide data rates of up to 100 kbit/s. Since GSM technology is very small and light, it has been used for tracking the movements of seals (McConnell et al., 2004).

HF radio means frequencies of 3–30 MHz. These frequencies may be reflected from the ionosphere and thus achieve very long ranges (thousands of km) if the propagation conditions are suitable. Due to this reliability issue, the use of HF has largely been eclipsed by satellite communications. However, HF is potentially cheaper than satellite as there is no airtime bill to pay. HF modems using the MIL-STD-188-110B standard are the current state of the art and are available from several defense electronics firms. They offer data rates of around 2400 bits/s.

Geostationary satellite

Geostationary systems are attractive on land because a stationary antenna does not need to track the satellite once the system has been initially set up. At sea, actively tracked antennas are required in order to keep the antenna pointed at the satellite regardless of its movement. Geostationary systems do not provide coverage to the polar regions – their footprints generally extend to 70° north and south.

Inmarsat

Inmarsat's constellation of four satellites covers the whole planet apart from the polar regions. They offer three services aimed at ships (Fleet, FleetBroadband and XpressLink) and two aimed at asset tracking (IsatM2M and IsatDataPro). Inmarsat's other services (such as BGAN, BGAN Link, and BGAN M2M) are designed for use with land-based terminals only and will not work in the marine environment.

Fleet comes in three versions – Fleet 33, 55, and 77. Fleet 33 offers 9.6 kbit/s dial-up data. Fleet 55 offers 64 kbit/s dial-up ISDN. Fleet 77 offers 128 kbit/s dial-up ISDN. All three can also offer an always-on packet-based data service known as MPDS, although this is expensive compared to other products on the market. Fleet terminals consume up to 150 W when transmitting.

FleetBroadband can provide a connection to the Internet at up to 432 kbit/s, although the data rate depends on the terminal used – the smallest, cheapest terminal will only deliver 150 kbit/s. The terminals need around 150 W of power. FleetBroadband airtime costs \$13/MB although bulk users should be able to negotiate a discount.

XpressLink is a hybrid service for ships, consisting of a FleetBroadband terminal and a Ku-band VSAT terminal connected to a common controller. When in range of a Ku-band satellite, the faster Ku-band service is used (up to 768 kbit/s downlink speed), and the system automatically switches over to FleetBroadband (up to 438 kbit/s) when outside the Ku-band area. Inmarsat has a new Ka-band satellite launching in 2014, and XpressLink is upgradeable to support the faster Ka-band service once it becomes available. XpressLink is priced according to bandwidth, not data usage, and prices start from \$2500 per month, including hire of the terminal.

IsatDataPro is a message-based service, supporting messages of a few kilobytes in size (6400 bytes send, 10000 bytes receive). Messages are delivered in around 60 s. There is a monthly subscription that starts at \$19 per terminal, which includes the first 10Kbytes of data. Subsequent data is charged at \$1 per Kbyte. The marine-grade terminal for IsatDataPro is the SkyWave IDP-690, which consumes 0.5 W in receive mode and 9 W in transmit.

IsatM2M is a message-based service, allowing a remote terminal to send messages up to 25 bytes long and receive messages of up to 100 bytes. Messages are delivered within 60s. A typical terminal weighs around 350 g and consumes 6 W on transmit.

Thuraya

Thuraya operates two satellites, providing coverage to Europe, Central and South Asia, and Australia. It covers the Mediterranean, the east Atlantic, the northern part of the Indian Ocean, and the western Pacific.

Thuraya offers dial-up data at 9.6 kbit/s, packet data (GmPRS (1. GmPRS is the name given to Thuraya's packet data service. It's a variant on the GPRS service used on the GSM phone networks)) at 60 kbit/s downlink and 15 kbit/s uplink, plus SMS messaging. All of these services are available from the ThurayaModule terminal, which is about the size of a pack of cards, weighs 60 g and consumes 3 W on transmit.

Thuraya also offers a high-bandwidth product, ThurayaIP, offering up to 444 kbit/s. Using ThurayaIP at sea requires an external stabilized antenna, purchased separately. The entry-level tariff for this service costs \$40/month and then \$6 per megabyte of data transferred.

VSAT

VSAT stands for "very small aperture terminal" which is a rather misleading term. It means the use of commercial telecom satellites (of the kind that are used to carry satellite TV broadcasts) with a relatively small antenna (<3 m diameter). With a VSAT service, you either lease a dedicated channel on the satellite for your exclusive use or join a shared channel operated by a network provider. VSAT is relatively expensive but becomes economic when handling large volumes of data (>100 MB per month).

DCS

The Data Collection Service is provided by a federation of meteorological satellite operators in Europe, the USA, Japan, Russia, and China. Unlike the other systems described, it's free to use. DCS terminals (known as Data Collection Platforms, DCP) normally report hourly or three-hourly and send a single 649 byte message, which takes 1 min to transmit. The system is unidirectional, so the DCP does not know that messages have been successfully received. Messages are delivered within 10 min. DCPs can use as much as 100 W of electrical power during transmission.

An upgraded version of DCS, known as High-Rate DCS (HRDCS), is now in service, and the US GOES satellites are phasing out the old 100 bps service. HRDCS operates at 1200 bps and can transmit the standard 649 byte message in 10 s. Longer messages are possible, up to a maximum of 65536 bytes.

Low earth orbit satellite

Satellites in low Earth orbit move rapidly with respect to the Earth's surface, and so they appear to track across the sky, usually being in view for around 10 min. As the satellites are much closer to the Earth than geostationary orbit, terminals can have smaller antennas and use less transmit power.

ARGOS

ARGOS is a unidirectional, message-based service like DCS, but it uses five polar-orbiting satellites to give global coverage. The message size is limited to 32 bytes, but the terminals can be extremely small and light and are often used for tracking birds, for example. Because there's no acknowledgment from the satellite, the message is repeated several times to try and maximize the chance of good reception.

ARGOS uses the Doppler effect to estimate the position of each transmitter as the message is transmitted. The accuracy of this technique ranges from 350 m to 1 km, depending on how many copies of the message were received by the satellite as it passed overhead. Entry-level ARGOS terminals cost in the region of \$2000, but a considerable premium can be paid for the smallest, lightest models.

A newer version of the system, called ARGOS-3, is being rolled out. At present few satellites support it, but it provides higher data rates (4.8 kbit/s) and two-way communications. The terminals are able to detect the presence of the satellite before it transmits, and to receive acknowledgments for messages received correctly, both of which improve power efficiency.

ARGOS's pricing structure needs some explanation. Rather than charge by the message or by the byte, they charge a monthly fee for each month the terminal transmits plus a fee for each 6 h slot in which messages are sent. Separate tariffs are used for commercial and scientific

Ocean Data Telemetry, Table 1 Comparison of message-based systems

System	Message size	Tariff	Monthly price, 1 message/day	Monthly price, 1 message/h	Terminal power consumption (during transmission)	Two-way comms?	Polar coverage? ^a	Data rate	Time to send one message	Delivery time
Iridium SBD	<340 bytes	\$13/month + \$0.0015/ byte ^b	\$14.24 (30 bytes)	\$31.48 (30 bytes – bulk tariff)	1 W	Yes	Yes		~1 s	<20 s
IsatM2M	25 bytes	\$0.06 for 10 bytes or \$0.120 for 25 bytes	\$5 (25 bytes – minimum spend)	\$89.28 (25 bytes)	9 W	Yes	No		10 s?	30 s
IsatDataPro	<6,400 bytes (tx) <10 kbytes (rx)	\$19/mo + \$1/kbyte ^c	\$19	\$28 (assuming 25 byte message)	9 W	Yes	No		~1 s	<15 s
ARGOS	32 bytes	Land-based fixed stations \$21/month + \$1/6 h slot ^d Other stations \$21/ month + \$1.9/6 h slot	\$54 \$81	\$151	<1 W	No ^e	Yes	480 bps	~1 s	Up to 2 h
DCS	650 bytes	Free	\$0	\$0	50–100 W	No	No	100 bps	75 s	<10 min
Orbcomm	<2,000 bytes?	Prices not available	24 W	Yes	Sporadic	2,400 bps	~1 s	Up to 6 h		
Globalstar simplex	<36 bytes	\$10–\$77/month \$0.2–\$1/msg ^f	\$30 (includes 100 9 byte messages)	\$860	2.5 W	No	No	100 bps	<1 s for 9 bytes, ~3 s for 36 bytes	<30 min

^aPolar coverage means coverage beyond the reach of geostationary satellites (i.e., latitudes higher than 75°)^bThere is a minimum fee per message of \$0.04, covering your first 30 bytes. SBD also has a bulk tariff, where for \$16 a month you get 12,000 inclusive bytes, subject to a minimum bill per message of 10 bytes^cIsatDataPro pricing by OCENS, July 2012. All other prices are from June 2010^dThis is the ARGOS JTA price for scientific applications. Marine animal-tracking devices get a further discount – they are only billed for a maximum of 48 h slots in a given month, regardless of how many they actually use. ARGOS is billed in Euros and the dollar prices here are based on an exchange rate of 1 euro = 1.4 USD^eARGOS currently has one two-way capable ARGOS-3 satellite in orbit, but the ARGOS-3 terminals are not on the market yet^fGlobalstar simplex pricing by Blue Oceans. Cheaper tariffs bill in 9 byte units, and bulk tariff (\$77/month) bills in 36 byte units

applications, and within the scientific tariff, there are different rates for fixed, mobile, and animal-tracking applications.

Iridium

Iridium operates a constellation of 66 satellites providing continuous global coverage and offers voice calls and data services. Although each satellite is only in view for 10 min at most, the network is capable of handing over calls between satellites without losing the connection. They offer three basic data services – Short Burst Data, dial-up data, and OpenPort.

Short Burst Data (SBD) is a bidirectional message-based system. The network supports SBD messages of up to 1960 bytes (2. These figures are for Mobile-Originated SBD messages (i.e., messages from an Iridium terminal). Mobile-Terminated messages (i.e., messages to the Iridium terminal) are slightly shorter Tables 1 and 2), but the lightweight SBD-only modem supports a maximum of 340 bytes per message. Because SBD is

bidirectional, the terminal receives an acknowledgment that its message has been sent successfully. The smallest SBD modem (model 9603) weighs 11 g and consumes ~1 W while transmitting.

Dial-up data offers a 2400bits/s connection in a similar manner to a conventional landline modem. Calls are routed via a modem at the Iridium gateway station and can take up to 40 s to connect. It costs in the region of \$1/min. The 9522B terminal is an off-the-shelf solution for dial-up data – it weighs around 400 g and consumes 4 W while transmitting. There's also a bare-board module (Iridium Core 9523) that weighs 32 g and consumes 3 W while transmitting.

OpenPort (also known as Iridium Pilot) is Iridium's higher-bandwidth product, offering data rates of up to 134 kbit/s. It is intended for use on ships, so the terminal is large and rugged – a cylinder 60 cm in diameter weighing 11 kg and consuming 100 W. OpenPort airtime is priced at around \$7/MB but gets cheaper for higher-volume usage.

Ocean Data Telemetry, Table 2 Comparison of data services

System	Airtime charges ^a Data rate, kbit/s ^c	Monthly airtime cost for... ^b						Polar coverage ^e
		Monthly fee	Charged rate	Equivalent cost per MB ^d	1 MB	10 MB	100 MB	
Iridium dial-up	2.4	\$14	\$1/min	\$58	\$72	\$594	\$5,814	Yes
Iridium OpenPort ^f	9.6	\$0	\$5–\$7/MB	\$5–\$7/MB	\$7	\$68	\$575	Yes
	32	\$0	\$5–\$8/MB	\$5–\$8/MB	\$7	\$72	\$611	
	64	\$0	\$5–\$8/MB	\$5–\$8/MB	\$8	\$76	\$647	
	128	\$0	\$6–\$9/MB	\$6–\$9/MB	\$9	\$84	\$719	
Fleet MPDS	28, 64, 128 ^g	\$0	\$34/MB	\$34	\$34	\$340	\$3,400	No
Fleet 33 dial-up	9.6	\$0	\$3/min	\$43	\$43	\$430	\$4,300	No
Fleet 55/77 ISDN	64	\$0	\$7/min	\$15	\$15	\$150	\$1,500	No
Fleet 77 ISDN2	128	\$0	\$12.50/min	\$14	\$14	\$130	\$1,300	No
FleetBroadband	432 ^h	\$0 ⁱ	\$13/MB	\$13	\$30	\$130	\$1,300	No
Thuraya dial-up	9.6	\$36	\$1/min	\$15	\$51	\$186	\$1,536	No
Thuraya GmPRS	15	\$60 ^j	\$5.50/MB	\$5.50	\$60 ^k	\$88	\$582.5	No
ThurayaIP	444	\$40	\$6/MB	\$6	\$46	\$100	\$585 ^l	No
Globalstar #777	9.6	\$14–\$49	\$1.12/min	\$16	\$30	\$49 ^m	\$49	No

^aAll prices are in US dollars and exclude taxes. Iridium airtime was priced from NAL Research. OpenPort prices were quoted by AST. Fleet prices were from KVH. BGAN, FleetBroadband, Globalstar, and Thuraya (dial-up/GmPRS) prices were from Satphone. ThurayaIP prices were from GTC

^bThis price is the cost per month for the data used in a given month. It includes monthly subscription charges, but does not include initial setup costs such as activation or SIM card fees. Figures have been rounded to the nearest dollar

^cFigures quoted here are uplink speeds – some systems have asymmetric uplink and downlink speeds

^dThis price shows the per-minute rates converted to per megabyte, ignoring monthly fees or any overheads like minutes used while establishing connections

^ePolar coverage means coverage beyond the reach of geostationary satellites (i.e., latitudes higher than 75°)

^fOpenPort allows a choice of data rates, slower is cheaper. It has no compulsory monthly fee, but by paying a monthly rate gets you an inclusive data allowance and a cheaper rate on any excess. Monthly plans start at 10 MB/month

^gMPDS operates at 28 kbit/s on Fleet 33, 64 kbit/s on Fleet 55, and 128 kbit/s on Fleet 77. Airtime prices are the same for all three systems

^hThere are currently two FleetBroadband terminals on the market. The smaller, cheaper unit offers 284 kbit/s data rate. Airtime pricing is the same for both units

ⁱFleetBroadband has no monthly fee, but there is \$30/month minimum spend

^jThe \$60 monthly fee includes the first 5 MB of data allowance

^kIncludes the first 5 MB of data allowance

^lThurayaIP offers 150 MB of data for \$585/month

^mGlobalstar Europe offers an unlimited burst data plan for €34.99 (= \$49). This deal only applies for service within Europe

Globalstar

Globalstar's network architecture means that satellites must be in range of one of its ground stations to operate, so their coverage at sea is limited. Their standard duplex service covers most of the North Atlantic Ocean, the Mediterranean, North Sea, and US Pacific coast. Users purchase a contract for use in a particular region of the world, and roaming to another region is considerably more expensive. Globalstar offers a 9.6 kbit/s dial-up data service and their modem consumes 4 W on transmit.

They also offer a simplex (i.e., unidirectional) message-based data service. This has larger coverage areas and can send up to 36 bytes per message. Simplex modems consume 2.5 W on transmit.

Orbcomm

Orbcomm operates a network of 29 satellites in low Earth orbit, offering a bidirectional message-based communication service. There is no fixed message size, although sending shorter messages is considered more reliable.

Unlike the other services described here, Orbcomm operates in the marine VHF band and hops between frequencies to avoid interference. Coverage is not continuous – holes in the coverage open and close as the satellites move – and there is presently only one polar-orbiting satellite, making polar coverage somewhat erratic.

Messages are downlinked by regional earth stations ("gateways"). If a satellite is in range, the messages are delivered in close to real time. Otherwise, the satellite will store the message and attempt to forward it on when it next comes in range. A terminal is normally associated with just one gateway, and additional fees are payable for "roaming" to other gateways elsewhere in the world.

Orbcomm would not quote airtime prices without a nondisclosure agreement.

Price comparisons

The following tables give indicative prices in US dollars excluding taxes. They are intended to give an estimate as to how much each system costs to operate. As most satellite systems sell airtime through a number of resellers, call more than one supplier in order to get the best price. These prices were obtained in 2010.

Summary

A wide variety of systems are available for data telemetry. Working in coastal waters permits the use of radio modems or cellular phone technology. Satellite technology is widely used for use in remote regions or on the open ocean. Where terminal size and power consumption are all important, a message-based service like Iridium SBD or ARGOS can provide basic communications. Dial-up data (on Iridium, Thuraya, or Globalstar) can provide two-way real-time data comms from compact terminals while still consuming less than 5 W, although airtime is expensive. If plenty of power is available, products like ThurayaIP,

FleetBroadband, and OpenPort provide high data rates at competitive prices for low-volume users. However, for high data volumes (i.e., more than 100 MB per month), VSAT is currently the most cost-effective solution.

OCEAN INTERNAL WAVES

Werner Alpers

Institute of Oceanography, University of Hamburg,
Hamburg, Germany

Synonyms

Waves in the interior of the ocean

Definition

Ocean internal waves are waves in the interior of the ocean which are generated when the interface between layers of different water densities is disturbed, usually caused by tidal flow over shallow bathymetry.

Introduction

Internal waves are waves of the interior ocean. They can exist when the water body is stratified, i.e., when it consists of water layers of different densities. This difference is usually caused by a difference in water temperature, but it can also be caused by a difference in salinity as in the Strait of Gibraltar. In order to generate internal waves, the interface must be disturbed. There are many ways to disturb the interface, e.g., by (1) water being pushed by the action of the tide over irregularities in shallow bathymetry, such as underwater ridges or shelf breaks (e.g., Lamb, 1994), (2) the transit of a surface ship or a submarine, (3) river outflow, or (4) the passage of an atmospheric front.

Unlike the familiar surface waves, internal waves are not (to first order) associated with an elevation of the sea surface, but with a variable surface current which modulates the sea surface roughness. Remote sensing instruments can capture internal waves via these roughness patterns. The most commonly used instrument for detecting ocean internal waves from space is the synthetic aperture radar (SAR), which is capable of measuring very small changes in the sea surface roughness in the centimeter to decimeter wavelength range. The wave-induced roughness patterns can sometimes even be seen by the naked eye provided that the observer looks at the sea surface with an angle which is close to the specular reflection angle of the sun (into the "sun glint"). Optical sensors flying in space can also be used for detecting internal waves,

but their applicability is restricted to daytime, clear skies, and favorable viewing geometry with respect to the position of the sun (Jackson, 2007).

Basics

When describing internal waves in the ocean, one often approximates the density structure of the water column by two layers of differing densities. Since the change in density is usually due to a change in temperature, one calls this interface the “thermocline.” In the presence of internal waves, the thermocline is distorted. Associated with internal waves are orbital motions of water particles which can move submarines tens of meters up and down. Internal waves as well as surface waves (the familiar waves seen on the ocean surface) are both gravity waves which are governed by the same hydrodynamic equations. The only difference is that in the case of internal waves, the difference in density between the two fluids (warm water above and cold water below) is about three orders of magnitude smaller than in the case of surface waves (air above and water below). This implies that the spatial and temporal scales of ocean internal and surface waves are quite different.

Typical wavelengths of internal waves in the ocean are hundreds of meters to tens of kilometers and typical periods are several minutes to several hours. The orbital motions associated with internal waves generate convergent and divergent flow regimes on the sea surface which

modulate the sea surface roughness by hydrodynamic wave-current interaction (Alpers, 1985). It is by this sea surface roughness pattern that internal waves become detectable by SAR and optical sensors.

Most often ocean internal waves, especially when they are generated by tidal flow over shallow underwater bottom topography, are highly nonlinear and occur in wave packets. The distances between the waves in a wave packet and also their amplitudes decrease from front to rear. Nonlinear internal waves are usually described in terms of soliton theories and are called internal solitons or internal solitary waves (ISWs). The first soliton theory was developed already in 1895 by Korteweg and de Vries.

In Figure 1, a typical example of a nonlinear internal wave packet consisting of three ISWs is depicted. The color coding denotes the water density and the arrows the velocity. This vertical profile was measured north of the Strait of Messina in the Mediterranean Sea on October 25, 1995, by a towed conductivity-temperature-depth (CTD) chain and by a vessel-mounted acoustic Doppler current profiler (ADCP). Note that the depression of the thermocline associated with the first solitary wave in the wave packet exceeds 50 m.

Internal waves in the Andaman Sea

The Andaman Sea, located between the Malay Peninsula and the Andaman and Nicobar Islands, is an ocean area

Ocean Internal Waves, Figure 1 Density distribution of the water column and distribution of the velocity north of the Strait of Messina measured by shipborne sensors during the passage of a highly nonlinear internal wave packet on October 25, 1995.

Ocean Internal Waves, Figure 2 ERS-2 SAR image acquired over the Andaman Sea on February 11, 1997, showing sea surface signatures of internal solitary waves. In the lower section of the image, the northwestern part of Sumatra and the Indonesian island Weh are visible. The imaged area is 100×300 km © ESA.

where ISWs of large amplitudes (peak to trough values of more than 60 m) are frequently encountered (Osborne and Burch, 1980). Roughness bands stretching from horizon to horizon generated by ISWs have often been observed in the Andaman Sea from ships. Also, optical images taken from satellites have occasionally revealed sea surface signatures of ISWs. But the ubiquity of large ISWs in the Andaman Sea has become apparent only after a large number of synthetic aperture radar images have become available from the first ESA Remote Sensing satellite ERS-1 launched in 1991 and later from the ERS-2, Radarsat, Envisat, and ALOS satellites launched in 1995, 1995, 2002, and 2006, respectively. Several of the early ERS SAR images of the Andaman Sea can be found in Brandt et al., 1997 and <http://www.ifm.uni-hamburg.de/ers-sar/Sdata/oceanic/intwaves/>

Figure 2 shows an ERS-2 SAR image (swath width: 100 km) which was acquired over the Andaman Sea north of the Indonesian island of Sumatra. The large-scale wave pattern is the sea surface signature of a strong internal solitary wave packet which was generated by the interaction of the tide with shallow bathymetry located between Sumatra and the Great Nicobar Island. Clearly visible are sea surface signatures of six internal solitary waves of decreasing intensity from front to rear. The leading soliton in the wave packet has a crest length of more than 200 km. Also visible in the upper section is a weak semi-circular small-scale wave pattern which is the sea surface signature of a secondary internal wave packet generated by scattering of a large-amplitude internal solitary wave at an underwater bank (Vlasenko and Alpers, 2005).

Internal waves in the South China Sea

The South China Sea is another ocean area where very large-amplitude and long-crested solitary internal waves

Ocean Internal Waves, Figure 3 Envisat ASAR Wide Swath image acquired over the South China Sea showing sea surface signatures of an internal soliton (the long curved line on the right) and several internal wave packets which were generated at successive tidal cycles. The internal waves are refracted by the shallow reef of the Dongsha Atoll. The imaged area is 400×250 km ©ESA.

Ocean Internal Waves, Figure 4 Optical image acquired by the Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) over the Mediterranean Sea on August 11, 2003. The land surface visible on the *left* is the east coast of Sicily; on the *right*, the west coast of Calabria (Italy); and on the *upper right* corner, the Strait of Messina. Sea surface signatures of a southward propagating internal wave packet generated in the Strait of Messina are visible in the *lower* section of the image (<http://asterweb.jpl.nasa.gov/gallery-detail.asp?name=messina-wave>).

are encountered (e.g., Liu et al., 1998), probably the largest in the world's ocean. They are generated by the interaction of the tidal current with shallow underwater bottom topography located in the Luzon Strait (between Taiwan and Luzon) from where they propagate westward toward the Chinese coast. On their way, they interact with the shallow topography of the Chinese Shelf, in particular with the Dongsha Atoll, and finally dissipate near the Chinese coast. Figure 3 shows an Envisat Advanced SAR Wide Swath image acquired June 18, 2008, at 0213UTC over the South China Sea east of Hong Kong. Visible are sea surface signatures of an internal soliton (the long bended line to the right) and of several internal wave packets generated at successive tidal cycles. Note that the distance between the wave packets decreases from east to west due to the decrease in propagation when the internal waves enter shallow waters.

Internal waves in the Mediterranean Sea

In the Mediterranean Sea, large-amplitude ISWs are generated in the Strait of Gibraltar (separating Spain from Morocco) and in the Strait of Messina (separating the Italian island of Sicily from the Italian Peninsula) by tidal flow over underwater ridges located in these straits. While the existence of internal waves generated in the Strait of Gibraltar had been demonstrated by in situ measurements by 1960, the existence of internal waves was first revealed by a SAR image acquired by the US Seasat satellite on September 15, 1978 (Alpers and Salusti, 1983). On this SAR image, sea surface signatures of a northward propagating wave packet were observed. But in the following years, internal waves propagating northward as well as southward have been detected by in situ measurements and on spaceborne SAR and optical images (e.g., Brandt et al., 1997). An impressive example of an optical image revealing the existence of southward propagating ISWs in the Strait of Messina is depicted in Figure 4. This image was acquired in the visible band by the Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) onboard the Terra satellite.

Summary

Although ocean internal waves are waves in the interior of the ocean, they are detectable from satellites because they leave a fingerprint on the sea surface by changing the small-scale sea surface roughness. In some cases, these roughness changes can be captured by optical instruments (when the imaged sea area lies in or close to the specular reflection area of the sun), but the best instrument for capturing internal waves from space is the synthetic aperture radar (SAR). SAR images acquired from satellites have greatly contributed to our knowledge of the distribution and dynamics of internal waves in the world's ocean.

Ocean color

Definition

Ocean color is the spectral variation of the water-leaving radiance that can be related to concentrations of the optically active constituents.

Water-leaving radiance, L_w , is the downwelling solar irradiance that has penetrated the water surface, interacted with the water body (optically active constituents), and then been backscattered towards the sensor used to detect it.

Optically active constituents are those substances dissolved or suspended within the water column that affect the color of the water through absorption and/or scattering.

Ocean color

Introduction and overview of the sensors

The color of water bodies (in this case termed ocean color as this entry will primarily focus on marine waters) was recorded as early as the 1600s; Henry Hudson, sailing from one sea to another while looking for a northeast passage to China and Japan, noted in his ship's log that a sea pestered with ice had a black-blue color (Hudson, 1608). For further information on the historical context (1600–1930), see Wernand (2008).

Spaceborne ocean color imagery was first obtained in the 1960s, through handheld cameras on manned space missions, and clearly demonstrated the potential of satellites for monitoring coastal total suspended matter (TSM) and phytoplankton-induced color variation, e.g., Badgley and Childs (1969). Clarke et al. (1970) undertook the first quantitative work using an airborne

spectroradiometer, recording the influence of different phytoplankton concentrations on the spectral variation of water-leaving radiance.

The first dedicated, but proof of concept, sensor was the Coastal Zone Color Scanner (CZCS) launched onboard the Nimbus-7 spacecraft in 1978. It recorded the water-leaving radiance in four wavebands (430–450, 510–530, 540–560, and 660–680 nm) with a broad near-infrared (NIR) waveband to differentiate sea from land and cloud (700–800 nm) and a thermal infrared band (10.5–12.5 μm) for determining *Sea Surface Temperature (SST)*. However, it was operated on an intermittent schedule (due to power demands), lost the thermal infrared waveband within the first year, and the other wavebands began degrading from 1981 onward although they remained useable to some degree until 1984. These data are still important today and have been reprocessed by both projects and space agencies so that they are as comparable as possible (within the limitations of what was collected) to modern-day datasets. Examples include the North Sea Atlas (Holligan et al., 1989), OCEAN project (Barale et al., 1999), and the NASA Ocean Biology Processing Group reprocessings (see Gregg et al., 2002 and http://oceancolor.gsfc.nasa.gov/CZCS/czcs_processing/).

Since CZCS, a number of ocean color missions have been launched although there was a large gap until the next mission in 1996; the Modular Optoelectronic Scanner (MOS) was designed and built by the German Aerospace Research Establishment (DLR) and launched onboard the Indian IRS-P3 spacecraft (Zimmermann and Neumann, 1997). MOS was launched into a sun-synchronous polar orbit. This is a traditional orbit for ocean color missions as they follow a path that passes close to the North and South Poles so that different parts of the Earth's surface are viewed during successive orbits and the whole of the Earth is covered in 2–3 days if the instrument has a suitable swath width. For MOS, global imagery was not possible as the sensor did not have suitable onboard storage; without this, data has to be directly downlinked while the satellite is in view of a receiving station or has to be relayed to Earth via a data relay satellite, e.g., Artemis, that works alongside Envisat.

The Sea-viewing Wide Field-of-view Sensor (SeaWiFS) has, to date, provided the longest time series of ocean color measurements; it was launched onboard the ORBVUEW-2 satellite in August 1997 (first data in September) and worked until December 2010 although there were several data gaps due to, e.g., problems with a telemetry collection anomaly. Therefore the SeaWiFS dataset is over 10 years in length, which considerably exceeds the original planned lifetime of 5 years. SeaWiFS was a commercial satellite, owned by GeoEye, but with the development funded by the National Aeronautics and Space Administration (NASA) which purchased (alongside agencies such as National Oceanic and Atmospheric Administration, NOAA, in later years) the right to use SeaWiFS data for academic research from

the commercial owner. From 2005, noncommercial data were limited to just the global area coverage (GAC; 4 km sampling) rather than the higher-resolution (approximately 1 km) local area coverage (LAC) measurements that were previously acquired by a number of receiving stations around the world as well as having a small amount recorded onboard. However, in 2008, NASA reactivated the opportunity to receive LAC data in a non-near-real-time (NRT) mode for United States (US) coastal waters; there was always an opportunity to purchase a commercial license. SeaWiFS had eight narrow (20–40 nm) bands in the visible and NIR (402–422, 433–453, 480–500, 500–520, 545–565, 660–680, 745–785, and 845–885 nm), but no thermal waveband for measuring Sea Surface Temperature (SST).

In the twenty-first century, SeaWiFS was joined by the global coverage Moderate Resolution Imaging Spectrometer (MODIS) and Medium Resolution Imaging Spectrometer (MERIS). The MODIS sensors were launched by NASA onboard both the EOS Terra satellite in December 1999 and the EOS Aqua satellite in May 2002. MODIS has additional ocean color wavebands compared to SeaWiFS totaling nine (405–420, 438–448, 483–493, 526–536, 546–556, 662–672, 673–683, 743–753, and 862–877 nm) plus visible and NIR wavebands for atmospheric and terrestrial applications; of particular interest is a narrow waveband for solar-stimulated chlorophyll fluorescence and additional thermal bands for SST.

MERIS was launched onboard the Envisat satellite, by the European Space Agency (ESA), in March 2002, and carried a total of nine instruments that include the Advanced Along-Track Scanning Radiometer (AATSR) instrument for SST applications; the Envisat satellite, and hence MERIS dataset, ceased operating at the beginning of April 2012. MERIS had narrow and selectable wavebands; the standard setup has been 407.5–417.5, 437.5–447.7, 485–495, 505–515, 555–565, 615–625, 660–670, 677.5–685, 700–710, 750.0–757.5, 758.75–761.25, 770–780, 855–875, 885–895, and 895–905 nm that included a solar-stimulated chlorophyll fluorescence waveband. It had a full spatial resolution of 300 m for coastal areas and a reduced resolution of approximately 1 km with global coverage every 2–3 days (Rast et al., 1999); the full-resolution data were available over the whole of Europe (because of Artemis) and where there were receiving stations worldwide. The MODIS ocean color wavebands have a resolution of approximately 1 km, but the terrestrial wavebands have a higher spatial resolution and so the wavebands at 500 and 250 m resolution have been used for coastal applications (e.g., Miller and McKee, 2004 and Shutler et al., 2007). Both MODIS and MERIS data suffer from sunglint contamination as, unlike SeaWiFS, they do not have the ability to tilt away from the sun glitter. The coverage of MERIS was further reduced by the relatively narrow swath (1,150 km as compared to 2,330 km for MODIS).

The Visible Infrared Imaging Radiometer Suite (VIIRS), which is a multispectral scanning radiometer with 22 wavebands between 0.4 and 12 μm , was launched in October 2011 on the National Polar-orbiting Operational Environmental Satellite System (NPOESS) Preparatory Project (NPP) satellite, satellite renamed to the Suomi National Polar-orbiting Partnership or Suomi NPP. Although NASA provided assistance with the prelaunch preparations and is distributing processed data, the mission is operated by NOAA as it is seen as an operational mission.

Europe plans to launch the Ocean & Land Colour Instrument (OLCI) on Sentinel-3 as part the Global Monitoring for Environment and Security (GMES) initiative. This sensor is of a similar design and specification to MERIS with an additional channel at 1.02 μm to enhance the existing MERIS atmospheric and aerosol correction capabilities. The first Sentinel-3 is planned for launch in 2014 with follow-up launches to meet observational requirements, such as improved global coverage, and to enable robust and continuous data provision.

Theory behind ocean color and its processing to biogeochemical products

The successful exploitation of ocean color requires a conversion of the top of atmosphere radiances (as detected by the sensor) to water-leaving radiances and then derivation of the optically active biogeochemical constituents such as (see Mueller et al., 2003 for details and references of the in situ determination techniques):

- TSM: It is also referred to as Suspended Particulate Matter (SPM). It represents the total mass of suspended particles that can be broken down into the inorganic and organic fractions. The organic fraction includes the weight of phytoplankton, and the in situ laboratory method for determining the TSM concentration involves filtering water samples through filter papers and then drying and weighing them to determine the added weight.
- Colored dissolved organic matter (CDOM): It is also called gelbstoff or yellow substances or gilvin and consists of humic and fulvic compounds of either terrestrial origin (are transported into marine waters by river/estuary systems) or those resulting from the breakdown of phytoplankton. The concentration is typically measured in a spectrophotometer as an absorption at a specific wavelength and slope of the exponential curve between two wavelengths. This can be combined with the organic matter absorption associated with TSM and called the colored dissolved and detrital organic materials (CDM).
- Chlorophyll-a (Chl-a): It is used to represent the phytoplankton biomass and an input to products such as primary production (PP). Chl-a is often the primary pigment in phytoplankton, but there are several other pigments and together these form the pigment

absorption spectra and are increasingly used in understanding phytoplankton functional types (Nair et al., 2008), e.g., phycoerythrin and phycocyanin (phycobilins) for cyanobacteria. Determining Chl-a in the laboratory or on ships can be via fluorescence or absorption, but the increasingly preferred method that also provides a full range of pigments is high-performance liquid chromatography.

Before the methods for determining the biogeochemical constituents are applied, an atmospheric correction (AC) must be performed as only 5–10 % of the total signal originates from the water. For the basic AC, the total reflectance at the top of the atmosphere can be written as

$$\rho_t(\lambda) = \rho_r(\lambda) + \rho_a(\lambda) + \rho_g(\lambda) + t \cdot \rho_w(\lambda) \quad (1)$$

where $\rho_r(\lambda)$ is the Rayleigh scattering reflectance, $\rho_a(\lambda)$ is the aerosol scattering reflectance, and $\rho_g(\lambda)$ is glitter from the water surface; see Figure 1 for the relative contributions of the various components in Equation 1. The diffuse atmospheric transmission, t , can be approximated as (Gordon et al., 1983)

$$t = \exp[-(0.5\tau_r + \tau_{oz})/\cos\theta_v] \quad (2)$$

where τ_r is the Rayleigh optical thickness, τ_{oz} is the ozone optical thickness, and $\cos\theta_v$ is an approximation of the path length (cosine of the satellite zenith angle).

In Case I waters (colored by biogenic materials alone, i.e., phytoplankton, its pigments, dissolved organic exudates, and detritus), the term $t \cdot \rho_w(\lambda_{NIR})$ approximates zero and so with the term $\rho_r(\lambda_{NIR})$ being calculated directly (a function of the path length and atmospheric pressure) then can be determined given two NIR wavebands: extrapolation of $\rho_a(\lambda)$ using either the Angstrom exponent, n , or a variable c given in Gordon and Wang (1994). From this point onward, only the Angstrom exponent will be considered.

The NIR aerosol reflectance ratio is

$$\varepsilon_a(\lambda_{NIR(1)}, \lambda_{NIR(2)}) = \rho_a \frac{(\lambda_{NIR(1)})}{\rho_a(\lambda_{NIR(2)})} \quad (3)$$

which is used to calculate Angstrom exponent:

$$n = \ln \frac{[\varepsilon_a(\lambda_{NIR(1)}, \lambda_{NIR(2)})]}{\ln \left[\frac{\lambda_{NIR(1)}}{\lambda_{NIR(2)}} \right]} \quad (4)$$

Then, $\rho_w(\lambda)$ is calculated as

$$\rho_w(\lambda) = \frac{\left[\rho_t(\lambda) - \rho_r(\lambda) - \rho_{as}(\lambda_{NIR(2)}) \cdot \left(\frac{\lambda}{\lambda_{NIR(2)}} \right)^n \right]}{t} \quad (5)$$

However, in Case II waters (major influence is TSM and/or CDOM), $\rho_w(\lambda_{NIR})$ is no longer zero and the observed $\varepsilon_a(\lambda_{NIR(1)}, \lambda_{NIR(2)})$ becomes

Ocean Measurements and Applications, Ocean Color,

Figure 1 Simplified diagram of the relative contributions to the signal received by a satellite-based sensor looking at a water surface as given in Equation 1.

$$\varepsilon_a(\lambda_{NIR(1)}, \lambda_{NIR(2)}) = \frac{[\rho_{as}(\lambda_{NIR(1)}) + t \cdot \rho_w(\lambda_{NIR(1)})]}{[\rho_{as}(\lambda_{NIR(2)}) + t \cdot \rho_w(\lambda_{NIR(2)})]} \quad (6)$$

In order to solve this problem, it is necessary to develop a coupled hydrological and atmospheric optical model in the NIR (700–900 nm) that provides estimates of $\rho_a(\lambda)$, often termed the bright pixel atmospheric correction as the waters are bright in the NIR. SeaWiFS initially used an iterative method (Siegel et al., 2000) to correct for non-negligible water reflectance arising from moderate to high phytoplankton abundances (chlorophyll concentrations greater than $\sim 2 \text{ mg m}^{-3}$) and so independent research was applied to correct for the effects of TSM (e.g., Ruddick et al., 2000 and Lavender et al., 2005), but the processing software was then updated so that it included non-phytoplankton scattering (Arnone et al., 1998), applied to both MODIS and SeaWiFS (Stumpf et al., 2002). For MERIS, the algorithm of Antoine and Morel (1999) was implemented as the AC with the additional bright pixel correction of Moore et al. (1999) implemented from launch. In addition, research has also been done using the longer shortwave infrared (SWIR) wavelengths, where these are available, as the water signal can still be assumed to be negligible (Wang and Shi, 2005).

Once the AC has been performed, the above-water reflectance, $\rho_w(\lambda)$, can then be used to derive the biogeochemical constituents using a hydrological optics model (Gordon et al., 1975; Morel and Prieur, 1977):

$$\rho_w(\lambda) = f \left[\frac{b_b(\lambda)}{a(\lambda) + b_b(\lambda)} \right] \quad (7)$$

where f is an interface term defined according to Morel and Gentili (1993) that approximately equals 0.33, b_b is

Ocean Measurements and Applications, Ocean Color, Figure 2 Normalized specific absorption for water and the different biogeochemical constituents (Chl-a and CDOM/TSM).

the total backscattering, and a is the total absorption. In turn, the total backscattering and absorption are the sum of the biogeochemical constituent components:

$$a = a_w + SPM \cdot a_{SPM} + a_{CDOM} + a_{ChI-a} \quad (8)$$

$$b_b = 0.5b_w + SPM \cdot b_{bSPM} + b_{bCDOM} + b_{bChI-a} \quad (9)$$

The factor of 0.5 in the water scattering term of Equation 9 converts the scattering values to backscattering values and can be applied because of the symmetry of the volume scattering function (Morel, 1974). The chlorophyll absorption and backscattering terms do not have concentration terms in Equations 8 and 9 because they have nonlinear relationships with concentration. Equation 9 also describes a monodisperse (no multiple scattering) system with particles of a given refractive index scattering light, i.e., the scattered light can be assumed to have the same wavelength as the incident light and the particles are independent (i.e., the intensities of the light scattered by each particle can be summed so that the total scattering is proportional to the number of particles). Figure 2 shows the spectral shapes of the normalized specific absorption for water and the different biogeochemical constituents (Chl-a and TSM/CDOM).

For SeaWiFS, instead of reflectance, the normalized water-leaving radiance has been used (i.e., the water-leaving radiance that would be measured by a sensor placed above the water surface if the sun were at the zenith and the atmosphere were absent). The full equation is given in Gordon et al. (1988) and it can easily be converted to a reflectance by dividing it by the solar irradiance.

One method of determining the concentrations of the optically active biogeochemical constituents is to rearrange Equation 7 so that the input is the spectral reflectance and the output is the total Inherent Optical Properties (IOPs), which can subsequently be split into the individual concentrations using Equations 8 and 9. Solving the equations can be performed in a number of ways with various assumptions being made, and so there are a number of IOP models with examples including the Carder model (Carder et al., 2003), the epsilon model (Pinkerton et al., 2006; Smyth et al., 2006), the GSM01 model (Garver and Siegel, 1997 and Maritorena et al., 2002), and the quasi-analytic algorithm (QAA) model (Lee et al., 2002). However, this diversity has caused problems in picking the “best” model. Therefore, algorithms have tended to use the empirical rather semi-analytical approach. There is also the analytical approach, but this is difficult to take forward because of the further work needed in measuring the specific and bulk IOPs, specifically the backscattering coefficient, as discussed in Morel and Maritorena (2001).

To recap, in Case 1 waters the reflectance primarily depends on the Chl-a concentration. This is not linear because of an interdependence that will not be described further here, but the concentration range varies from very low values ($\sim 0.02 \text{ mg/m}^3$) in the oligotrophic areas (such as the open ocean gyres where the chlorophyll maximum is at depths of 150–200 m) up to high values (typically $5\text{--}20 \text{ mg/m}^3$) in upwelling areas and bloom events in coastal areas and the mid to high latitudes. For SeaWiFS and MODIS, the empirical approach is employed with the standard Chl-a product for SeaWiFS, for example, the OC4v4 chlorophyll algorithm

(O'Reilly et al., 1998, 2000), as chosen during the SeaWiFS Bio-optical Algorithm Mini-workshop (SeaBAM) and shown in Equations 10 and 11. For MERIS, the semi-analytical approach is used with a maximum band-ratio algorithm in Case I waters (MERIS, 2007) and an Inverse Radiative Transfer Model-Neural Network (IRTM-NN) in Case II waters (Schiller and Doerffer, 1999 and Doerffer and Schiller, 2000). A detailed overview of these different approaches is given in IOCCG (2006).

$$\text{Chl-a} = 100^{0.366 - 3.067x + 1.930x^2 + 0.649x^3 + 1.532x^4} \quad (10)$$

$$x = \log_{10} \left(\frac{R_{rs443} > R_{rs490} > R_{rs510}}{R_{rs555}} \right) \quad (11)$$

Increasingly important in remote sensing is merging of the data from different sensors to produce multisensor products. Individual sensors typically have a predicted (planned for) lifetime of 5 years, but in reality they can have lifetimes that are much shorter (e.g., the Ocean Color Temperature Sensor (OCTS) onboard the ADEOS platform lasted for only 11 months due to a technical fault) and longer (SeaWiFS and MERIS collected data for over a decade as previously mentioned). Several merged ocean color datasets have become available in recent years:

- NASA OBPB merged Chl-a dataset based on MODIS-Aqua and SeaWiFS
- NASA REASoN merged Chl-a, CDM, and particulate backscattering (b_{bp}) datasets based on MODIS-Aqua and SeaWiFS (e.g., Maritorena and Siegel, 2005)
- ESA DUE GlobColour multiparameter (19 in total) dataset based on MERIS, MODIS-Aqua, and SeaWiFS (Pinnock et al., 2008)

The merging not only provides a potentially longer time series, but also increases the temporal coverage and error characterization of the final dataset. For SeaWiFS, MODIS-Aqua, and MERIS, the average daily cover is between ~8 % (MERIS) and ~16 % (SeaWiFS); see IOCCG (2008). When pairs of sensors are combined, the daily coverage reaches the ~20–25 % range, while the combination of the three sensors allows about 30 % of the ocean to be covered daily (IOCCG, 1999). Similar improvements in coverage occur for 4 day composites with a maximum of about 60 % ocean coverage with three sensors (Gregg et al., 1998). The main causes for loss of coverage are clouds and sunglint.

Applications

This section highlights some example applications from open ocean to coastal waters and also the linkage with satellite/model sources of nonoptical data. A more complete review of the applications of satellite ocean color data is given within IOCCG report 7 titled “Why Ocean Colour?” (IOCCG, 2008).

SST has previously been mentioned and it is often used together with ocean color data for biological applications;

for an overview of SST, see “*Sea Surface Temperature*.” Increased Chl-a levels and variations in SST are frequently found along frontal zones, within upwelling regions and physical features, e.g., eddies, where zooplankton and fish populations are known to accumulate for early life development spawning and feeding. Figure 3 shows an example MODIS image from December 26, 2006, for an area north of South Georgia where the Antarctic Circumpolar Current, the Subantarctic Front, and the Polar Front produce eddies that can be seen in both the pseudo true-color and SST imagery. A paper analyzing SeaWiFS imagery in this area is Korb et al. (2004) with fisheries discussed further in “*Fisheries*.”

In addition, PP can be derived from the combination of ocean color and SST and has previously been linked to fish yields and coastal upwelling regions (e.g., Carr, 2001; Simpson, 1994, and Platt and Sathyendranath, 2008). The simplest PP models are depth integrated and based upon Chl-a or the product of depth-integrated Chl-a and daily integrated surface Photosynthetically Available Radiation, PAR (Behrenfeld and Falkowski, 1997). The more complex versions bring in SST and an understanding of plankton physiology that characterizes light absorption (Platt, 1986). Campbell et al. (2002) compared a selection of satellite PP algorithms developed by several teams and concluded that the level of agreement between the algorithms had no apparent relationship to the mathematical structure or complexity of the algorithms. A further comparison in 2006 (Carr et al., 2006) that also included biogeochemical ocean general circulation models (BOGCMs) concluded that the groups did not follow model complexity with regard to wavelength or depth dependence, though they were related to the manner in which temperature was used to parameterize photosynthesis. Carr et al. (2006) summarized that further progress in modeling PP required an improved understanding of the effect of temperature on photosynthesis and better parameterization of the maximum photosynthetic rate. Friedrichs et al. (2009) compared satellite-based depth-integrated PP algorithms and BOGCMs to a tropical Pacific PP in situ database, concluding that interdecadal and global changes will be a significant challenge for both EO PP algorithms and BOGCMs.

As previously mentioned, MODIS and MERIS also have a relatively narrow waveband at around 682.5 nm to detect the solar-stimulated chlorophyll fluorescence peak (Rast et al., 1999 and Gower and Borstad, 2004), which is closely linked to cell physiology and can vary with nutrient status, species composition, and growth rate. Behrenfeld et al. (2009) suggest satellite fluorescence is a valuable tool for evaluating nutrient stress predictions in ocean ecosystem models and provide the first synoptic observational evidence that iron plays an important role in seasonal phytoplankton dynamics of the Indian Ocean. In addition, research has extended this fluorescence waveband to applications such as floating sargassum seaweed (Gower et al., 2006). PAR can be derived from ocean color data (Frouin et al., 1989 and Frouin et al.,

Ocean Measurements and Applications, Ocean Color, Figure 3 MODIS-Aqua Level-2 image from December 26, 2006, showing the area north of South Georgia as (a) pseudo true-color composite with 667 nm as red, 531 nm as green, and 443 nm as blue and (b) SST with a rainbow color palette applied. Black indicates the presence of clouds.

2005) and is a useful parameter because it can act as a limiting factor for bloom initiation/growth, e.g., Raitso et al. (2006) described coccolithophore bloom size variation in response to the regional environment of the subarctic North Atlantic and showed that the combined effect of high solar radiation (PAR), shallow mixed layer depth (derived from a 3D physical model), and increased temperatures (SST) was highly correlated with abundance.

Harmful algae blooms have commonly been called red or brown tides as it has been assumed the red or brown coloration is given to the water by high concentrations of phytoplankton such as dinoflagellates. However, Dierrsen et al. (2006) showed that the color shift, from green to red, comes from an overlap in spectral response of the human eye's red and green cones (centered at 564 and 534 nm, respectively) rather than absorption by the phytoplankton. As shellfish filter large quantities of water, they concentrate the phytoplankton in their tissues, which can affect the aquaculture industries directly by mass fish mortalities and indirectly by shellfish accumulating toxins that can, under certain circumstances, render the shellfish unsafe for human consumption. The monitoring of a bloom (once it has been detected) is important, but it would also be desirable to forecast its occurrence from spectral quality, thermal signature, and hydrography (Tester and Stumpf, 1998). The spectral information can be used to identify different groupings of phytoplankton if they are in abundance and have characteristic absorption/scattering properties, and hence provide an assessment of the potential risks; functional type information is an active area of research (e.g., Sathyendranath et al., 2004; Alvain et al., 2005, 2008; Nair et al., 2008; Raitso et al., 2008). An understanding of biological variability may also be enhanced with additional satellite data

sources such as wind stress (e.g., Pradhan et al., 2006, derived from the second European Remote-Sensing Satellite, ERS-2, and NASA QuikSCAT mean wind fields) and radar altimetry Sea Surface Height (SSH) that links to biophysical coupling (e.g., Wilson and Adamec, 2002).

Water quality is of paramount importance to managers in coastal waters, especially in Europe with the implementation of the EU Water Framework Directive (WFD) that came into force in 2000. Traditional water quality monitoring depends on in situ measurements and the subsequent laboratory analysis of the samples with satellite remote sensing, allowing for the integration and extrapolation of these measurements. The optical remote sensing techniques and products detailed here apply, but these waters cause particular remote sensing challenges as they are a complex mixture of optically active constituents, exhibit significant heterogeneous patterns, and may only be a few pixels in an ocean color satellite image with a significant number of "edge" pixels contaminated by the brighter land signal. Therefore, this community has also relied on land-orientated satellites and airborne remote sensing, e.g., Doxaran et al. (2002). Figure 4 shows a MERIS full-resolution (300 m) Level-2 image from February 11, 2008, showing the southern UK, English Channel, and northern France. Both the pseudo true-color composite and TSM image (processed using the MERIS Case II Regional Neural Network) show the TSM variations with a particular feature around the Channel Islands.

Since the 1980s, inland water monitoring has tended to use the statistical correlation between broad-waveband reflectances and optically active constituents (Chl-a and other pigment concentrations such as Phycocyanin within

Ocean Measurements and Applications, Ocean Color, Figure 4 MERIS full-resolution Level-2 image from February 11, 2008, showing the southern UK, English Channel, and northern France as (a) pseudo true-color composite with 665 nm as red, 510 nm as green, and 443 nm as blue and (b) TSM with a rainbow color palette applied.

cyanobacterial blooms, Secchi disk depth, and TSM) of the water column (e.g., Kloiber et al., 2002; Vincent et al., 2004). Many studies have also used satellite imagery to map the surface temperature of freshwater inland lakes (e.g., Li et al., 2001; Oesch et al., 2005), and important future variables will also include water levels derived from radar altimetry (e.g., Frappart et al., 2006; Berry et al., 2011).

In nearshore coastal waters, the water depth may be sufficiently shallow that the light penetrates to and returns from the bottom allowing users to map bathymetry, habitats, and vegetation. Mumby et al. (2001) demonstrated the use of fine (1 m) spatial resolution airborne multispectral imagery. Lubin et al. (2001) explored the suitability of existing sensors such as Landsat, while Mumby and Edwards (2003) examined the cost and accuracy of IKONOS as compared directly to a suite of satellite and airborne instruments including CASI and Landsat and SPOT sensors.

Future global or geostationary hyperspectral satellite sensors (with increased spectral resolution) would aid our ability to remotely sense rapidly changing nearshore coastal environments and undersampled inland waters. ESA's Compact High Resolution Imaging Spectrometer (CHRIS), launched in October 2001 onboard the Project for On-Board Autonomy small satellite (Cutter et al., 2003; Barnsley et al., 2004), was not designed as an ocean color mission. However, its multiangle (fly-by zenith angles of 0 , ± 36 , and $\pm 55^\circ$) and hyperspectral (although the users have defined modes with a selection of 18–62 wavebands and 17–34 m spatial resolution) capabilities have spawned

inland and coastal applications (Lavender et al., 2005; Sterckx et al., 2005; Van Mol and Ruddick, 2005). In addition, Neukermans et al. (2009) undertook a feasibility study with SEVIRI where the determination of TSM was assessed. In 2010 the South Korean launched the first ocean color sensor into a geostationary orbit.

Summary

This entry started by reviewing the history of ocean color and then moved on to the theory and processing with a final section on the applications. The opportunities provided by ocean color satellite missions during the past decade have resulted in major advances in our ability to derive in-water biogeochemical properties linked to key processes within ocean ecosystems. The focus has primarily been on science in service of societal needs. However, ocean color has matured to the level where operational communities are looking to use the data directly, but there still needs to be a link to research that will improve our understanding of oceanic processes and undertake climatic research, e.g., the production of Essential Climate Variables (ECVs). As an example response to the need for ECV datasets, ESA set up the Climate Change Initiative programme that includes the Ocean Colour CCI project.

Assimilating biogeochemical properties, and in future IOPs, into ocean models is the focus of both research and operational activities, e.g., predicting CO_2 fluxes (Hemmings et al., 2008) and the wider remit GMES marine core service project called MyOcean/MyOcean2;

further details are available within “[Ocean Modeling and Data Assimilation](#).” Commercial operators are also realizing the value of ocean color-derived information, and its utilization among private sector customers is expected to increase significantly over the coming years due to a greater demand for marine environment information and high sensitivity to the cost-effectiveness of the different data-gathering approaches (IOCCG, 2008).

Definition

Ocean modeling. Finding solutions to the equations of motion describing the movement of the ocean fluid and its properties as a function of time and geographic location.

Data assimilation. Constraining ocean model solutions by observations to obtain a more realistic description of the ocean.

Ocean modeling

Introduction

Ocean modeling, like atmospheric modeling and numerical weather forecast, is a mature field of computational fluid dynamics. It is concerned with a dynamical description of the general ocean circulation, aiming at (1) simulations of the time-varying ocean circulation or aspects of it, (2) providing a dynamical description of the time-varying ocean circulation, (3) simulating its transport properties, and (4) quantifying the relation between the movement of water, forces acting at the ocean's boundaries, and dissipation and mixing processes retarding the flow. As tools, ocean modeling uses *numerical circulation models* to solve the dynamical *equations of motion* that govern the motion of the ocean's flow in response to forces acting on it. An overview to ocean modeling is provided by, e.g., Haidvogel and Beckmann (1999).

The ocean is a forced-dissipative fluid, with forcing essentially provided at the boundaries and dissipation taking place everywhere at the molecular scale. The volume of seawater is bounded by complex land-sea boundaries and motions of seawater are constrained by rotation of the planet and stratification of the water column. In response to forces acting especially at the sea surface of

the ocean, flow in the ocean interior exhibits a rich mix of dynamical phenomena, including boundary currents, large-scale gyres and jets, boundary layers, linear and nonlinear waves, and quasi-geostrophic and three-dimensional turbulence. Those phenomena are summarized in Figure 1 along with their spatial and temporal scales.

Clearly, motions of the ocean cover temporal scales ranging from less than an hour (e.g., surface waves) to hundreds of years (deep circulation and mixing processes) and spatial scales ranging from a few millimeters (turbulence and diffusion) to the circumference of the Earth (global circulation). An overview of processes acting as part of the ocean flow field is provided by Steward (2005) and dynamics are described, e.g., by Vallis (2006).

Models are being used experimentally to investigate hypotheses for ocean phenomena, to simulate and nowcast the observed flow, to consider future scenarios such as those associated with human-induced climate warming, and to forecast ocean conditions on weekly to decadal timescales using dynamical modeling systems. In the context of remote sensing, numerical models of the ocean became an important tool for interpreting and correcting *satellite observations of the ocean* (see below).

Ocean Modeling and Data Assimilation, Figure 1 Dynamical phenomena occurring in the ocean and their space and timescales plotted against their respective space and timescales (D. Chelton, pers. communication.).

Equations of motion

The equations of motion, governing the circulation of the ocean and the atmosphere alike, are based on Newtonian mechanics and irreversible thermodynamics applied to a continuum fluid. The conservation of momentum builds the backbone for the dynamical description of the flow providing information of the three-dimensional flow field. Together with additional conservation equations of heat and material constituents, such as potential temperature or salt, they comprise a system of scalar equations, called the Navier–Stokes equations. These equations exist in various levels of approximation. In compressible form and z -level representation, the equations can be expressed as:

$$\begin{aligned} \frac{D\mathbf{v}_h}{Dt} + f\mathbf{k} \times \mathbf{v}_h + \frac{1}{\rho} \nabla_z p &= \mathbf{F} \\ \frac{Dw}{Dt} + \frac{gp}{\rho_0} + \frac{1}{\rho_0} \frac{\partial p}{\partial z} &= F_w \\ \frac{1}{\rho_0 c_s^2} \frac{Dp}{Dt} + \nabla_z w + \frac{\partial w}{\partial z} &= 0 \\ \rho &= \rho(\theta, S, p) \\ \frac{D\theta}{Dt} &= Q_\theta \\ \frac{DS}{Dt} &= Q_s \end{aligned}$$

Here $D/Dt = \partial/\partial t + \mathbf{u} \cdot \nabla$ is the total derivative, $\nabla = \partial/\partial x + \partial/\partial y + \partial/\partial z$ is the nabla operator, and $\nabla_z = \partial/\partial z$ is the vertical component of the nabla operator. $\mathbf{v}_h = (\mathbf{u}, \mathbf{v})$ is the two-dimensional horizontal flow field; w is the vertical component of the flow field; ρ is the density of sea water with ρ_0 being a reference (mean) density; p is the hydrostatic pressure; $\mathbf{F}$ represents forcing and dissipation acting on momentum; Q_θ and Q_s are sources of potential temperature and salt; and c_s is the speed of sound.

Usually the equations of motion as stated above or in other forms of approximation are too difficult to solve analytically, largely due to the nonlinear and turbulent nature of the ocean's flow, involving processes from the mm scale (e.g., dissipation of energy) up to basin and global scale spanning thousands of km, and the very long time-scales (decades to centuries). Over those scales, water mass properties, e.g., potential temperature, salinity, oxygen, CO_2 , or nutrients, are preserved in the ocean interior and ocean models need to show similar conservation properties. All those difficulties together require the use of computers to solve the equations numerically and to use numerical models to explore the immense phase space of solutions.

A detailed account for approximations of the Navier–Stokes equations and the effect of the approximations on the dynamical description of the ocean is provided by Müller (2006) and Olbers et al. (2012). As an example, there are two approximations that independently

filter out acoustic modes. The *non-divergence approximation* (associated with *Boussinesq fluids*) removes three-dimensional acoustic waves, and the hydrostatic balance removes vertical acoustic waves.

Numerical implementation

Numerical solutions of the equations of motion (or any other differential equation) are obtained by approximating differential operators in space and time through difference operators involving finite length or finite volume elements of the model domain:

$$\begin{aligned} \frac{dx}{dt} &\approx \frac{\Delta x}{\Delta t} = \frac{x_i - x_{i-1}}{t_i - t_{i-1}}; \\ \frac{d^2x}{dt^2} &\approx \frac{\Delta(\Delta x)}{(\Delta t)^2} = \frac{x_{i+1} - 2x_i + x_{i-1}}{(t_i - t_{i-1})^2} \end{aligned}$$

Here t_i can be a time index or a space index. Written in this way, the model domain is split into many elements, each of which represents a small fluid parcels (Figure 2). Each variable then represents a mean value of the finite element of the model domain, typically reaching between 10 and 100 km horizontally.

Rewriting the equations of motion in a finite difference form allows for computing the model variables (also called state variables) for each time step from those available during the last time step accounting for forcing terms. Applied many times, this process leads to an initial value problem and boundary value problem for the state vector, $\mathbf{x}(t)$:

$$\mathbf{x}(t + 1, i, j, k) = \mathbf{A}(t)\mathbf{x}(t, i, j, k) + \mathbf{F}(t)$$

The state vector, $\mathbf{x}$, which exists on the typically regular model grid, includes values of temperature, salinity, pressure, and velocity. Here $\mathbf{A}$ is the step operator stepping the model forward from one time step to the next, and in this form one needs to be provided initial conditions from which the equation is being integrated forward, surface forcing terms ($\mathbf{F}(t) = \mathbf{G}(t)\mathbf{u}(t)$, including wind stress, heat, and freshwater fluxes as well as river runoff) and subgrid-scale parameterization. Also, information about the bottom topography (shape of the sea floor) and coastlines needs to be provided. From the state vector, $\mathbf{x}$, one can compute any derived quantity (e.g., enstrophy, potential vorticity, or enthalpy flux) of interest.

There are various ways to arrange the full suite of model variables horizontally, usually referred to as Arakawa staggered grids (Haidvogel and Beckmann, 1999). An example of such a grid is given in Figure 3, representing a so-called Arakawa C-grid. On this grid, the velocity variables and temperature and salinity are shifted relative to each other in space. As an example, the MITgcm is specified on an Arakawa-C grid (e.g., Marshall et al., 1997). Discretization is also applied in the vertical, dividing the ocean in layers, e.g., of constant depth or constant density.

Ocean Modeling and Data Assimilation, Figure 2 Horizontal model grid (<http://acmg.seas.harvard.edu/curresh.html>).

Ocean Modeling and Data Assimilation, Figure 3 Example of a horizontal model grid, illustrating an Arakawa-C grid.

Ocean models are typically characterized in terms of geography, physics, surface approximations, vertical discretization, and density variation. Treating the ocean in finite elements also requires a description of processes

that are happening on subgrid scales in terms of resolved fields (*turbulence closure*). Griffies and Adcroft (2008) discuss numerous questions that arise when discretizing the ocean equations, such as how to conserve properties tracer conservation and consistency with mass conservation. Ocean codes that fail to respect these properties are severely handicapped for use in studies of ocean dynamics or climate.

Applications

The present status of ocean modeling and anticipated improvements is addressed by Griffies et al. (2001, 2010). Applications of ocean models for studies of fluid dynamics in general include direct numerical simulations (DNS) where attempts are being made to resolve all processes, large-scale eddy simulations (“LES”) where subgrid-scale processes are being presented by the properties of the large-scale flow, and long, coarse-resolution climate simulations. The first class of simulations is much akin to what is being performed in computational fluid dynamics (CFD), where an attempt is made to directly solve all relevant phenomena without involving subgrid-scale parameterizations. Ocean climate modeling represents the other end of the spectrum and is an application of a very different nature to those found in other areas of CFD. Here the timescales of interest are decades to millennia, yet simulations require resolution or parameterization of phenomena whose timescales are minutes to hours. Furthermore, the most energetic spatial scales are of order 10–100 km (mesoscale eddies), yet the problem is fundamentally global in nature. Ocean modeling can also be subdivided into classes of applications:

1. Process-oriented modeling
2. Operational now- and forecasting
3. Climate-oriented sensitivity experiments of predictions

An example of state-of-the-art eddy-resolving but climate-oriented ocean modeling is given in Figure 4, showing the simulation of the near-surface flow field of the ocean. The field is taken from the German consortium effort STORM (www.dkrz.de/STORM; see von Storch et al., 2012 for details) and was run at the German Climate Computer Center (DKRZ). The goal of the project is to run a coupled climate model in eddy-resolving mode parallel to traditional lower-resolution versions of the same model used as part of the IPCC AR5 process and thereby to investigate the impact of “weather” in the atmosphere and ocean and the projection of climate variability and climate change. Shown in the figure is an instantaneous field of the speed of the ocean in about 75 m depth. The figure clearly reveals the chaotic, turbulent nature of the flow field. Ocean modeling aims to improve our understanding of the underlying physical processes, the interaction of the turbulent flow field with biological and geochemical processes in the ocean, including primary production and CO₂ uptake.

Ocean Modeling and Data Assimilation, Figure 4 Near-surface flow and temperature fields as the results from the German STORM effort in 75 m depths. Shown are the temperature in °C (color) and the speed (shading) at one instant. Both fields can be observed at the surface by satellites using radiometry and altimetry (see von Storch et al., 2012 for details).

Importance of satellite data for ocean modeling

In terms of numerical simulations of the ocean, satellite observations play a major role in testing and improving ocean models. This is being done through a comparison of models and observations (e.g., eddy variability) because satellite data provide a unique database of the time-varying features at the sea surface which is nearly impossible to observe with conventional technology. Satellite data also build a very important basis for improving models through data assimilation. At the same time ocean models (with and without data assimilation) are needed to interpret satellite data. A typical application in this respect is that of observing surface temperature using remote sensing. Because infrared radiometers on satellites measure the emission from only the top few tenths of a mm of the water column, which is typically affected by air-sea interaction, we need ocean models to extend the measurements into the water beneath. This includes the correction of the ocean thermal skin effect and the daily cycle in temperature; these also have to be taken into account before observations taken at different times of the day can be merged into a single field.

Data assimilation

Introduction

Data assimilation is a subfield of ocean modeling. Its goal is to increase the realism of model simulations by merging them with ocean data and by doing so to improve the

model state, model parameters, or both. This is akin to practices in atmospheric weather prediction. However, there are several important differences. In particular, weather prediction is targeted at best possible forecasts. In contrast, many applications of assimilation in the ocean are mostly targeted at describing the history of ocean variability and the present state of the ocean (so-called nowcasts): Ocean state estimation (data assimilation) has as its goal to obtain the best possible description of the changing ocean by combining, in some suitably optimum way, all the diverse ocean observations with theoretical knowledge of the ocean circulation as embodied in numerical ocean circulation models. If carried out properly, the result is a dynamically self-consistent estimate of the time-evolving ocean circulation, one, which has greater information and forecast skill than does either model or data alone. Aspirations of forecasting are to provide seasonal to interannual predictions. However, they are gaining increased attention now in the context of ocean and climate services, including decadal climate forecasts.

Assimilation approaches

Regardless for which purpose and with which detailed approaches pursued, state estimation or “data assimilation” in general is just least-squares fitting of models to data, taking into account the model equations as constraints. Regardless of the details, all approaches attempt to minimize a model-data misfit. In doing so, assimilation methods deal, in principle, with the state vector $\mathbf{x}(t)$,

representing again a time-dependent simulation of the state of the ocean. All oceanic measurements can be associated with its model equivalent through a functional relationship that can be written as:

$$\mathbf{E}(t)\mathbf{x}(t) + \mathbf{n}(t) = \mathbf{y}(t),$$

where $\mathbf{E}$ is a matrix, $\mathbf{n}(t)$ is the measurement error including data noise, and $\mathbf{y}(t)$ is the vector of observations. An estimated time-dependent solution, $\mathbf{x}(t)$, is sought that minimizes the model-data misfits, which then can be written as:

$$J = \sum_t (\mathbf{y}(t) - \mathbf{E}(t)\mathbf{x}(t))^T \mathbf{R}(t) (\mathbf{y}(t) - \mathbf{E}(t)\mathbf{x}(t)) + \mathbf{x}_0^T \mathbf{Q} \mathbf{x}_0 + \mathbf{u}^T \mathbf{P} \mathbf{u}$$

subject to the model dynamics as embedded in the numerical model code. $\mathbf{R}(t)$, $\mathbf{Q}$, and $\mathbf{P}$ are the error covariances representing observations, the model, and the model parameters. The choice of those three covariances determines the solution as they select one solution from the multitude of all possible solutions.

As described in detail by Wunsch (2006), there are many methods for solving *constrained least-squares problems*, either exactly, by iteration, or sequentially. In terms of nomenclature, they include Nudging, 4DVAR, 3DVAR, adjoint, objective interpolation (OI), Kalman filter (KF), RTS smoother, ensemble KF, Pontryagin principle, relaxation, line-searches, breeding vectors, SVD, and many more. All these apparently different methods are nonetheless just variant algorithms used to find the minimum of an objective (or cost) function measuring the deviation of the model's state from observations. They essentially differ in the extent to which an approximation to that minimum is acceptable, whether one intends to find a dynamically self-consistent solution and whether or not one seriously seeks an estimate of the error in the result.

Much of the assimilation technology used today in oceanography was first developed for atmospheric application. However, for several decades, ocean applications evolved as well and now constitute a sustained activity in support of ocean services and climate research. Underlying assimilation schemes range from simple and computationally efficient (e.g., optimal interpolation) to sophisticated and computationally intensive (e.g., adjoint, Kalman filters, and smoothers). However, it is also worth mentioning that as compared to atmospheric systems, some ocean estimation approaches are dynamically self-consistent, guaranteeing the conservation of heat, freshwater, and momentum. This is an important requirement for climate applications of reanalysis results, and here the ocean applications are ahead of the atmospheric applications (see also Bengtsson et al., 2007).

Differences between filters and smoothers are schematically illustrated in Figure 5. Filters lead to a new model state, once observations become available, by merging the simulated state with the observations, thereby

neglecting all model conservation equations. In contrast, smoothers attempt to find uncertain model parameters by using observations from the past and the future, which then lead to an optimal simulation of the observations by the improved model. Simplified methods (e.g., nudging, robust diagnostic, and objective mapping), thus, intended to find approximations to the minimum of J by relaxing the model constraints. They are easy to set up and are computationally inexpensive. However, the temporal evolution of such ad hoc solutions is not necessarily dynamically consistent and usually implies internal sinks and sources of momentum, heat, and freshwater. Rigorous methods, such as provided by an adjoint approach, are computationally much more demanding. We note, however, that they are needed to obtain dynamically self-consistent ocean estimates useful for understanding the physics of the system by exploiting all the information contained in the data.

Important milestones in the development of ocean state estimation included the development of *inverse methods* (adjoint, Kalman filter, etc.) that can be applied to ocean circulation models using supercomputers. As an example, the development of ocean adjoint models encompassed the existence of modern primitive equation (PE) models, the development of automatic differentiation tools (Giering and Kaminsky, 1998), their pilot applications to ocean problems (Marotzke et al., 1999; Stammer et al., 2002a), and for that purpose, enhancements and adjustments of the computer infrastructure to finally encompass long optimization runs. In almost all cases, achieving accomplishments in the development of the infrastructure required nearly a decade of sustained consortium efforts (Stammer et al., 2002b). This development has proven to be a large endeavor that requires expertise in ocean observations, modeling, assimilation, as well as information technology, which needs to be sustained and to have a long-term perspective to be effective. If ocean state estimation were to be established as a firm part of an ocean or climate information system, a sustained effort will be needed for the synthesis part.

Applications of ocean assimilation

Present applications of data assimilation in the ocean can be subdivided roughly into three application areas: (1) operational ocean oceanography and nowcasting, (2) climate-oriented data synthesis, and (3) initialization of predictions in the ocean or of coupled climate models. Similar to the applications, approaches also differ, ranging from simple but computational cheap nudging techniques to computational demanding but mathematically rigorous methods. A summary of most of those efforts can be found in Lee et al. (2010) and Reinicker et al. (2010). The high frequency and high spatial coverage of satellite data now allow for global high resolution operational ocean products produced by efforts such as MERCATOR, MyOcean, NAOCEANO, etc.). See Bell et al. (2009) for details.

Ocean Modeling and Data Assimilation, Figure 5 Schematic of data assimilation (From I. Fukumori, JPL, Personal communication).

At the time of writing, several successful ocean syntheses exist which are being exploited in terms of ocean dynamics, their potential as initial conditions for climate models or simply to describe ocean variability over the last 50+ years. Ocean efforts are targeting long-duration descriptions of the ocean. Some of the existing assimilation products span the period of the past several decades and are relatively coarse in spatial resolution; others focus on the data rich period, roughly from 1992 to present and tend to be eddy permitting, and sometimes only regional in extent. Typical applications include the estimate of ocean transports, change in the oceans' heat and freshwater content, transports of heat and salt, the interaction of the ocean with the atmosphere in terms of heat and freshwater fluxes through the ocean surface, or the important aspect of sea level variability and change. In the context of the global energy balance, questions specific to the ocean include the following: What is the present rate of change of heat storage in the ocean over the last 10 years and the last 50 years and how is it distributed with depth and location? What are the key regions and their significance of ocean–atmosphere feedbacks? What is the meridional heat transport of the oceans and its variability on seasonal, interannual, and decadal timescales? What is the variability on global scales of the deep and shallow meridional overturning circulations and of the interoceanic exchange of heat? How does the global ocean heat storage relate to imbalance in the planetary radiation budget?

During recent years, several data-based estimates of changes of the ocean heat content and freshwater were published from which the emerging picture of the upper ocean's heat content changed substantially, partially due to correction of errors found in the underlying data sets (XBT and ARGO), and these improvements will continue in the future. In this context, dynamically consistent state estimation can make especially valuable contributions by providing estimates of climate-relevant indices or quantities and also by providing estimates of residuals in the data

not compatible with the dynamics and other components, such as surface forcing, thereby giving important information about potential data errors not yet accounted for (see also below).

A quantity of general concern is sea level and its variability, which represents an integral over many individual aspects of the ocean state. Questions related to [sea level rise](#) are among those most directly related to anthropogenic climate change and its impacts. Changes in sea level can have a potentially substantial impact on society and understanding of ongoing and past changes and their regional character is therefore of specific importance. [Figure 6](#) shows estimates of local sea-surface height (SSH) changes as they follow from observations and from the GECCO estimates (Köhl and Stammer, 2008). We realize that large-scale trends in the simulated SSH agree with observed trends over the last 15+ years of altimetric satellite observations. Over the large parts of the world's ocean, GECCO results suggest that SSH changes induced by heat content changes and changes in salinity counterbalance, to some extent, as this either would follow from advection of water masses along isopycnals (e.g., wind-driven changes in GECCO) or imposed by the use of T/S relations.

The focus of ocean data assimilation has now shifted more to aspects of forecasting the ocean and climate system in support of ocean services and climate services. Work has been continuing now for several years in the context of seasonal predictions of the climate system (Anderson, 2010; Balmaseda et al., 2010) and is now being extended towards seamless predictions in the ocean and of the coupled climate system. To perform predictions in the ocean, one needs proper initial conditions as well as surface forcing fields. While the latter have to come from an atmospheric or a coupled ocean–atmosphere forecast model, the initial conditions of the ocean have to be prescribed through suitable ocean measurements, including satellite observations of the ocean. Theoretically, initial conditions should represent accurately the state of the

Ocean Modeling and Data Assimilation, Figure 6 Trends in sea level as observed by the TOPEX/Poseidon altimeter mission (top) over the period 1993–2001 and as simulated by the GECCO 50 year ocean state estimation approach (Köhl and Stammer, 2008). Units are cm/year.

real world. However, given the fact that measurements have uncertainties, this would not necessarily be the best initial condition for optimizing the forecast skill. Among the practical ways of creating ocean initial conditions is to estimate the initial conditions of a coupled climate model. An application of ocean state estimation is that of ocean initialization for seasonal and decadal forecasting.

Importance of satellite data for ocean assimilation

The skill of data assimilation depends on the quality of underlying models, but also on the quantity and quality of available observations. While the amount of ocean data has been substantially increasing since the 1990s, satellite data are still, and will remain, the largest source of information obtained about the ocean quasi-globally and in quasi-real time. On the other hand, because the ocean is essentially opaque to electromagnetic radiation, satellite data by itself represent first of all the surface of the ocean (excepting the visible part of the electromagnetic

spectrum, where the penetration depth of light is up to about 50 m). In the context of remote sensing, ocean modeling and data assimilation therefore have the specific role of extrapolating information available at the ocean surface and connecting it to the three-dimensional ocean circulation. Thus, data assimilation is based on the understanding that a complete picture of the ocean for the purpose of climate research and applications will come only from a synergy between observations, modeling, and data assimilation.

As in atmospheric applications (e.g., weather forecasting), the quality of observed ocean data is a major concern for ocean state estimates, as are the changes in data coverage due to changes in observing systems, changes in quality of the data by improving instrumentation, or even new types of observations available since recently, e.g., time-varying gravity from US/German GRACE mission or salinity from the ESA SMOS satellite and the US-Argentine Aquarius/SAC-D mission. As an example, the lack of salinity data before the deployment of Argo floats severely hampers our ability to describe decadal variability of the ocean circulation because of the salinity influence on density and thus on the ocean circulation. Over recent decades, satellite data (e.g., altimeters and scatterometers) have proven to be of utmost importance in producing a global view of the ocean and especially in providing information about small space- and time-scales hardly available from other observing components. Much of the future progress hinges on continuity of these satellite missions and the ability to produce climate data records.

Summary

Ocean modeling and assimilation have both become a mature field within oceanography. *Ocean modeling* is concerned with finding solutions to the equations of motion describing the movement of the ocean fluid and its properties as a function of time and geographic location. Applications range from process studies of the ocean on almost all space and timescales, but include also simulations required to improve the analyses of satellite data. In contrast, *data assimilation* is concerned with constraining ocean model solutions by observations to obtain a more realistic description of the time-varying ocean circulation and its interaction with the atmosphere or sea ice. In both cases, satellite data play a major role, for improving models through model-data comparison studies, through merging the data with models through the approach of data assimilation or through the use of observations as initial conditions. The future will see many more applications of all of those aspects. It can be envisioned that model resolution will be increased further, making results more realistic and applicable, especially near frontal structures in the ocean or ocean boundaries. Satellite data will continue to play a key role in the process of data assimilation and increased focus will be put on biological and biogeochemical applications, especially in coastal regions.

Outlook: It can be envisioned that a combination of simulated (through numerical models) radiances with observed radiances will become a basic tool for merging and calibrating data from different satellite missions and to provide products of physical fields. While already substantially used in atmospheric applications, this approach is still in its infancy in satellite oceanography.

OCEAN SURFACE TOPOGRAPHY

Lee-Lueng Fu

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA, USA

Definition

The deviation of the height of the ocean surface from the geoid is known as the ocean surface topography. The geoid is a surface on which the Earth's gravity field is uniform. The ocean surface topography is caused by ocean waves, tides, currents, and the loading of atmospheric pressure. The main application of ocean surface topography is for the determination of large-scale ocean circulation.

Introduction

The determination of global ocean circulation has been a challenging goal of physical oceanographers. The fluid

motion of the ocean has a wide range of spatial and temporal scales. We all have the experience of watching ocean surface and being awed by the ever-changing waves and their breaking into turbulence and white caps. In order to measure the velocity of an ocean current, we must average out these wave effects. At longer periods, there are ocean tides. If the timescales of our interests are longer than tides, we must also average out the effects of tides. Fortunately, there is a dynamic property of large-scale ocean currents called the geostrophic balance. This balance occurs when the Rossby number, defined as U/fL , is much smaller than unity. In the notation, U is the speed of the current, L is the spatial scale, and f is the Coriolis parameter defined as $f = 2\Omega \sin\phi$, where Ω is the Earth's rotation rate (7.292×10^{-5} rad/s) and ϕ is the latitude. For example, if $U = 50$ cm/s at 45° latitude, geostrophic balance occurs when $L \gg 5$ km. Then the geostrophic velocity of the current at ocean surface can be computed from the pressure at ocean surface as follows:

Ocean Surface Topography, Figure 1 Schematic illustration of the measurement system of satellite altimetry (From Chelton et al., 2001).

Ocean Surface Topography, Figure 2 OST derived from a combined analysis of satellite altimeter data, surface drifter data, and a geoid model (From Rio and Hernandez, 2004).

$$fv = \frac{1}{\rho} \frac{\partial p}{\partial x} \quad (1)$$

$$fu = -\frac{1}{\rho} \frac{\partial p}{\partial y} \quad (2)$$

where p is the pressure, ρ is the density of sea water, and u and v are the zonal and meridional velocity components, respectively. The large-scale ocean currents are also in hydrostatic balance, namely, $p = g \eta$, where η is the elevation of the ocean surface topography (denoted by OST hereafter), defined as the deviation of the ocean surface from the geoid, and g is the Earth's gravity acceleration. The geoid is defined as the ocean surface on which the Earth's gravity field is uniform. In the absence of any motions, the ocean surface would be conformed to the geoid.

The role of OST for ocean currents is thus equivalent to the role of atmospheric surface pressure for winds. The speed and direction of large-scale wind blowing at

the Earth's surface can be computed from the gradient of the atmospheric surface pressure; similarly, the speed and direction of large-scale ocean surface currents can be computed from the gradient of OST as shown by Equations 1 and 2. OST has been traditionally estimated from the density field of the ocean as follows:

$$\eta_s = -\frac{1}{\rho_0} \left(\int_{-h}^0 \frac{\partial \rho}{\partial T} T' dz + \int_{-h}^0 \frac{\partial \rho}{\partial S} S' dz \right) \quad (3)$$

where T' and S' are the temperature and salinity deviations from their mean values, and ρ and ρ_0 are the density and its depth average, respectively, and h is the depth of the ocean. This quantity, η_s , has been traditionally referred to as the steric sea level, which is an approximation of OST. In most places, the steric sea level is predominantly determined by temperature, and therefore is a good indicator of the heat content of the water column of the ocean. OST is also influenced by other factors such as

Ocean Surface Topography, Figure 3 A snapshot (May 30, 2007) of the temporal change of OST from its time-mean value. The unit is cm.

wind, atmospheric pressure, and tides. However, our knowledge of OST has primarily been obtained through shipboard measurement of ocean temperature and salinity using Equation 3 until the recent development of satellite altimetry (Fu and Cazenave, 2001).

Satellite altimetry

The concept of using a radar altimeter for measuring the height of sea surface was developed in the 1960s. The measurement of the round-trip travel time of a radar pulse from a satellite to the surface of the ocean allows the determination of the distance between the satellite and the ocean surface. If the location of the satellite in orbit is also known in an Earth-fixed coordinate, then the height of the sea surface is determined in this coordinate and so is the OST if the knowledge of the geoid is available as well. The first satellite altimeter was carried by Skylab launched in the early 1970s. The first satellite altimeter with sufficient precision for detecting OST was onboard Seasat, which was launched in 1978 returning only about 100 days of data. However, the first image of the ocean reflecting the variability of OST caused by ocean currents provided a revolutionary impact on the

oceanography community. Oceanographers began to realize the potential of observing the global ocean circulation from OST determined from space.

The challenges of determining OST from satellite altimetry were the measurement accuracies. For example, an error of 1 cm in OST is capable of producing an error in the mass transport by ocean current of the magnitude of several million tons per second, which is a significant fraction of the transport of major ocean currents. The technique of satellite altimetry is conceptually straightforward, but there are numerous sources for measurement errors as illustrated in Figure 1. Corrections for these errors constitute the enterprise of precision altimetry beginning with the TOPEX/Poseidon Mission. The reader is referred to Chelton et al. (2001) for a treatise of the details. Only the major components of the measurement system are briefly described in this entry.

First, the free electrons in the Earth's ionosphere slow down the radar signals and have a net effect of more than 20 cm in error if not corrected. To correct for this error, radar altimeter must transmit in two channels, for example, the Ku band (13.6 GHz) and the C band (5.3 GHz) as the TOPEX/Poseidon altimeter. The signal delays are different for the measurements made at the two channels, which are used

Ocean Surface Topography, Figure 4 The standard deviation of the temporal change of OST in unit of centimeters.

to determine the total electron content and the signal delay. Second, the water vapor in the Earth's troposphere also has the effect of delaying radar signals by more than 40 cm in the tropics. The approach of the TOPEX/Poseidon Mission was to carry a three-frequency microwave radiometer for making measurement of the water vapor content and the corresponding signal delay of the altimeter. Third, the precise location of the satellite in orbit must be determined. This requires onboard precision tracking systems and well-maintained geodetic ground systems. For example, the TOPEX/Poseidon Mission carries three independent orbit tracking systems: laser retroreflectors, GPS receivers, and a Doppler system called DORIS.

After Seasat, there were two satellite altimeters flown without the full suite of capabilities of error corrections: the US Geosat and the European Remote-Sensing Satellite (ERS). The first satellite altimeter mission that was dedicated to optimal measurement of OST was the joint American/French TOPEX/Poseidon Mission, launched in 1992. Aside from the complete measurement system, the 66° orbit inclination was chosen for the determination of ocean tides, and the 1336 km orbit altitude was chosen for precision orbit determination. The results from the mission have revolutionized the study of global ocean circulation from the OST determined from the mission and its follow-on, the Jason Mission, which was launched in 2001. Jason-2 was launched in 2008 to succeed Jason-1

to continue the precision altimetry data record. In the mean time, the other satellite altimeters from the ERS, ENVISAT, and Geosat Follow-On (GFO) missions have contributed to the measurement of sea surface height and OST by providing enhanced spatial and temporal resolutions. These missions have, however, benefited from the cross-calibration with the precision missions for correcting for large-scale errors such as orbit errors and tidal effects. It has been recognized by the altimetry community that the continuation of precision missions (e.g., Jason) in combination with other missions (e.g., ENVISAT) is essential for the measurement of OST for a variety of applications.

Ocean general circulation

The measurement of sea surface height from satellite altimetry is not sufficient for the determination of OST. The missing link is the geoid. Direct measurement of the Earth's gravity field for geoid determination is limited to a resolution of 300 km at present (Jayne, 2000). The OST derived from subtracting the geoid from the altimetry sea surface height data is thus lacking accurate information at smaller scales. In order to obtain OST with sufficient resolution to reveal the detailed features of the ocean general circulation such as the Gulf Stream and other ocean current systems, we have to supplement the satellite-derived result

Ocean Surface Topography, Figure 5 Maps of the temporal change of the OST of the Pacific ocean during the 1997 El Niño (upper globe) and the 1999 La Niña (lower globe).

with information derived from in situ measurements of ocean current velocity and density field. Displayed in Figure 2 is a map of time-averaged global OST estimated from combined data from satellite and in situ measurements (Rio and Hernandez, 2004). The spatial gradient of OST reveals the patterns of the ocean general circulation. The concentration of OST contours in major ocean current systems is clearly shown: the Gulf Stream in the western North Atlantic, the Kuroshio (or the Japan Current) in the western North Pacific, and the Antarctic Circumpolar Current around Antarctica. The data used for constructing the map were collected during the period 1993–1999, which is relatively short for representing the time-averaged ocean general circulation. Many of the details of OST and its gradient cannot be determined to be permanent features or manifestations of unaveraged temporal variability of ocean currents. Nevertheless, Figure 2 represents an estimate of the steady state of OST based on a state-of-the-art set of modern observations.

Mesoscale variability

Displayed in Figure 3 is an instantaneous map showing the temporal change of the OST from its time-averaged value shown in Figure 2. The map is constructed from a merged product from the altimeter data of the TOPEX/Poseidon and the ERS satellites

(Ducet et al., 2000). It is apparent that the spatial scales of the temporal variability in the tropics are much larger than those at the mid- and high latitudes, where the variability is dominated by the mesoscales with wavelengths shorter than 500 km. This mesoscale variability is the ocean's analog of the storms in the atmosphere. These mesoscale eddies are primarily created by the instability of ocean currents. They have maximum strength near the major current systems of the ocean, as illustrated by Figure 4 which is a map of the standard deviation of the OST calculated from the same merged data. The standard deviation of OST is a measure of the intensity of the ocean eddy field, which contains 90 % of the kinetic energy of ocean circulation and plays a significant role in transporting heat, salt, dissolved gases (e.g., CO_2), and nutrients around the global oceans.

Basin-scale variability

The strongest variability at the scales of the ocean basins takes place in the tropics, as illustrated by the features in the Pacific Ocean and the Indian Ocean in Figure 3. In the Pacific Ocean, the tropical region is characterized by a seesaw pattern of exchange of heat between the western and eastern parts of the ocean resulting from an ocean–atmosphere coupled climatic system. When the heat content is anomalously high in the eastern and central tropical Pacific with OST higher than normal by up to 30 cm, the condition is called El Niño; when the heat content is anomalously low there with low OST, the condition is called La Niña (see Figure 5). The tropical Pacific is in these alternating states every 2–7 years with worldwide impact on weather and climate.

The basin-scale variability at mid- and high latitudes is quite different from that in the tropics. At high frequencies (with periods less than a season), such variability has a magnitude of generally less than 10 cm caused by the fluctuations of the volume of water mass in the entire water column driven by wind and atmospheric pressure at timescales of days to weeks. At low frequencies (with periods of a season and longer), the variability is associated with the seasonal, interannual, and decadal variability of the ocean. The forcing is a combination of thermal, hydrological, and wind origin. Displayed in Figure 6 is the geographic pattern of the linear trend of the temporal change in OST estimated from satellite altimetry data collected in the period from 1993 to 2008. The timescales of the variability are on the order of a decade, reflecting the climatic change of the ocean circulation and the global sea level. Note that the sea level in most regions of the global ocean is rising, causing a global mean sea level rise at a rate of 3.3 mm/year. Part of the rise is caused by the warming of the ocean that expands the volume of sea water, and the other part is caused by the melting of ice on land that adds water to the global oceans.

Practical applications

The information obtainable from OST on the circulation and the heat content of the ocean finds many practical

Ocean Surface Topography, Figure 6 The linear trend of temporal change of OST from 1993 to 2008. The unit is mm/year.

applications. For example, the fluctuations of ocean current velocity in the Gulf of Mexico have important effects on the safety and operational cost of the offshore oil drilling industry in the region. The data product of OST and current velocity has been made available to the offshore operators, resulting in cost savings of up to a half million US dollars in a single operation involving towing oil rigs along optimal routes. The upper ocean heat storage estimated from OST has proven useful for the prediction of the strength of hurricanes. This is because a hurricane draws its energy for growth from the heat stored below the sea surface. While the information of [sea surface temperature](#) reflects the heat only in a thin layer of the ocean surface, the heat stored below the ocean surface estimated from OST contains the fuel for hurricane to grow. Other applications include El Niño and La Niña predictions, fisheries management, marine mammal research, ship routing, and monitoring global [sea level rise](#).

Outlook

We have come a long way since the first global OST observed from Seasat. The observations from all the satellite altimeters have since revolutionized the fields of

oceanography and geodesy, as well as created many practical applications. However, there is a significant limitation in the conventional radar altimetry. The size of the pulse-limited radar footprint underlying the conventional radar altimetry increases from 2 to 10 km with the height of ocean waves. Even with thousands of pulses averaged over a second, the measurement noise over the large footprint has limited the spatial resolution of altimeter observation to wavelengths longer than 100 km. A major fraction of the ocean's kinetic energy is contained at wavelengths shorter than 100 km. Furthermore, the dissipation of ocean energy and the associated stirring and mixing of ocean properties like temperature and carbon dioxide content are controlled by physical processes at these short wavelengths. Many of the ocean processes in the coastal zones like the upwelling of nutrients, currents, fronts, and eddies that affect offshore operation, navigation, and waste disposal also have small scales that cannot be resolved by the conventional altimeter measurements.

A new technology of radar interferometry coupled with synthetic-aperture technique offers the opportunity of making high-resolution wide-swath measurement of OST (Fu and Rodriguez, 2004). This approach has been demonstrated by the Shuttle Radar Topography Mission

for mapping the land topography (Farr et al., 2007). By operating at a frequency above 30 GHz and a look angle of 4°, the concept of a wide-swath altimeter mission based on SAR interferometry has been proposed for mapping OST as well as the elevation of the water levels of rivers and lakes. A satellite mission with this capability will make breakthroughs in both ocean dynamics and land hydrology, which hold the key to understanding the evolving climate change as well as to monitoring and mitigating its consequences. Such a satellite mission called Surface Water and Ocean Topography (SWOT) has recently been established by a joint effort of the USA and France with contributions from Canada. SWOT is currently planned for launch in 2020.

Doppler shift anomaly. Residual signal Doppler frequency from geometrically predicted Doppler frequency
Range Doppler velocity. Velocity conversion from Doppler shift anomaly estimate

Introduction

Regular repeat global measurements of absolute surface currents as well as ageostrophic processes including convergence and divergence along meandering fronts and eddies at scales smaller than 30 km are rare.

To derive global ocean surface current estimates from space, the basic tool is the radar altimeter. High-class altimeters (TOPEX, JASON, ERS, ENVISAT) are indeed measuring the oceanographic surface topography with good precision. Ocean surface current estimates are then retrieved assuming a linear balance between the gradient of the sea surface topography and surface geostrophic current. Satellite altimetry is a very mature satellite remote sensing technique with an extensive literature describing advances in knowledge and understanding of ocean circulation.

Satellite altimetry has in particular been suited to infer the statistical characterization of mesoscale variability. Thanks to its global, repeat, and long-term sampling, the estimation of sea surface height (SSH) wave number spectra has been a unique contribution of satellite altimetry to quantitative assessment of spectral slopes at scales ranging from about 50 to 100 km up to a spectral peak that generally emerges at twice the wavelength of the internal deformation radius (i.e., 300–400 km at mid-latitudes). Presently, assimilation of altimetry sea level anomaly (SLA) is routinely applied in several ocean modeling and forecasting systems. As such the availability and continuity of altimetric measurements are essential for operational oceanography. Yet, the finer-scale (less than 50 km) oceanic mesoscale and submesoscale energy is difficult to map with conventional radar altimeters because of the narrow illuminated swath, regardless of the orbital configuration.

Mesoscale and submesoscale processes are recognized for their importance and impact on biogeochemical processes and mixing, on air-sea interactions, and for the transfer of energy between scales. To adequately resolve

mesoscale eddies and ageostrophic processes and gradually fill this knowledge gap to advance the understanding of mesoscale and submesoscale processes, observations with finer space and time resolutions are consequently required. Unfortunately, clouds over the global ocean strongly inhibit regular use of very high 1 km resolution spaceborne optical sensors to delineate surface patterns and estimate surface advection. These observation deficiencies, in turn, are also manifested in the performance and quality of high-resolution ocean models. High-resolution observations are also obviously crucial for coastal applications for which the structure of surface currents is generally very complex, influenced by local bathymetry, tidal cycles, and wind and sea state conditions.

To complement spaceborne altimetric range measurements and to obtain direct surface velocity information from space, a different approach can be envisaged. Ideally, it is to use ocean surface waves as proxies to infer the mean ocean surface motion. Indeed, surface waves obey a dispersion relation, i.e., their phase velocities are wavelength dependent, linearly modified in the presence of a surface current. Such a principle is currently very successfully applied with in situ HF radar measurements. Anomalies between the theoretical phase speed of the probed ocean surface wavelength and the measured return signal frequency peak spectra are then interpreted in terms of surface currents.

From space, the interactions between electromagnetic and surface waves are less straightforward than for the near-grazing HF signals. More advanced technical developments and algorithms must then be invoked to exploit the measured Doppler information. Conventional along-track interferometry techniques have already been successfully implemented to measure the instantaneous sea surface scatter velocity by using the phase difference between two return signals from the same surface patch, separated by a very short time interval (Romeiser et al., 2005). In turn, this phase difference can be attributed to instantaneous sea surface scatter velocity. This is illustrated in Figure 1 showing an image acquired during the NASA Shuttle Radar Topography Mission (SRTM) over a complex and tidal-dominated coastal area off Brittany in France. The agreement with the range component of the 2D barotropic tidal current model is very good, both in magnitude and spatial pattern. The TerraSAR-X Synthetic Aperture Radar (SAR) mission launched in June 2007 and which has experimental along-track interferometry (ATI) capabilities provides a more systematic demonstration of this promising measurement technique for direct retrieval of surface current (e.g., Romeiser et al., 2010).

Direct, instantaneous frequency determination from the phase history analysis of single-antenna SAR returns is less conventional, but can also be used to retrieve a Doppler shift anomaly. As demonstrated by Chapron et al. (2005) and Johannessen et al. (2008), this Doppler anomaly is associated with an overall bulk velocity corresponding to the mean velocity of the radar-detected scatterers on the illuminated ocean surface, including a contribution from the ocean surface current. This

Doppler anomaly estimation is then dependent on the instrument characteristics (radar wavelength, incidence angle, polarization) and environmental conditions (mostly wind speed and direction). The partitioning of the signal to these contributing factors is very challenging, but the method has the potential to meet very high spatial resolution requisites. In all cases, the measurement of a Doppler frequency shift can complement the normalized radar cross section, so that both kinematic and dynamical properties of the ocean scene can be simultaneously derived.

Regular access to radar backscatter measurements and Doppler grid information from the ESA ENVISAT ASAR Wave Mode and Wide Swath Mode products has become feasible since mid-2007, thanks to ESA's upgrading of the ground segment. This has led to the gradual generation of a new and comprehensive data set for new explorations of spaceborne surface current measurements. In the next sections, the range Doppler shift signal retrievals are further examined and assessed in respect to (1) removal of the wind contribution, (2) the basin-scale equatorial surface velocity monitoring of the East Pacific, and (3) the strong and persistent surface velocity monitoring associated with the greater Agulhas Current. The subsequent section provides a summary of the key findings followed by a short outlook.

Range doppler velocity retrievals

Technically, single-antenna Doppler shift anomalies are obtained by subtracting the predicted from the measured return signal spectral peak frequencies, i.e., Doppler centroids. The method works best for homogeneous scenes, exhibiting small radar cross-sectional variations, and yields estimates with a resolution (azimuth, range) of about 10 km by 6 km for ENVISAT Advanced Synthetic Aperture Radar (ASAR) Wave Mode (WM) images and about 8 km by 4 km for ENVISAT ASAR Wide Swath Mode (WSM) images. For WSM products, prior to geophysical interpretations, corrections are applied to compensate along-track large cross-sectional variations and biases are further removed using land surface references. In order to use this method to derive quantitative information corresponding to the surface current, it is necessary to identify and remove the wind contribution to the measured Doppler anomaly.

Using a two-scale asymptotic decomposition of the surface roughness (or radar cross section), the radar imaging model (RIM) described by Kudryavtsev et al. (2005) provides estimations for the expected range Doppler scatter velocity by invoking a Doppler shift module following the approach outlined by Chapron et al. (2005). The Doppler shift results from the combined action of near-surface wind on shorter waves, longer wave motion, wave breaking, and surface current (Johannessen et al., 2008). Both kinematic (NRCS-normalized radar cross section) and dynamic properties of the moving ocean surface roughness can therefore be derived from the ENVISAT ASAR observations. Over an ocean imaged scene, the Doppler frequency f_D becomes a mean quantity:

Ocean Surface Velocity, Figure 1 (Top) NRCS measured from the SRTM mission. (Left) 2D tidal model current map. (Right) Coincident surface current map obtained from the SRTM interferometric technique (Courtesy P. Flament).

$$\frac{\pi f_D}{k_R} = - \frac{(u \sin \theta - w \cos \theta) \sigma_0(\theta + \Delta\theta)}{\sigma_0(\theta + \Delta\theta)} \quad (1)$$

Here k_R is the radar wave number, u and w are the horizontal and vertical velocities of the scattering facets, and $\Delta\theta$ is the modification of the incidence angle θ due to the local tilt induced by the longer waves. The two-scale assumption helps to consider the NRCS variations caused by both the change of the local surface tilt ($\Delta\theta$) and the hydrodynamic modulation ($\tilde{\sigma}_0^h$) of the scattering facets, as $\tilde{\sigma}_0 = \Delta\theta \frac{\partial \sigma_0}{\partial \theta} + \tilde{\sigma}_0^h$, where $\Delta\theta = -(\cos \phi_R \cdot \zeta_x + \sin \phi_R \cdot \zeta_y)$, ϕ_R is the radar look direction, and ζ_x, ζ_y are the local components of the sea surface slope. Effects of surface tilt out of the incidence plane are ignored. To the second order in steepness, the RIM-derived radial velocity V_D of the target (assumed positive if directed away from the radar) then becomes

$$V_D = -\pi f_D / k_R \sin \theta = \bar{c}_f + u_s + c_f^{TH} \quad (2)$$

where $\bar{c}_f$ is the mean velocity of the scattering facets, u_s is the radial surface current velocity, and c_f^{TH} is the contribution due to tilting and hydrodynamic modulation of the facets. From the ability to partition the NRCS between regular scatter elements and breaking waves, the radial Doppler velocity in Equation 2 is further expressed as

$$V_D = u_s + \sum P_j^P(\bar{c}_j + c_j^{TH}) \quad (3)$$

where subscript j stands for Bragg waves (br), specular mirror points (sp), and breakers (wb). The specular point velocity always dominates V_D at low incidence angles (Mouche et al., 2008). With increasing incidence angles, this part of the Doppler velocity becomes negligible. At moderate incidence angles, the simulation of the total

Ocean Surface Velocity, Figure 2 (Left) ECMWF monthly wind field projected along the radial direction of the ENVISAT ASAR antenna (ascending pass). (Right) Monthly range Doppler velocity estimated from the ASAR measurements. The average is performed for the month of November 2006 in boxes of 1° in latitude and 2° in longitude for the area centered to the east equatorial Pacific. Values are signed with respect to the orientation toward the SAR antenna so that radial velocity is positive (negative) when the wind blows with its radial component directed toward (away from) the antenna.

Doppler velocity predicts values that are about 35 % of the wind speed. This is significantly larger than expected from the phase speed of the Bragg waves and the wind-induced surface drift (about 3 % of wind speed). The two-scale decomposition with tilting and hydrodynamic effects explains this difference. Moreover, at moderate to large incidence angles, the breaking contribution cannot be neglected, and for HH, it eventually dominates V_D at very large angles. Further details of this approach are provided in Johannessen et al. (2008).

Estimating the wind contribution to the range doppler anomaly signal

Under favorable and well-known wind conditions, inference of absolute surface velocities along the radar line-of-sight direction is highly feasible as suggested by Collard et al. (2008) and further applied in Johannessen et al. (2008). By taking full advantage of the large data set of the ENVISAT C-band ASAR collocated with ECMWF wind fields, Collard et al. (2008) developed a model relying on a neural network to predict the expected Doppler anomaly for a given wind speed. This empirical model thus allows systematic removal of the wind contribution to the measured Doppler anomaly, and the residual range Doppler velocity can be further assessed in view of surface current signatures.

At first order, the Doppler anomaly obtained using the Wave Mode products (at 23° incidence angle and VV polarization) is mostly wind dependent. This property of the Doppler anomaly is illustrated at a large scale in Figure 2 that presents the ECMWF monthly wind field projected along the radial direction of the ENVISAT ASAR antenna (Figure 2, left) and the corresponding monthly radial Doppler velocity estimated from the ASAR measurements (Figure 2, right). The correlation between radial wind given by ECMWF and Doppler radial velocity from ASAR is evident. Based on this collocated data set, the neural network model (called CDOP_23) is

Ocean Surface Velocity, Figure 3 Observed WM (color) and simulated (solid line) wind dependence of C-band Doppler shift VV polarization at 23° incidence angle. The color represents the spread in number of observation points. The open circles mark the mean fit to the observations. Upwind corresponds to positive radial velocity.

created, where the inputs are the wind and the relative direction of the wind with respect to the azimuth angle of the antenna. Furthermore, using the Doppler grid now available for each Wide Swath product, the CDOP_23 model has been extended to incidence angles from 17° to 42° . In so doing, a gradual decreasing trend in Doppler anomaly with increasing incidence angle is revealed. Such a result was anticipated by model simulations reported in Mouche et al. (2008) and Johannessen et al. (2008). In addition, a significant difference between up- and downwind directions is also encountered. As for the radar cross section, this difference increases with incidence, meaning that the relative distribution for small scatterers lying along longer waves is certainly not symmetric.

Ocean Surface Velocity, Figure 4 (Upper left) Residual radial velocity obtained from Doppler anomaly analysis. (Upper right) Radial velocity obtained using MERCATOR ocean circulation model, (lower left) monthly climatology available from the global drifter program, and (lower right) the ocean surface current derived from altimetry data and wind field analysis (OSCAR) Data and model fields are from November 2006.

As reported in Figure 3, the simulated Doppler frequency shifts display a functional relationship with wind speed in good agreement with the observations, in particular up to a wind speed of about 15 m/s. The simulated Doppler frequency shifts for VV polarization (and HH polarization, not shown) provide an acceptable shape versus wind speed. These results give strong confidence that the extended RIM simulations make an excellent analyzing tool to the ASAR NRCS and range Doppler velocity observations.

Ocean basin-scale range doppler velocity monitoring

Exploiting the larger number of ASAR Wave Mode observations and the development of the CDOP model, the detection capability of the Pacific equatorial current regime has been examined. The residual radial Doppler velocity obtained after the removal of the wind effect is presented in Figure 4 (upper left). It exhibits a band with significant easterly (negative) directed radial velocities around 7 °N latitude and two bands of westerly (positive directed) values on either side centered at 2 °N and 12.5 °N latitude. This latitudinal variation of the range-directed surface Doppler velocity is in general agreement with the expected positions of the equatorial current and the countercurrent.

Assessment of this result is carried out by comparison to the sea surface current projected along the line of sight of the radar (Figure 4, upper right) given by the numerical global ocean circulation model MERCATOR (<http://www.mercator-ocean.fr/>), the drifter-derived climatology

of global near-surface currents (Figure 4, lower left) produced by NOAA in the framework of the global drifter program (Lumpkin and Pazos, 2007), and the ocean surface current derived from altimetry data and wind field analysis (Figure 4, lower right) from NOAA through the OSCAR project (Bonjean and Lagerloef, 2002). The overall agreement between the four radial velocity maps is noteworthy. The locations of the equatorial currents and countercurrents are predicted and measured at about the same latitudes, while the range of Doppler velocity values agrees with the sea surface current predictions and the independent measurements.

Further quantitative comparisons along three selected longitude bands are shown in Figure 5. Overall, the radial velocity from ASAR follows the variations of radial velocities given by the other sources. The equatorial countercurrent reaches up to 0.65 m/s and exceeds the equatorial current by 0.15 m/s. This is fairly consistent and with a difference that is slightly larger than the mean difference between the four individual sources which is less than 0.10 m/s. This suggests that both qualitatively and quantitatively, the sea surface current signature manifested in the Doppler anomaly from SAR Wave Mode data can be used, in combination with altimetry, surface drifters, and models, to advance the study of dynamics in the equatorial current regimes.

Regional Doppler range velocities: the Agulhas Current

The main flow directions of the Agulhas Current have an optimum configuration with respect to the line-of-sight

Ocean Surface Velocity, Figure 5 Comparisons of the radial velocity (m/s) given by MERCATOR (green), OSCAR (blue), drifters (red), and ASAR (black dotted) along the longitude bands marked in the upper left plot.

Ocean Surface Velocity, Figure 6 Illustration of the wind correction effect in the case of the Agulhas Current for January 8, 2008. (Left) Full range Doppler velocity. (Center) Wind contribution only. (Right) Range Doppler velocity after wind correction and removal.

velocity captured by the ASAR sensor for the ascending acquisitions as indicated in Figure 6 (left). Hence, after removal of the wind contribution to the signal, it becomes feasible to examine the residual velocity in connection with the strength and pathway of the greater Agulhas Current effect as demonstrated by Johannessen et al. (2008). After subtracting the estimated wind contribution (Figure 6, middle) using the empirical CDOP

relationship (Collard et al., 2008), the remaining range-directed Doppler velocity reaches 2 m/s in the Agulhas Current and nearly 1.5 m/s in the return current (Figure 6, right).

The large-scale surface current patterns are clearly visible, especially the core of the Agulhas Current and the return current. From this promising result, further evidence of the persistent range-directed surface

Ocean Surface Velocity, Figure 7 ASAR Wide Swath (420 km) Doppler velocity map from November 6, 2007 (*upper left*), November 11, 2007 (*upper right*), and November 12, 2007 (*lower left*). The *color bars* mark the radial Doppler velocities ranging from -2.4 m/s to $+2.7$ m/s. Positive speed is directed toward the SAR look direction. Weekly map of surface geostrophic current at 25 km resolution derived from radar altimetry from November 4 to 11, 2007, (*lower right*) with the rectangular box of the November 11 ASAR image inserted. The *color bar* marks the value of the surface geostrophic current ranging up to 1 m/s. The *black curve* marks the location of maximum geostrophic current derived from altimetry.

speed and pattern associated with the greater Agulhas Current can be assessed by the time series shown in [Figure 7](#) for acquisitions on November 6, 11, and 12, 2007. Note that these depict the signals after subtracting the wind contribution using CDOP. Forming part of the South-West Indian Ocean subgyre, the Agulhas Current flows poleward along the

southeastern coast of Southern Africa from 27°S with a speed of about 2 m/s, eventually retroflecting and meandering eastward back into the South Indian Ocean around 40°S at a reduced speed of around 1 m/s. This reversal of the mean flow translates into opposite sign radial surface velocities as indeed captured in the series of images.

The validation of such measurements remains a challenge as coincident reliable sea surface current measurements are very rare. However, using synoptic radar altimetry measurements, we can at least conduct a validation by comparison. The core position of the maximum surface geostrophic current derived from the mean 7 day (4–11 November) composite map of altimeter data superimposed on the Doppler velocity maps derived from ASAR is also shown in Figure 7. The mean location and flow direction of the southern part of the Agulhas Current and the beginning of the Agulhas Return Current agrees very well. However, the strength of the altimeter-derived surface geostrophic current appears suppressed. In particular, with respect to the Agulhas Current where the maximum geostrophic current is only about 0.6–0.7 m/s compared to the range-directed Doppler velocity that reaches more than 2 m/s, the latter speed is also reported from surface drifters trapped in the main current stream. Hence, this distinct expression of the Agulhas Current with a maximum speed around 2 m/s and a sharp shear of about 10^{-4} s^{-1} is predominantly reflecting the influence of the Agulhas Current on the Doppler velocity measurement. The same is valid for the Agulhas Return Current. Under favorable imaging geometry and reliable removal of the wind contributions, this demonstrates that it is possible to derive quantitative information of intense surface currents from the radial Doppler velocity. The ability to study surface current dynamics in combination with surface drifters and altimeter-derived surface geostrophic current should therefore advance.

Summary

Introducing direct observations of scatter velocity from space, SAR-derived Doppler anomalies, when corrected for wind effects, are found to regularly provide estimates of the surface velocity. With a persistent surface current flow direction versus the radar look direction, the greater Agulhas Current and the Pacific equatorial current become ideal for the examination of the Doppler shift measurements. Comparisons with estimates derived from surface drifters, geostrophic current derived from altimetry, and modeled surface current yield very promising results. The current regimes are depicted with greater detail than generally possible from altimetry, due to the geostrophic assumption, and from surface drifters due to inhomogeneous distribution. In particular, the SAR-derived range Doppler velocity seems to be able to retrieve the variation of the equatorial and counter-equatorial surface currents across the intertropical convergence zone. Similarly the full strength and persistence of the Agulhas Current with variable dominance of shear, convergence, and divergence zones are detected in contrast to altimetry that tends to suppress the strength of the highly topographically steered Agulhas Current (Gründlingh, 1983).

In summary, the results are considered promising for strengthening the use of SAR in quantitative studies of the ocean currents. Combined with surface drifters and

altimeter-derived surface geostrophic currents, monitoring of the dynamics of intense current regimes may certainly be advanced. However, promising and exciting as these results are, the SAR-based Doppler velocity retrievals are in need of careful validation. A dedicated field campaign is therefore highly recommended. Execution of a campaign would also be very timely in view of the Sentinel-1 SAR mission, expected to be launched in 2014, to ensure continuation of C-band SAR data from ESA's ERS-2 and ENVISAT satellites. Important applications driving Sentinel-1 include marine vessel detection, oil spill mapping, and sea ice monitoring. With adequate validation and retrieval accuracy of the new method and products reported here, Sentinel-1 could be expected to provide additional consistent information on winds, waves, and currents.

Acknowledgments

This work was supported by the Norwegian Space Centre and the European Space Agency (ESA) through the Prodex Arrangement with contract no. 90266 and by the Research Council of Norway, project number 177441/V30. Support by ESA through the study contract no. 18709/05/I-LG, Service Hydrographique et Océanographique de la Marine (SHOM) through contract 05.87.028.00.470.29.25, and INTAS Association through the INTAS-06-1000025-9264 project are also acknowledged. We are also grateful for the altimeter data obtained from www.aviso.oceanobs.com, AVISO-Centre National d'Etudes des Spatiales (CNES).

Definition

Oceanography. The scientific study of the ocean and its contents, including the biology, chemistry dynamics, and physics of the sea and the geological and geophysical processes affecting the sea floor.

Impact of remote sensing on oceanography

Introduction

It is well over four decades since oceanographers first started to consider what they might learn about the ocean by observing it from above, using sensors on high-altitude platforms. It is remarkable how creative and farseeing their early proposals were (Ewing, 1965). Long before low-power electronics, computer-based digital signal processing, and high-capacity data storage devices were technologies familiar to environmental scientists, the first pioneers envisaged temperature- and phytoplankton-mapping radiometers, altimeters for determining ocean currents, and radars to measure wind, waves, and other phenomena that create sea surface roughness patterns. It took another 15 years, during which men first landed on the moon, before it was possible to prove the feasibility of these basic concepts (Gower, 1981; Saltzman, 1985). This success followed the launch in 1978 of three satellites (Seasat, TIROS-N, and Nimbus-7) which convincingly demonstrated that sensors on satellites could provide ocean scientists with measurements of ocean properties that revealed new insights and changed the way they perceived the ocean.

By 1985 the subject of satellite oceanography was becoming established, with the publication of three textbooks (Maul, 1985; Robinson, 1985; Stewart, 1985)

outlining the principles and methods for measuring ocean properties from satellite data. These have not changed fundamentally, although more recent general textbooks (Martin, 2004; Robinson, 2004) and technique-specific monographs (e.g., Cracknell, 1997; Halpern, 2000; Fu and Cazenave, 2001; Gade, 2005) show improved accuracy and reliability of sensors and twenty-first century satellite data being used for a remarkable range of applications to diverse branches of oceanography (Robinson, 2010).

This entry first considers the factors in satellite oceanography that provide a unique view of the ocean. It outlines the main sensor classes, the remote sensing techniques associated with them, and the different ocean parameters that each can measure. It summarizes the types of ocean phenomena which are observed, emphasizing where satellite data have opened up new fields of oceanographic research. It also notes the more recent development of operational applications of satellite data for warning of hazardous sea conditions, supplying observations that constrain forecasting models, and monitoring the climate of the ocean. It identifies some challenges for future development and reflects on the overall impact that remote sensing has made on our knowledge of the ocean. Although airborne or land-based remote sensing methods are sometimes used to view the sea, their impact has been much less than satellites and they are not discussed here.

The unique ocean perspective offered by remote sensing

Earth orbiting satellites offer a number of unique advantages as platforms for ocean-viewing sensors. First is their capacity to acquire spatially detailed views of the ocean surface. Their typical height of 700–900 km in polar orbit, or 36,000 km in geostationary orbit over the Equator, gives them a wide synoptic view over the surface of the planet. Typical scanning sensors on polar-orbiting satellites resolve spatial detail down to about 1 km, although the resolution of different types of ocean-viewing instruments ranges from 50 km down to 25 m. There is a practical limit of between 1,000 and 4,000 for the ratio between the linear extent of a synoptic image and its spatial resolution. Thus a scanning radiometer with a nadir resolution of 1 km typically has a swath width of 1,000–2,000 km, but beyond the swath extremities, the view is too oblique to be useful. Given the dynamic nature of the ocean and the way in which its surface properties are continually changing, conventional in situ ocean observing instruments lack the sampling capability to capture a nearly instantaneous spatially detailed “snapshot” of the two-dimensional distribution of ocean surface properties. The capacity of satellite data to do so has given the oceanographer a previously inaccessible perspective, which accounts for the pervasive impact that remote sensing has had on ocean science in recent years.

A second unique advantage of remote sensing is the global coverage of polar-orbiting satellites. This allows

data to be sampled in distant and dangerous waters such as the Southern Ocean just as easily as places more readily sampled using conventional ocean observing techniques. Furthermore, sensors in polar orbit provide consistent measurements across the world ocean. Within the limitations of particular methodologies, oceanographers can make confident comparisons between ocean measurements in different oceans or at different latitude made by a single sensor, without the need for complex intercalibration of the many different in situ instruments that would be needed to replicate the global reach of satellites. This capacity has helped ocean science to evolve into the study of basin-scale and global-scale phenomena in the last two decades.

A third significant ocean sampling capability of satellite observing systems is the repeated acquisition of data over many years. While the revisit interval for polar-orbiting sensors places a lower limit on the sampling period of 12 h, or several days if sensors have a fine spatial resolution (Robinson, 2004, pp. 72–75), they continue to sample regularly for several years over the lifetime of a sensor. Where data are acquired as part of an operational service, replacement satellites have maintained the collection of global-coverage time series for well over two decades in some cases. This has given oceanographers a new opportunity to study long-lived phenomena and especially, by extracting mean or seasonally varying climatologies from a longtime series, to immediately detect any anomalous behavior of the ocean relative to the climatology.

The space-time sampling capabilities of some of the main classes of ocean observing sensors are shown as rectangular boxes in Figure 1. The bottom left corner of each box represents on the y-axis the spatial resolution of the sensor or the pixel size (whichever is the larger) and on the x-axis the sampling interval assuming no data losses due to cloud or other factors. The top boundary represents the spatial size of the synoptic view from a single overpass and the right boundary is the length of the time series acquired. It is evident that there is a trade-off between spatial and time resolution, and the ratio between spatial resolution and near-instantaneous coverage is shown by the height of each box, given the logarithmic axes of the figure. The area covered by each box encompasses the range of length and timescales which the sensor is capable of detecting. In all cases, this far exceeds the capacity of an in situ array of moorings, drifting buoys, or vessels in transit. By plotting the sampling capabilities of sensors in this way, comparison can be made with the space and timescales of ocean phenomena, which are shown as shaded ellipses in Figure 1. In general, the short-length-scale phenomena have short timescales and larger phenomena have longer timescales. If ocean processes are to be effectively observed, it is important to match the space-time sampling capacity of instruments to the space-time variability and extent of the ocean phenomenon. Figure 1 shows that satellite data are very well matched to the observation of ocean processes at the basin scale down to the scale of

Ocean, Measurements and Applications, Figure 1 Schematic showing in rectangular boxes the space-time sampling capabilities of four different sensor types representative of ocean remote sensing instruments. Note that “polar” and “geostationary” refer to the orbit of the satellite platform and IRR stands for “infrared radiometer.”

shelf seas. Crucially there is a very good match to the ocean mesoscale, which is the scale of geostrophic turbulence in the ocean, typified by ocean eddies. Failure by in situ instruments to sample this scale properly not only makes it difficult to detect important ocean phenomena without ambiguity but can also lead to aliasing when trying to monitor the large-scale ocean circulation. Figure 1 also makes it clear that satellites are not able to sample adequately the variability scales of estuarine and coastal sea phenomena. Although fine resolution sensors such as imaging radars or land mapping instruments can acquire occasional snapshots of phenomena down to tens of meters, it is normally several days before the next view can be obtained by which time the phenomenon has probably disappeared and so its evolution cannot be tracked.

Fundamentally it is the near-perfect match of satellite sampling capacity to the ocean mesoscale, as well as the global and basin scale coverage, that has given remote sensing such an important role in modern oceanography, irrespective of which ocean variable is being measured. This impact has been made in spite of the other main limitation of remote sensing methods, that they cannot penetrate far, if at all, below the sea surface.

Methods and measurements of ocean remote sensing

In order to grasp the scope of ocean remote sensing, it is important to distinguish between the different classes and types of remote sensing instruments, the primary physical properties that they detect, the oceanographically relevant variables that can be retrieved from the primary

Ocean, Measurements and Applications, Figure 2 Schematic showing the different classes and types of satellite sensors used for viewing the ocean, the primary measurement that they make, and some of the ocean properties that are derived.

property, and the ocean phenomena that are revealed by the measured variables. Figure 2 makes this distinction in summarizing the different classes of sensor used for satellite oceanography, what they individually detect, and the ocean measurements that can be derived. The ocean phenomena that can be observed will be mentioned later.

Sensors used to observe the ocean

Ocean remote sensing methods (Robinson, 2004, pp. 11–26) use three different sources of electromagnetic radiation (EMR) to communicate information about the sea from its surface to a sensor in Earth orbit above the atmosphere. These are the following: (a) solar radiation reflected at or below the sea surface in the visible and near-infrared wavelengths of the EMR spectrum, (b) thermal radiation emitted by the sea surface in both the thermal infrared and the microwave, and (c) pulses of microwave radiation generated on the satellite, emitted toward the Earth, and then reflected by the sea surface. Passive sensors use (a) and (b), whereas active sensors are needed to use (c). As shown in Figure 2, the sensors and main methods of ocean remote sensing can be classified by the part of the spectrum being used and whether the sensor is active or passive. Passive sensors operate in the three principal spectral windows through which EMR passes through the atmosphere, that is, the visible and near-infrared waveband, the thermal infrared, and the microwave. Active sensors on satellites all operate in the microwave and so are types of radars. So far no lidars, active sensors operating in the visible waveband, have

been used for ocean remote sensing from satellites, although they are used from aircraft. Detailed information about the main types of sensor is found under their separate entries. Their capabilities are outlined here to show the wide scope of ocean remote sensing methods.

Visible waveband radiometers measure radiance at the top of the atmosphere (TOA), sampled in discrete spectral bands across the visible and near infrared in order to describe its spectral composition or “color”; hence, these instruments are typically referred to as “ocean color sensors.” The primary variable delivered by an ocean color radiometer system is the water-leaving spectral radiance, although this differs significantly from what is detected by the sensor above the atmosphere. Atmospheric correction (Gordon, 1997) is a major component of the primary processing required to retrieve the ocean color (i.e., the water-leaving radiance). The near-infrared channels are essential for this atmospheric correction procedure. There is almost no component of near-IR in the water-leaving radiance and so any detected in the TOA signal provides a measure of the amount of atmospheric path radiance that is present.

Ocean color in itself is not of particular interest for most marine scientists, but it is influenced by a number of different components which determine the water’s inherent optical properties. Most important of these is the concentration of the pigment chlorophyll-a associated with the presence of phytoplankton and with primary production. Chlorophyll-a concentration is the main ocean variable derived from ocean color sensors, although other factors also influence the color such as dissolved organic material

and suspended particulates. In the open ocean, these other factors are correlated with chlorophyll, which strongly absorbs blue light around 440 nm, giving the water a characteristic green color. This forms the basis of geophysical algorithms to retrieve the chlorophyll-*a* concentration from the green/blue spectral ratio in the water-leaving radiance (O'Reilly et al., 1998). However, where the other optically important water constituents have a source independent of the local phytoplankton population, which often happens in shallow and coastal seas, it is much harder to retrieve chlorophyll-*a*. This remains a major challenge for ocean color remote sensing. Despite this, image datasets of chlorophyll are produced daily from ocean color sensors at a resolution of 1–2 km, allowing detailed mapping of phytoplankton blooms. A record of weekly global composites over 10 years is now available to serve the needs of the international ocean biology and biogeochemistry community (McClain et al., 2006).

The next class of sensor in Figure 2, *passive infrared radiometers*, measures the thermal emission from the sea surface skin (approximately the top 10 μm), after it has passed through the atmosphere and been slightly absorbed by water vapor and other “greenhouse” gases. The primary measurement is the TOA brightness temperature (the temperature of a black body emitting the same radiance as that measured by the radiometer), and the main derived ocean variable is the [sea surface temperature \(SST\)](#). To retrieve this requires atmospheric correction, which relies on sampling multiple spectral bands across the thermal IR, since the water vapor absorption is wavelength dependent (McMillin and Crosby, 1984). Stratospheric aerosols also scatter and absorb the radiation, but these are less reliably detected, unless a dual view strategy is adopted, which observes the same location twice, at different incidence angles and hence through different atmospheric path lengths (Brown et al., 1997). There are several different platforms in near-polar orbits carrying IR radiometers and delivering SST maps that cover the globe with a resolution of 1–2 km at least daily. Sensors on geostationary platforms deliver SST maps, restricted to the horizon from the platform, at 4–5 km resolution every hour. Satellite SST data have a wide variety of ocean applications since many phenomena influence the surface temperature, creating a “signature” for the phenomenon in the spatial distribution of SST. However, since clouds are opaque to infrared radiation, there are many gaps in individual images, but this is partly overcome by producing composite maps over a few days. SST is also important operationally to provide a boundary condition for numerical [weather prediction models](#), and as a climate indicator. A time sequence of global SST maps from IR sensors has been available since 1981 (Kilpatrick et al., 2001). A recent major development in the field has been a move to create global SST maps, climatologies, and anomalies that combine the best data from several different types of sensors in a complementary approach (Donlon et al., 2007). One of the current challenges in the field is to safeguard the absolute accuracy and long-term stability of the

SST climate record even during adverse conditions of stratospheric aerosols following major volcanic eruptions.

The next class of sensors, *passive microwave radiometers*, detects the top of atmosphere brightness temperature in a number of different microwave bands and obtains additional independent information by separately measuring the H and V polarized radiation. Microwave emission from the sea is more complex than for infrared (Swift, 1980; Ulaby et al., 1981, 1982). While the blackbody emission is linear with absolute temperature, the emissivity is less than 0.5 and varies with the viewing angle (and hence the surface slope distribution over the field of view, typically driven by the local wind stress) and with the dielectric properties of seawater which depend on temperature and salinity. Consequently the actual dependence of the brightness temperature on the SST is very complex and requires information about the surface roughness and dielectric properties. The positive outcome of this complex behavior is that the additional dependencies provide the opportunity to retrieve wind speed and direction and salinity as well as temperature from microwave radiometry.

Microwaves pass through clouds but are still affected by water vapor and other gases. In practice the atmospheric correction to remove these effects and the geophysical algorithm to convert brightness temperature into the required ocean variable of SST are performed in a single empirical algorithm which is based on the different sensitivities of each different frequency and polarization channel to different factors (Wentz, 1997). Thus depending on which frequency bands they use, microwave radiometers deliver products of SST (based on the temperature of the top few mm of the sea), wind speed (and in one case wind direction), atmospheric water vapor, cloud liquid water, and rain over the sea. These are all useful measurements for oceanographers. Two sensors are now orbiting that are able to measure sea surface salinity (SSS) through the low-frequency microwave emission at about 1.4 GHz. The NASA Aquarius sensor uses three non-scanning radiometers each with a field of view of about 100 km that are swept along the ocean surface by the satellite trajectory (Lagerloef et al., 2008). The ESA SMOS (Soil Moisture and Ocean Salinity) mission (Drinkwater et al., 2009a) uses 69 radiometers in a “Y” formation to measure the microwave emission and an interferometric approach to aperture synthesis to provide a cross-track imaging capability with a retrieval cell size of 35–50 km (Drinkwater et al., 2009b).

Present microwave radiometers have a spatial resolution coarser than 50 km for SST, although they oversample to deliver pixels with a dimension of 0.25° . Since 2002, daily global SST maps have been routinely produced from microwave radiometry from the previous three days. Because they are unobstructed by cloud and return null data only where there is very heavy rain, they have a number of important applications in monitoring larger ocean features and serve as a complement to infrared-derived SST in operational contexts and in the

compilation of climate datasets (Chelton and Wentz, 2005; Donlon et al., 2007).

In contrast to the passive radiometers mentioned so far, active microwave devices supply their own energy, in the form of radar pulses which are emitted from the spacecraft, reflected from the sea surface, and received back at the sensor again. A major advantage is that the echo pulse can be compared to the emitted pulse in order to detect changes in its amplitude, shape, phase, or frequency, each of which may be used to derive particular information about the sea surface from which it was reflected. The effect of the intervening atmosphere can also be largely, though not entirely, ignored. The first class to consider is oblique viewing radars, and there are two special types used for ocean remote sensing, scatterometers, and synthetic aperture radars, normally referred to as SARs.

In the case of oblique viewing radars, when the emitted pulse encounters a smooth sea surface, most of its energy is reflected by specular reflection away from the sensor. If the surface is roughened, the incident energy is scattered more diffusely and with increasing roughness more energy is backscattered to the radar. While it is difficult to describe this behavior precisely (Ulaby et al., 1982), the main mechanism for backscatter at incidence angles between 20° and 70° is based on Bragg scattering theory. This shows that it is the elements of sea surface roughness with a wavelength of $\lambda_{sea} = \lambda_{radar} / 2 \sin \theta$ (where θ is the radar viewing incidence angle) that contribute most to the backscattering. The primary measured quantity is the radar backscatter cross section. This is the ratio between the returned and emitted signal, normalized for geometrical spreading; so, it changes only with the change in surface roughness and is usually given the symbol σ_0 . Depending on the radar frequency and its viewing angle, the Bragg wavelength is typically in the range between 1 and 30 cm. These are the small ripples that are produced by wind stress on the sea surface, and so oblique viewing radars are very sensitive to wind conditions over the sea.

A *scatterometer* exploits this in order to serve as a wind-monitoring instrument. It measures the average backscatter from a fairly wide region. The backscatter is compared with an empirical database relating σ_0 to wind speed and direction (Stoffelen and Anderson, 1997). A scatterometer is designed so that the same patch of sea is viewed from more than one direction within a few minutes, which enables both wind speed and direction to be retrieved, with a typical spatial resolution of 50 km. Using a single scatterometer the distribution of wind speed and direction can be sampled over the world ocean in about 2 days.

A SAR samples the return pulse in very fine detail and applies signal processing techniques to map at a spatial resolution of about 20 m, using the echoes from several hundred pulses to contribute to defining the magnitude of σ_0 at each pixel on the reconstructed image. The magnitude of σ_0 across a SAR image is set mainly by the spatial distribution of wind speed and direction, so a SAR image can map small-scale variability of the

wind field. However, local convergence, divergence, or shear in the sea surface currents causes modulation of the wind-driven Bragg ripples. This allows signatures of the underlying small-scale ocean dynamics to be created as patterns on the image. A variety of features have been revealed by this means, most notably internal waves, surface swell waves, bathymetric features in shallow tidal seas, ocean fronts, and small-scale eddies (Alpers and Hennings, 1984; Alpers, 1985; Robinson, 2004, pp. 521–555). Slicks, where surface-active material damps the amplitude of the Bragg waves, are also visible as dark patches on SAR images (Alpers and Hühnerfuss, 1988).

The final class of radars is the altimeter which views the surface at normal incidence using a nadir-pointing antenna. Its primary purpose is to measure the travel time of a radar pulse reflected from the sea surface and hence the distance between the altimeter and the sea surface. Precise knowledge of the satellite's position relative to the center of the Earth then allows the absolute height of the sea surface to be determined. As it travels along its orbit above the Earth, an altimeter can therefore measure the gradual along-track slope of the sea surface, which is another of the primary observable quantities of satellite oceanography. The slope of the sea surface over a distance of tens to hundreds of kilometers is an extremely important measurement since from it can be derived the surface geostrophic flow of the ocean. After corrections for the effect of the atmosphere on the speed of EMR, the most successful altimeters can measure height with a resolution of about 2 cm and therefore resolve much subtle detail in the time varying patterns of ocean circulation (Chelton et al., 2001). To make absolute retrievals of the geostrophic currents requires a determination of the geoid independent of altimetry measurements. Without this it is possible to measure only the variable part of the ocean dynamic surface topography, relative to the long-term mean altimeter height, which depends on both the geoid and the steady ocean surface current distribution that remains undetermined. Nonetheless, the availability of high accuracy altimetry since 1992 has greatly increased knowledge and understanding of the time variable component of the world ocean circulation and has had a great impact on dynamical oceanography. The challenge remains to be able to determine the absolute dynamic topography to an accuracy of 1 cm over horizontal distances less than 100 km, which requires knowledge of the geoid to the same accuracy. The European Gravity and Ocean Circulation Experiment (GOCE) was designed to meet this need (Johannessen et al., 2003; Bingham et al., 2011) as the best independent estimates of the geoid from the GRACE satellite gravity mission do not match this requirement, although by combining them with best estimates of the ocean mean circulation derived from hydrographic data, the absolute dynamic topography produced from altimeters has acceptable accuracy for many applications at lengths scales of 1,000 km and greater (Rio and Hernandez, 2004).

In addition to the altimeter's height measurement, the difference between the shape of the outward and return pulses is interpreted to provide an estimate of the sea surface wave height to an accuracy as good as that of wave buoys. The regular global mapping of significant wave height (SWH) for more than 20 years has greatly enhanced our knowledge of global wave statistics. Finally, the magnitude of the reflected energy is inversely related to the short-scale surface roughness from which the wind speed, but not direction, can be estimated. These capabilities make the satellite radar altimeter a highly versatile instrument, since each type of measurement is essentially independent of the other.

Producing ocean data products from raw satellite measurements

In the early years of Earth observation from satellites (the 1970s and 1980s), the motivation for new sensors and missions was primarily to develop the technological capabilities to prove the validity and utility of the satellite measurements to the communities who could make use of them. Users typically had to perform atmospheric corrections themselves and to develop the “geophysical algorithms” for deriving practically useful ocean quantities from the sensor's primary measurement. By the 1990s, the data processing infrastructure had evolved as the best processing procedures were validated and standardized. It is now a general practice for the agency managing a satellite to take responsibility for the whole chain of procedures needed to deliver calibrated and validated data products in the form of ocean quantities that can be applied immediately by users without specialist technical knowledge of the processing techniques. In the last decade the Internet has made it possible to broadcast data products widely within hours or less of the raw data acquisition.

Given the difference between the diverse methodologies identified in the previous section, the details of the processing chain to convert raw data into a useful data product differ considerably from sensor to sensor. Nonetheless, there is a generic set of tasks that need to be performed on data as part of the so-called ground segment of each Earth observation satellite mission, as illustrated in Figure 3. This is largely self-explanatory, but it is important for users of satellite data to know that the “level” assigned to a data product relates to the stage of processing that has been reached. Table 1 presents the definitions set by the Committee on Earth Observation Satellites (CEOS). Users requiring data containing oceanographically useful products would not be advised to use anything below level 2. At this level the data will be geographically defined, but in the native sampling grid of the sensor (aligned along and across the satellite track rather than north–south), and be at the finest resolution possible. It will have had atmospheric corrections applied (if appropriate) and will consist of useful ocean variables. Level 3 products will be resampled onto a regular geographical grid and may well be composed from several overpasses

Ocean, Measurements and Applications, Figure 3 An outline of the procedures required to convert raw satellite data into ocean data products ready for use in ocean science and marine-related applications. The data product levels are defined in Table 1.

of the same sensor. Level 4 products result from the analysis of data from sources beyond a single satellite and may include in situ data and the products of models.

As operational applications of satellite data products have matured, it is desirable for derived ocean variables to be accompanied by error estimates or values that allow the quality of the information in each pixel to be compared with other pixels in the same image and with other image products. For example, the cloud detection, atmospheric correction, or geophysical calibration processes may reach a more confident result for one pixel than another, as a result of which the user may wish to attach more weight to the influence of one pixel than another in driving a model or making an operational decision. Such an approach has already been established for SST processing (Donlon et al., 2007) and is emerging for others. It makes it essential to perform independent validation of the satellite data products, using coincident in situ measurements where possible.

Limitations of ocean remote sensing methods

As satellite measurements of ocean variables like SST, sea surface height anomaly, SWH, wind speed, and

Ocean, Measurements and Applications, Table 1 Levels of data product indicating the degree of processing that has been applied

Product level	CEOS definition
Raw data	Data in their original packets, as received from a satellite
0	Reconstructed unprocessed instrument data at full space-time resolution with all available supplemental information to be used in subsequent processing appended.
1	Unpacked, reformatted level 0 data at full space-time resolution with all supplemental information to be used in subsequent processing appended. Optional radiometric and geometric correction applied to produce parameters in physical units. Data generally presented as full time/space resolution. A wide variety of sublevel products are possible.
2	Retrieved environmental variables at the same resolution and location as the level 1 source data.
3	Data or retrieved environmental variables which have been spatially and/or temporally resampled (i.e., derived from level 1 or 2 products). Such resampling may include averaging and compositing.
4	Model output or results from analyses of lower level data (i.e., variables that are not directly measured by the instruments, but are derived from these measurements).

chlorophyll are well accepted, by most oceanographers, the inherent limitations of the approach must not be overlooked. Satellite data should complement rather than replace conventional ocean observations. There are many measurements that cannot be made from satellites and others that are better made by in situ sensors, depending on the particular application.

Firstly, as [Figure 1](#) shows, we cannot always obtain satellite measurements when and where we wish, being limited by the coupled sampling characteristics of scanning sensors in satellite orbits. It is inappropriate to rely on satellite data for observations of small-scale processes in estuaries and close to coasts, since the timescales are generally too short to sample adequately at fine spatial resolution.

Secondly, the calibration and validation of satellite-derived observations of ocean quantities must be based on in situ measurements of the same quantities. Even when geophysical algorithms are well calibrated, in situ data coincident with the satellite overpass must continue to be acquired for validation of a complete satellite mission. Ideally, validation samples should be well spread geographically. Since satellite sensors are unavailable for inspection at the end of a mission, the quality of their data sets becomes suspect without a satisfactory validation program.

Thirdly, remote sensing has a limited repertoire of ocean variables that can be measured, even given the innovative techniques developed to infer useful properties

from the four primary measurements that can be summarized as color, brightness temperature, surface roughness, and surface height. Most derived measurements are of physical properties. Apart from chlorophyll concentration derived from color, remote sensing makes no other marine biological measurements (excluding satellite tracking of tagged marine animals). Neither can chemical samples be made, other than salinity. The contribution of satellite data to marine biogeochemistry comes through providing a space-time overview of the physical environmental context in which conventional chemical and biological observations are interpreted.

Finally, remote sensing relies on EMR emerging from the sea surface. For infrared and microwaves, this means that only quantities at the very surface of the sea can be detected. For visible wavebands, the light comes from the photic zone, typically 1 to 30 m deep depending on water turbidity. Present remote sensing methods do not measure any ocean properties below the ocean surface layer, which is a fundamental limitation that must always be taken into account when interpreting satellite data. That is not to say that remote sensing cannot be used to study phenomena occurring deeper in the water column, as explained below, but this is only possible if the phenomenon causes changes to the surface water that can be interpreted as a “surface signature” within satellite datasets.

Ocean applications of remote sensing

It misses the real strength of satellite data to consider them simply as an alternative to replace conventional in situ data. The unique contribution of satellite data to ocean science comes from spatial maps of ocean properties, repeated as a regular time series, that show how the detailed two-dimensional patterns of ocean surface properties vary with time. This is enhanced when different types of measurements from different classes of sensor are compared with each other, opening up new understanding of ocean processes. Therefore, the essence of satellite oceanography is to be found not simply in the technology and clever measurement methodologies, but in the creative ways in which satellite data are analyzed, blended with other observations, and assimilated in theoretical models, leading to new scientific insights about the way the ocean behaves.

Ocean phenomena observable from space

For the reasons implicit in [Figure 1](#), mesoscale variability is the class of ocean phenomena that are revealed particularly well in many types of satellite data. [Figure 4](#) demonstrates this with the [sea surface temperature](#) distribution in a 500 km square region of the S.W. Atlantic Ocean. Careful inspection shows a wealth of complex mesoscale eddy structures at a range of scales, from the central dominant eddy with a diameter of about 200 km down to small features of less than 10 km diameter. This “snapshot” of what is evidently a highly dynamic and evolving temperature

Ocean, Measurements and Applications, Figure 4 Sea surface temperature image of the S.W. Atlantic Ocean acquired on October 13, 1992, by the Along-Track Scanning Radiometer (ATSR) on the ERS-1 satellite of the European Space Agency. In this 500×500 km image with 1 km pixels, the contrast has been stretched to enhance the visibility of the mesoscale variability. The gray tone ranging from *black* to *white* represents a temperature range of 8°C , *black* being coldest and *white* being warmest.

distribution provides insight into the interrelationships and dynamic similarity between the scales. It provides a classic picture of two-dimensional turbulence in a rotating frame, at its true size and full complexity in place of the scaled-down laboratory experiments that had to be used before satellite images such as [Figure 4](#) became available. In cases where there is primary production occurring, similar mesoscale patterns can be seen in the chlorophyll maps derived from ocean color. The capacity to see the distribution of color and SST relative to each other is not only instructive for ocean dynamics but has led to a better understanding of the interaction between physical and biological processes at the mesoscale and given new insights to marine biologists (Saraceno et al., 2004, 2005). Satellite data confirm the presence of similar structured mesoscale features in all parts of the world ocean (Robinson, 2010, chs.3–5), although outside this very vigorous confluence of the Brazil and Malvinas currents, their signatures may be much weaker in terms of the temperature gradients across them. The trajectory of larger eddies can be tracked in the surface height maps from altimetry (Schonten et al., 2000). Coastal upwelling is also evident from the SST field as ribbons of cold water along coastlines and can be correlated with the wind forcing of upwelling, using satellite-derived wind field maps.

Exploring beyond individual features, the statistical characteristics of the variability field can also be monitored from space. From altimetry it is possible to map the eddy kinetic energy as a derived variable (Ducet et al., 2000). Using automatic detection of fronts on SST images, it is possible to analyze long records of satellite data to produce climatologies of fronts (Belkin and Cornillon, 2003). Fronts, upwelling, and mesoscale eddy activity, all promote vertical mixing and transport of nutrients to the surface, supporting enhanced primary production. Basin scale satellite maps of chlorophyll from ocean color can be compared with the mapped eddy activity, fronts, and upwelling to illuminate the ways in which ocean dynamics influence marine biology on the large scale. Fisheries science benefits from such an approach (Santos, 2000). Studies on this scale, with an ocean-wide perspective that looks at the integrated effect of many individual mesoscale features, are needed to understand the Earth system as a whole. They are dependent on satellite mapping of ocean properties integrated on the global scale, but which must be derived from fine-scale images to avoid aliasing.

Another class of ocean phenomenon revealed readily in satellite data are the large-scale ocean waves whose dynamics are associated with the planetary beta effect, a consequence of the local Earth rotation parameter varying with latitude over the Earth. [Figure 5](#) illustrates how such waves show up when a time series of satellite maps over an ocean basin are sliced to show how an ocean property such as sea surface height varies with longitude (x -axis) and time (y -axis) (Chelton and Schlax, 1996). The diagonally trending structures provide evidence of westward propagating features. In many cases these can be identified as Rossby waves which are very difficult to detect using conventional observations, mainly because their timescale is so large, taking years to cross an ocean basin. Their ready detection from satellites has led to a healthy interplay with theoretical modelers as their early theories were tested against the new observational evidence from satellites and found to be in need of refinement (Killworth and Blundell, 2003). Having used altimetry to confirm the existence of Rossby waves, it was interesting to discover that they also had a signature in the global maps of SST anomaly and even in ocean color (Cipollini et al., 2006), which prompted further theoretical analysis (Charria et al., 2006).

In general, remote sensing has proved in practice to be most readily accepted by oceanographers when it delivers unique data for displaying slow, large-scale processes. A good example is the El Niño phenomenon in the tropical Pacific Ocean (Picaut et al., 2002). Satellites deliver SST anomaly and surface height anomaly maps which show the strong characteristic differences between El Niño, non-El Niño, and La Niña conditions. They provide maps of wind speed and direction, and rainfall over the sea, which are relevant to the atmosphere–ocean coupling that is central to understanding how to model and predict the onset of an El Niño event. They also deliver maps of

Ocean, Measurements and Applications, Figure 5 A time versus longitude plot of sea surface height (SSH) measured by altimeter at 25 °S in the Indian Ocean between 60° and 90°E. The arrow and lines define a single contribution to the plot, from the SSH map for Cycle 60 (1–11 May 1994) of the TOPEX/POSEIDON mission (Figure courtesy of Paolo Cipollini).

chlorophyll concentration showing the impact on primary production and hence the fisheries resources. Another category of phenomena whose study has benefited from satellite data is tropical cyclones (called hurricanes when they occur in the Atlantic Ocean), their prediction, tracking, and the changes they leave behind in the ocean. Passive microwave radiometers have the unique capacity to monitor SST under large amounts of cloud surrounding hurricanes. A third example concerns the unprecedented melting of the Arctic sea ice during summer 2007 and again in 2012, which satellites monitored as it happened. Once the ice had melted, the temperature on the newly exposed sea could be monitored until the surface froze over again.

In addition to these meso- and large-scale features that lend themselves to observation from space, there is a variety of other smaller scale phenomena in coastal and

Ocean, Measurements and Applications, Figure 6 SAR image showing internal solitons propagating from left to right across the Andaman Sea. This image from the ERS-1 SAR is 100 km across (see Robinson, 2004, Figure 10.47).

shelf seas that have benefited from satellite data. Where shallow seas are well mixed vertically, then the surface properties measured by remote sensing are uniform throughout the water column. Here SST characterizes the total heat content of the sea, and ocean color represents the whole depth, allowing chlorophyll concentration or the suspended particulate content to be measured. In summer, when the deeper parts of tidal shelf seas start to stratify, the location of the frontal edge shows up as a characteristic signature on SST images. Studies in this field were among the earliest cases where satellite data made a significant contribution to oceanographic research (Simpson and Bowers, 1979).

Another class of phenomena revealed very clearly on SAR images when the wind conditions are appropriate is that of internal waves which propagate on the thermocline (Alpers, 1985). This is a clear example of how remote sensing can provide important information from a unique view of a subsurface ocean process, centered as much as 50 m below the surface. Through the action of the convergence of currents associated with internal waves modulating the sea surface roughness, the phase pattern (troughs and crests) of the internal waves is “painted” in the SAR images of σ_0 . Thus it is possible to differentiate between different wave trains and how they refract as they propagate across a region. Figure 6 illustrates a particular type of large-amplitude nonlinear internal wave, an internal soliton (Liu et al., 1998), in this case propagating across the Andaman Sea toward the Thailand coast. Even though such features have only a very small amplitude at the sea surface, the thermocline may rise and fall by up to 50 m as the soliton passes and so the ability to monitor them from satellites is very valuable.

Operational applications of satellite oceanography

In the last two decades, operational applications have followed in the wake of mature scientific understanding of what can be learned about the ocean from satellite data. The simplest and most direct of these are based on providing satellite images to mariners, as in the case of SST and surface chlorophyll maps being used by deep sea fishing fleets. In coastal regions where fish farming and other aquaculture activities are threatened by harmful algae, remote sensing is used to provide advance warning of phytoplankton blooms, although ship sampling is needed to determine whether the algal species is problematic. Wave height data from altimetry are made publicly available in near-real time (NRT – within minutes to hours of acquisition) so that mariners can keep a watch on developing sea state and validate forecasts. Rather more elaborate, but still basically image based, is the use of SAR data for surveillance of oil spills, both for enforcement of antipollution legislation and to alert pollution protection agencies. For example, the European Marine Safety Agency has developed the CleanSeaNet service, which provides for the European seas a range of detailed information to Member States, including rapid delivery of available satellite images and oil slick position (EMSA, 2008).

Another important operational use of satellite ocean data is the incorporation of wind measurements from scatterometers into numerical [weather forecasting](#). Although this might be considered to be a purely meteorological application, the benefits to the marine community in terms of improved offshore weather forecasts are significant. Ocean wave forecasting is closely linked to weather forecasting, being based on wind forcing of ocean models, but increasing use is now being made of direct wave measurements (SWH from altimetry or wave spectra from SAR) for assimilation into, or validation of, third-generation wave models.

A much more complex, interactive, and far-reaching use of satellite ocean data for ocean forecasting systems is in the process of becoming operationally active in Europe (Johannessen et al., 2006). This is where NRT measurements of SST and surface height anomaly derived from satellite data are assimilated into forecasting systems based on numerical ocean general circulation models. These generate nowcasts and short-term forecasts of the physical properties of the ocean, at depth as well as at the surface. NRT observations from subsurface floats and satellites are needed to constrain the models so that they follow the actual ocean behavior. Meeting the model requirements of resolution, timeliness, and accuracy has presented a challenge to satellite ocean data producers, which has been met through the complementary use of products from different satellites in both the SST (Donlon et al., 2007) and surface height (Pascual et al., 2006) communities. It is intended that in future the ocean models will include biogeochemical components forecasting primary production and using products derived from satellite

ocean color data as assimilation variables. Finally, satellite data are recognized to have an essential contribution to make in monitoring changes in the climate of the ocean in response to global warming.

Conclusions

There is little doubt that the increasing availability of well-calibrated ocean measurements derived from satellites has changed the way oceanographers go about their science. It has encouraged both a more global approach with an emphasis on understanding the spatial structures of phenomena and a more holistic approach, allowing new views of the connections between marine biology, dynamics, physics, and biogeochemical processes. Moreover, the disciplined delivery of data within the operational constraints of timeliness and accuracy has increased the wider impact of satellite oceanography on many aspects of human interaction with the ocean for transport, food, industry, and leisure.

There remain significant technical challenges that include the acquisition of a more precise ocean geoid, beyond that provided by GOCE, improving the accuracy and resolution of salinity measurements from space and improving techniques for directly measuring surface currents at short-length scales from interferometric radars (Romeiser and Runge, 2007) or from Doppler analysis of SAR data (Chapron et al., 2005). There is also a political challenge to develop and maintain the continuity of existing satellite ocean observing capacity within an international infrastructure of open access to data. This will be essential to provide us with knowledge of how the ocean changes in coming decades in response to the accelerating impact of man's occupation of the planet, and it will hopefully contribute to an internationally shared strategy to reduce that impact before its effect has grown beyond control.

OCEAN-ATMOSPHERE WATER FLUX AND EVAPORATION

W. Timothy Liu and Xiaosu Xie

 Technology, Pasadena, CA, USA

Definition

The ocean–atmosphere water exchange is the difference between evaporation and precipitation at the surface of the ocean. Evaporation is the turbulent transport of water vapor from ocean to the atmosphere. Precipitation is the return of water to the ocean from the atmosphere in the form of rain and snow.

Introduction

The equation of water conservation in the atmospheric column is

$$\frac{\partial W}{\partial t} + \nabla \cdot \Theta = E - P = F \quad (1)$$

where

$$\Theta = \int_0^{p_s} q u dp \quad (2)$$

is the moisture transport integrated over the depth of the atmosphere, and

$$W = \frac{1}{g} \int_0^{p_s} q dp \quad (3)$$

is the precipitable water or column-integrated water vapor. In these equations, p is the pressure, p_s is the pressure at the surface, and q and u are the specific humidity and wind

vector at a certain level. Bold symbols represent vector quantities. F is the freshwater exchange between the ocean and the atmosphere and is the difference between evaporation (E) and precipitation (P) at the surface. The first term is the change of storage. For periods longer than a few days, it is negligible, and there is a balance between the divergence of the transport ($\nabla \cdot \Theta$) and the surface flux. The balance gives rise to two ways of estimating the fresh water flux. One is to measure E and P separately; the other is to estimate Θ .

The first method, through the small turbulent-scale processes, has been called the “supply side” estimation; the water is supplied by transport from the ocean. The second method has been called the “demand side” estimation; the large-scale atmospheric circulation demands the water flux from the ocean (WCRP, 1983). One of the most advanced statistical techniques, support vector regression (SVR), has been used to retrieve surface specific humidity (q), E , and Θ , from space-based data.

The scientific need of the flux is presented in section [Significance](#). Space-based estimations of q and E are described in section [Bulk Parameterization: The Supply Side](#). The validation of the water flux is difficult because of the lack of credible direct measurements. The conservation principles post constraints of the accuracy of these fluxes. The space-based estimation of $\nabla \cdot \Theta$ as water flux is described in section [Divergence of Moisture Transport: The Demand Side](#), which includes the validation through mass conservation of global ocean and the continent of South America. In turn, $\nabla \cdot \Theta$ is used as a constraint to the accuracy of E retrieval ([Equation 1](#)) in section [Marine Atmosphere Water Conservation](#). The feasibility of applying further constraints is explored in section [Ocean Heat and Surface Salinity Conservation](#).

There are many programs to produce P (e.g., Huffman et al., 1997; Adler et al., 2003; Joyce et al., 2004). The Tropical Rainfall Measuring Mission (TRMM, Kummerow et al., 2000) measures rainfall between 38° latitude north and south of the equator and has provided important calibration of P since 1998. The Global Precipitation Mission (GPM) will extend the coverage to extratropical regions, with increased sensitivity and accuracy. See Rainfall, by R. Ferraro, in this book for further discussion.

Significance

Water is the essential element for life. Over 70 % of the Earth’s surface is covered by the ocean, which forms the largest reservoir of water on Earth. The never-ending recycling process in which a small fraction of water is continuously removed from the ocean as excess evaporation over precipitation into the atmosphere, redistributed through atmospheric circulation, deposited as excess precipitation over evaporation on land, and returned to the ocean as river discharge, is critical to the existence of human life and the variability of weather and climate.

With their high specific heat and large thermal inertia, the oceans are also the largest reservoir of heat and the fly-wheel of the global heat engine. Since water has high latent heat, evaporation is also an efficient way to transfer the energy. Besides releasing latent heat to the atmosphere, the water evaporated from the surface forms clouds, which absorb and reflect radiation. Water vapor is also an important greenhouse gas, which absorbs more long-wave radiation emitted by Earth than the short-wave radiation from the Sun. Redistribution of clouds and water vapor changes the Earth's radiation balance.

The hypothesis of the amplification of water cycle resulted from global warming, which essentially states that wet places get wetter and dry places get dryer, is a typical problem joining the water and energy balances. Increase in global mean precipitation down to the surface has to be balanced by equal amount of evaporation from the surface to conserve water in the atmosphere. Increase in latent heat from the surface carried by evaporation requires increase in long-wave radiation down to the surface; any imbalance will result in climate changes.

The differential heating of the atmosphere by the ocean fuels atmospheric circulation, which in turn drives ocean currents. Both wind and current transport and redistribute heat and greenhouse gases. Adding heat and water changes density of air and seawater. The heat and water fluxes, therefore, change both the baroclinicity and stability (horizontal and vertical density gradients) of the atmosphere and the ocean. These in turn modify the shears of wind and current.

Bulk parameterization: the supply side

Most productions of space-based evaporation data sets in the past were based on bulk parameterization. Latent heat flux (LH) is related to E by the nearly constant value of latent heat of vaporization (L): $LH = L \times E$. LH , rather than E , is used in many of the past studies. The two parameters are used interchangeably in this entry, and our discussion on E applies equally to LH .

The computation of E by the bulk parameterization requires sea surface temperature (SST), wind speed (u), and q .

$$E = C_E \rho u (q_s - q) \quad (4)$$

where C_E is the transfer coefficient and ρ is the surface air density. q_s is usually taken to be the saturation humidity at SST multiplied by a factor of 0.98 to account for the effect of salt in the water. u and q should be measured in the atmospheric surface (constant flux) layer, usually taken at a reference level of 10 m. Over the ocean, u and SST have been measured from space, but not q . A method of estimating E using satellite data was demonstrated by Liu and Niiler (1984), based on an empirical relation between W and q on a monthly timescale over the global ocean (Liu, 1986). The physical rationale is that the vertical distribution of water vapor through the whole depth of the atmosphere is coherent for periods longer than

a week (Liu et al., 1991). The relation has been scrutinized in a number of studies and many variations of this method have been proposed to improve on the estimation (see Liu and Katsaros, 2001, for a review of earlier studies). Modification of this method by including additional estimators has been proposed (e.g., Wagner et al., 1990; Cresswell et al., 1991; Miller and Katsaros, 1991; Chou et al., 1995) with various degrees of improvement. Recently, neural network has also been used to mitigate the nonlinearity problem in deriving q (Jones et al., 1999; Bourras et al., 2002; Roberts et al., 2010). Algorithms to retrieve q from brightness temperatures (BT) measured by microwave radiometers were developed and improvements were demonstrated (e.g., Schulz et al., 1997; Schlüssel et al., 1995; Jackson et al., 2009). Yu and Weller (2007) have combined space-based observations with model output. Figure 1 shows the validation of q derived from BT measured by the Advanced Microwave Scanning Radiometer – Earth Observing System (AMSR-E) through a statistical model built on SVR. The model outputs are compared with coincident q measured at buoys. For the year of 2008, 30,000 buoy data were randomly selected for validation. The mean and root mean square (rms) differences are 0.05 and 1.05 g/kg, respectively. The rms difference is only 5 % of the range of 20 g/kg and the statistical model appears to be successful. However, E depends on $\Delta q = q_s - q$, which is the small difference between the two large terms (q_s and q), and a small percentage error in q may still cause a large error in Δq and E .

Liu (1990) suggested and demonstrated two potential ways to improve E retrieval from satellite data. The first is to incorporate information on vertical distribution of humidity given by atmospheric sounders. Jackson et al. (2009) have recently adopted this suggestion. The other is to retrieve E directly from the radiances, since all the bulk parameters used in the traditional method could be derived from radiances measured by a microwave radiometer. The direct retrieval method may improve accuracy in two ways. The first is the use of a single CE to derive E (in training the statistical model). The second is to mitigate the magnification of error caused by multiplying inaccurate measurement of wind speed with inaccurate measurements of humidity (q and q_s) in the bulk formula.

Figure 2 compares the uncertainties of two sets of LH derived from the two methods. For the first set, SST and u from AMSR-E produced by Remote Sensing System (Wentz and Meissner, 2000) are used with q derived from AMSR-E BT (same as those in Figure 1). The second set is the output of a statistical model built on SVR, predicting E from the 12-channel AMSR-E BT. A total of 30,000 randomly selected LH computed from three groups of buoy data in 2008 are used in the validation exercise. Direct retrieval of daily mean values reduces the rms difference from 77 W/m² of the bulk parameterization method to 38 W/m². This is equivalent to a reduction from 19 % to 9.7 % of the dynamic range of 400 W/m².

Ocean-Atmosphere Water Flux and Evaporation, Figure 1 Bin-average of near surface specific humidity (q) derived from the statistical model compared with values measured at three groups of buoys. Standard deviation is superimposed on each bin-average as error bar.

The available E (or LH) products and the bulk parameters used to derive them exhibit substantial differences even for monthly means (e.g., Brunke et al., 2002; Bourras, 2006; Smith et al., 2011; Santorelli et al., 2011). The results of our direct retrieval depend on the mix of training data (buoy and ship measurements and NWP products). The conservation principle Equation 1 and the demand-side evaluation may serve as an effective way to evaluate current E products.

Divergence of moisture transport: the demand side

The computation of Θ , as defined in Equation 2, requires the vertical profile of q and u , which are not measured by space-based sensors with sufficient resolution. Θ can be viewed as the column of water vapor W advected by an effective velocity u_e , so that $u_e = \Theta/W$, and u_e is the depth-averaged wind velocity weighted by humidity. W has been derived from microwave radiometer measurements with good accuracy. Methods were developed to relate u_e to the equivalent neutral wind measured by scatterometers, u_s , based on polynomial regression (Liu, 1993) and neural network (Liu and Tang, 2005). Xie et al. (2008) added cloud-drift winds at 850 mb to u_s and used SVR instead of neural network. The scatterometer measurement and the cloud-drift winds represent ocean surface stress and free-stream velocity, respectively. Xie et al. (2008) showed that Θ derived from their statistical model agrees with Θ derived from 90 rawinsonde stations from synoptic to seasonal timescales and from equatorial to polar oceans. Hilburn (2010) found very good agreement between this data set and data computed from Modern Era Retrospective-analysis for Research and

Applications (MERRA) over the global ocean. MERRA is a NASA atmospheric reanalysis using a major new version of the Goddard Earth System Data Assimilation System (Rienecker et al., 2011). Figure 3 shows that, for a total of 26,000 pairs randomly selected data, 2/3 from rawinsonde and 1/3 from the reanalysis, the rms difference is 57.5 kg/m/s and the correlation coefficient is 0.95 for zonal component, and 49.7 kg/m/s and 0.89 for meridional component, for a range of approximately -600 to $+600$ kg/m/s.

Validation of our space-based estimation of $\nabla \cdot \Theta$ (as F) was achieved through mass balance of oceans and continents, using data of the Gravity Recovery and Climate Experiment (GRACE), which is a geodesy mission to measure Earth's gravity field. The variations of the gravity field are largely the results of the change of water storage. The air-sea water flux given by $\nabla \cdot \Theta$ integrated over all ocean area, together with river discharge (R) from all continents, should balance the rate of mass change ($\partial M/\partial t$) of all oceans:

$$\iint \frac{\partial M}{\partial t} = \int R - \iint \nabla \cdot \Theta \quad (5)$$

where $\int$ and $\iint$ represent line and area integrals, respectively. Figure 4 shows that monthly rate of mass change ($-\partial M/\partial t$), measured by GRACE, integrated over all oceans, agrees in magnitude and in phase with $\nabla \cdot \Theta$, derived from the statistical model of Xie et al. (2008) integrated over all ocean areas minus the line integral of R over all coastlines. The difference between $-\int \partial M/\partial t$ and $\iint \nabla \cdot \Theta - \int R$ has a mean of 2.1×10^8 kg/s and a standard deviation of 2.6×10^8 kg/s. The standard

Ocean-Atmosphere Water Flux and Evaporation, Figure 2 Bin-average of LH derived directly from the satellite measured radiances (a), and computed from bulk parameters (b), compared with coincident measurements at three groups of buoys. Standard deviation is superimposed on each bin-average as error bar.

deviation is 18 % of the peak-to-peak variation of $12 \times 10^8 \text{ kg/s}$. The uncertainties in time varying river discharge and ice melt contribute to a large part of error. In the long term, mass is conserved, and the first term in Equation 5 is negligible. The total ocean surface water flux should balance the total water discharge from continent to ocean. The $\int \nabla \cdot \Theta$ 4 year mean of 10.6 cm/year, computed from outputs of the statistical model, is lower than the climatological value of 12 cm/year given in textbook published 36 years ago (Budyko, 1974) and higher than the climatological river discharge of 8.6 cm/year (Dai and Trenberth, 2002). Large and Yeager (2009) compiled available E and P to give an annual mean of 11 cm/yr. There are, in general, 20 % uncertainties of these hydrologic balances over global ocean (Figure 4).

Based on Green's Theorem, the areal integral of the flux divergence should balance the line integral of flux out of the boundary. The last term of Equation 5 should equal to total water vapor across the coastlines of all continents. Another example of validation by the conservation principle is given by Liu et al. (2006). They first demonstrated the continental water balance in South America (Figure 5). With climatological river discharge ($\int R$) removed from $\int \Theta$ across the entire continental coastline, the residue agrees, both in phase and in magnitude, with monthly rate of mass change ($\int \partial M / \partial t$). The standard deviation of the difference between $\int \partial M / \partial t$ and moisture flux-river discharge is $0.9 \times 10^8 \text{ kg/s}$, which is 7 % of the peak-to-peak variation of $13 \times 10^8 \text{ kg/s}$.

Ocean-Atmosphere Water Flux and Evaporation, Figure 3 Bin-averaged zonal component (a) and meridional component (b) of integrated moisture transport (Θ), derived from satellite data, compared with coincident data computed from rawinsondes.

Marine atmosphere water conservation

The two flux products should agree with the conservation principle (Equation 1). As an example, the 3 year averages of $\nabla \cdot \Theta$ and E-P are shown in Figure 6. In this example, P is based on TRMM merged data product 3B42, and E is from our direct retrieval from BT. There are general agreements in the magnitude and geographical distribution, but differences in the details. Away from coastal regions, the supply side is larger than the demand side in the tropical southeastern Pacific, tropical south Atlantic, and a region from the Somali coast extending

into the northern Arabian Sea. The demand side is larger than the supply side in the warm pool of the western tropical Pacific and under the Intertropical Convergence Zone (ITCZ). Two operational E products : the Hamburg Ocean Atmosphere Parameters and Fluxes from Satellite Data (HOAPS 3, Andersson et al., 2010) and the Objectively Analyzed air-sea Fluxes (OAFlux) (Yu and Weller, 2007), combined with the same TRMM precipitation are also shown as comparison.

The differences between supply and demand side may reveal regional hydrodynamics. E is the air-sea

Ocean-Atmosphere Water Flux and Evaporation, Figure 4 Annual variation of hydrologic parameters integrated over global oceans.

Ocean-Atmosphere Water Flux and Evaporation, Figure 5 Annual variation of hydrologic parameters over South America: mass change rate $\int \partial M / \partial t$ (solid green line), climatological river discharge $\int R$ (solid black line), total moisture transport across coastline into the continent $\int \Theta$ (red line), and $\int \Theta - \int R$ (dashed green line).

exchange of water vapor by turbulence; the small-scale turbulence is largely independent of factors governing large-scale atmospheric circulation (e.g., baroclinicity, Coriolis force, pressure gradient force, cloud entrainment), while Θ is not as sensitive as E to small-scale ocean processes.

Ocean heat and surface salinity conservation

Evaporative cooling is a major variable component of ocean surface heat balance. The LH has been combined with sensible heat flux (SH) and radiative fluxes to provide the net surface thermal forcing of the ocean (Liu and Gautier, 1990; Liu et al., 1994).

Ocean-Atmosphere Water Flux and Evaporation, Figure 6 Three year (2003–2005) annual mean distribution of (a) the divergence of integrated moisture transport, (b) evaporation-precipitation derived from AMSR-E and TRMM, (c) and (d) are the same as (b) except for evaporation from HOAPS 3 and OAF flux.

The meridional heat transport (MHT) at a latitude θ is derived by integrating from θ to θ_0 across the width of an ocean basin (x_1 to x_2), the rate of heat content changes subtracting the net surface heat flux,

$$\text{MHT}(\theta) = \int_{\theta}^{\theta_0} \int_{x_1}^{x_2} \left(\frac{\partial H}{\partial t} - \text{SW} + \text{LW} + \text{LH} + \text{SH} \right) dx dy \quad (6)$$

where H is the heat content, SW is the net incoming short-wave radiation flux, and LW is the net outgoing long-wave radiation flux.

The northern end of the ocean basin (θ_0) is treated as enclosed by land. The long term mean meridional heat transport of the major ocean basins have been estimated from the ocean surface fluxes (WCRP, 1982). With recent intense effort to measure the meridional overturning current and the feasibility of measuring H by Argo floats, GRACE, and radar altimeter, we may even examine the temporal variation of the meridional heat transport as a constraint to the LH .

There are large uncertainties in long-term annual mean of MHT compiled in past studies, including those derived from surface flux climatology and from oceanographic

Ocean-Atmosphere Water Flux and Evaporation,
Figure 7 Comparison of annual mean MHT at the Atlantic as a function of latitude. Red curve is calculated using the surface heat balance from satellite observations (SW and LW from the Surface Radiation Budget (SRB), LH and SH from AMSR-E). The green curve is computed from ECCO data.

measurements. Figure 7 shows that the MHT computed from our space-based surface heat flux (red line) is lower than those from the simulation of the Estimating the Circulation and Climate of the Ocean (ECCO) model (green line, Fukumori, 2002) between the equator and 30 °N and higher than ECCO between 30 °N and 50 °N. It agrees with ECCO surprisingly well south of the equator.

The equation of water balance in the upper ocean is

$$\frac{h_0}{S_0} \left(\frac{\partial S}{\partial t} + \mathbf{V} \cdot \mathbf{S} \right) = E - P \quad (7)$$

where V is current and S is salinity in the surface mixed layer with average depth h_0 and average salinity S_0 . Salinity measurements have advanced by the Argo floats and space-based sensors of Aquarius and the Soil Moisture and Ocean Salinity Mission (SMOS). The current velocity has been derived from the displacements of drifters with drogues centered at 15 m depth (Niiler, 2001). Ocean surface currents are also provided by the Ocean Surface Currents Analysis-Real-time (OSCAR) program, using a combination of scatterometer and altimeter data (Lagerloef et al., 1999), at a 5 day and 1° resolution between 70 °S to 70 °N. The ocean surface salinity balance can also be used to put constraints on the accuracy of F . The first term represents the change of storage could be neglected in the long-term mean.

Figure 8 shows the distribution of the surface flux agrees with the distribution of salinity advection in the general features, using Argo data for the 11 year mean and using Aquarius for the 1 year mean.

Summary

There have been continuous endeavors to estimate E and LH over global oceans using satellite data and based on bulk parameterization of turbulence transport, since Liu and Niiler (1984) successfully estimated the flux by introducing an empirical relation between monthly W and q . With some improvement in this “supply side” approach, a number of data sets have been operationally produced in the past two decades, but large differences among these data sets and between products from satellite data and from reanalysis of operational weather prediction remain (e.g., Curry et al., 2004). We have introduced a new method of direct retrieval of E and LH from the radiances measured by microwave radiometers, which improves the random error of the daily value of LH to 10 % of the dynamic range, as compared with the 19 % error using the methods we pioneered 30 years ago of computing the fluxes from bulk parameters derived from the same radiances.

Evaluations to find the optimal flux product are difficult because of the lack of credible standards (e.g., extensive direct flux measurement). One good constraint to the uncertainties is the closure of the atmospheric water budget, which dictates that $E - P$ should balance $\nabla \cdot \Theta$. The “demand side” approach of estimating Θ and $\nabla \cdot \Theta$ from satellite data serves not only as a credible way to evaluate traditional “supply side” flux products but also to provide the ocean freshwater exchange as a whole, without the need of securing precipitation data separately. The Θ data have been extensively tested in comparison with all available rawinsonde data and products of numerical models. The water flux data, as $\nabla \cdot \Theta$, are also validated through mass conservation using data from GRACE and river discharge climatology; the validation study shows 20 % uncertainties of the seasonal water balance. The feasibility of using upper ocean heat and salinity conservations is also demonstrated with very preliminary results.

There is still much room left for improvement in estimating water flux over global ocean. The new space-based data products, with better spatial and temporal resolution, have many ongoing scientific applications.

Acknowledgment

This report was prepared at the Jet Propulsion Laboratory (JPL), California Institute of Technology, under contract with the National Aeronautics and Space Administration (NASA). The Precipitation Measuring Mission, NASA Energy and Water Studies, and the Physical Oceanography Program (through the Ocean Surface Salinity and the Ocean Surface Vector Wind Science Teams) jointly supported this effort. Open data access is provided at <http://airsea.jpl.nasa.gov/seaflux/water-exchange.html>, by the Climate Science Center of JPL as its strategic planning.

OPERATIONAL TRANSITION

Richard Anthes
University Corporation for Atmospheric Research,
Boulder, CO, USA

Synonyms

Research to operations; Technology transfer

Definition

Operational transition is the end-to-end set of processes that lead to the successful development and implementation of a research idea, technology, or observation in an ongoing and useful application (operations). An example is the use of atmospheric observations in daily weather forecasts, which have many applications of benefit to society.

Introduction

Observing Earth through remote sensing and using the observations to increase scientific understanding as well as in various practical applications is critically important for society as it attempts to achieve health, prosperity, safety, and sustainability (NRC, 2007). The use of observations in the research process to increase understanding generally works well, as researchers' careers are dependent upon peer-reviewed publications and other forms of disseminating their research. They are highly motivated to use the observations for discovery and to increase knowledge. However, the process for moving or transitioning the use of observations from research into operations is fraught with peril, and like other forms of technology transfer, the metaphor "crossing the valley of death" is often used (NRC, 2000, 2003). There are various pathways that can result in a successful traverse of the valley, but there are also many challenging hazards and obstacles that can block the pathways so that the transitions fail and opportunities to realize the potential value of research and technologies in operations are lost.

The pathways connecting research and operations are not one-way streets; ideally there is healthy two-way traffic, with operational experience feeding back to the research community, causing additional advances in research and subsequent improved operational processes and products. An example of this productive two-way exchange is the early testing of new atmospheric sounding technologies such as IASI (Infrared Atmospheric Sounding Interferometer) in operational numerical weather prediction models (NRC, 2007). The models, with their use of many other independent observations, often detect errors in new observations or processing algorithms, which provide valuable information to the researchers, who can then diagnose and eliminate the sources of errors.

Most of the research and operational uses of remote sensing of Earth involve NASA on the research side and NOAA and other federal agencies, such as DoD and USGS, on the operational side. Universities and national labs often partner with NASA, NOAA, and other federal agencies on the basic and applied research and to some extent on the transitioning process itself.

There is a growing private sector involvement in providing satellite data, primarily imagery, to paying customers. In many of these enterprises, the private sector carries out the entire transitioning and operational process in order to develop and protect its own intellectual property. In this entry we will focus on government-to-government transitions, since these account for the majority of transitions of remote sensing research to operations.

Transition pathways

Transition pathways are end-to-end sets of processes that lead to a successful transition (NRC, 2003). Pathways generally begin with an idea and involve a basic research phase, a testing for operational utility through a prototype,

and development of a full operational system. Each pathway must include a solid research foundation, often including laboratories, instruments, and other equipment; computers; models; and information technologies. Each step of the pathway must be adequately supported with financial resources; very often excellent ideas are never transitioned into operations because funds are lacking for the transition process and/or continued operations. Above all, people with energy, talent, and vision to see the entire pathway, as well as work together toward the final goal, are needed.

Pathways may be successful through either a "push" of new ideas and opportunities from the research side, a "pull" from the operations side to meet new needs or requirements, or ideally a combination of both. Cultural differences between the research and operational communities may impede a robust transition pathway; researchers may have little interest in applications and operations, and operational communities may have little time or even capability to see and understand the potential value of new technologies. Mechanisms to encourage communication and dialog between the communities involved in all parts of the pathway need to be present, and information should flow in both directions. As described above, feedback from the operational testing and implementation of research data or products to the developers can be very useful in the research process and for improving the technology and products. Test beds may be helpful in the final step before operations, to fully test the technology and associated products, demonstrate their value, and optimize them for routine use in operations.

Transition pathways may occur entirely within the government or private sectors, with or without involvement of the academic sector, or they may involve all three sectors simultaneously. Most aspects of the transition process remain the same in all cases, but the financial support of the transitioning process and the ownership of intellectual property associated with the final operational products may vary considerably.

Bayh-Dole Act of 1980

The Bayh-Dole Act of 1980 was a landmark piece of legislation designed to encourage the transfer of government-funded research done at universities and national laboratories into commercial products for the benefit of society. Prior to the Bayh-Dole Act, most of the new developments and technologies generated with government funding were never patented, but were placed in the public domain, where they languished in the valley of death because industry could not claim any proprietary or competitive advantage. Less than 5 % of patents owned by the government were licensed by industry for development of commercial products. The Bayh-Dole Act permitted ownership of new technologies developed with government funds by the university or lab, so that they could grant exclusive rights to commercial developers. The government retained rights to use the technologies for its own

purposes, but the ability to grant exclusive licenses to private companies provided a valuable incentive to the company to develop the technology for sale and thereby make it available to the public.

The Bayh-Dole Act was successful in encouraging universities to transfer new technologies to the private sector, and the result has been the development of many new products and technologies that benefit the public, as well as the private sector, through creation of jobs and profits. The Bayh-Dole Act also encourages partnerships and collaborations between industry and universities.

Characteristics of successful transitions

Successful transitions from research to operations involve a number of important factors:

1. *Good idea.* The idea must be sound and potential must exist for a useful product. This may seem obvious, but it is fundamental to the entire process. Sometimes attempts are made to transfer weak or incomplete ideas through the research process into operations, only to fail when the idea or its potential fails to be proven in the research or testing process. Many transitions fail because the rigorous research and testing process does not confirm the initial promise of the idea.
2. *Good people.* Talented and dedicated people must be involved at all stages of the transition process. Excellent ideas can take years to implement or not be implemented at all because people fail to understand the potential application of the new research, lack a vision for its use, or are otherwise incapable of carrying the idea through the research and testing phases into operations.
3. *Supporting infrastructure.* Adequate supporting infrastructure, such as laboratory, instruments, computers, and information technology, must be available. As with human resources, this is usually a question of having adequate financial resources.
4. *Financial resources.* Adequate financial resources must be invested into all stages of the transition pathway. This requires investors who have the vision and capability to understand the idea or concept and its potential and the willingness to invest the necessary resources. Lack of adequate resources is probably the number one reason why transitions take too long or fail altogether. This requirement is closely connected with other requirements, notably adequate human resources and supporting infrastructure.
5. *Receptive cultures, people, and responsive organizations.* The culture of the research and operational communities involved in the transition must be supportive and complementary. Organizations must be supportive rather than getting in the way of the transition. Adequate two-way communication and coordination among knowledgeable and dedicated people on the transition pathway must be nurtured and encouraged. Transitions often fail because of cultural differences between the operational and research communities, lack of organizational support, or resistance to change (NRC, 2007). Sometimes new ideas are met with outright hostility because they compete with vested interests and old ways of doing things – the status quo (A quote from Machiavelli is relevant: “There is nothing more difficult to take in hand, more perilous to conduct, or more uncertain in its success, than to take the lead in the introduction of a new order of things. For the reformer has enemies in all those who profit by the old order, and only lukewarm defenders in all those who would profit by the new order, this lukewarmness arising partly from fear of their adversaries . . . and partly from the incredulity of mankind, who do not truly believe in anything new until they have had actual experience of it.”).
6. *Planning.* Formal planning may not be essential (some ideas are so great that transitions occur in spite of lack of planning), but like any complicated, long journey, good plans – revised as necessary – can make the process more efficient and enable reaching the goal more quickly.
7. *Time is right.* Sometimes great new ideas are proposed, but the scientific knowledge or the technology to support the idea is not ready. In this case, the transition pathway may wait for decades before the process is ready to begin. An excellent example is L.F. Richardson’s concept of numerical weather prediction (Richardson, 1922) which was advanced in the early 1920s but could not be implemented until the advent of computers some 30 years later.

Having laid out all of these characteristics that assist or hinder the transition process, it is worth noting that there are no recipes or formulas that will guarantee success, and serendipity and just pure luck often play a role. Scott Berkun in *Myths of Innovation* puts it this way:

The dirty little secret – the fact often denied – is that unlike the mythical epiphany, real creation is sloppy. Discovery is messy; exploration is dangerous. No one knows what he’s going to get when he is being creative. Creative work cannot fit neatly into plans, budgets, and schedules. Magellan, Lewis and Clark, and Captain Kirk were all sent on missions into the unknown with clear understanding that they might not return with anything, or even return at all.

This quote applies not only to the discovery phase of research to operations pathways, but to the entire transition process.

Examples of successful and unsuccessful transitions

The NRC (2003) report provides a number of examples of successful and unsuccessful transitions of research and technologies to operations. These are generally transitions of research results and technologies from NASA and its partners into operational use by NOAA. Even the successful ones, like the use of infrared sounders from satellites in numerical [weather prediction models](#), took decades to complete. Some, like lightning detection, radar altimetry,

and scatterometry, have yet to be completely transitioned. These examples are instructive in understanding the complex process of research to operations.

Conclusion

In order to achieve maximum societal benefits from observations and research, the research results must be transferred to the operational community so that they can be used on a routine basis for a variety of useful applications. In order to have a successful transition process, it is necessary to have good ideas that are ready to be implemented; talented and dedicated people; adequate supporting infrastructure and financial resources; receptive people, organizations, and cultures; and effective planning. With these pieces of the bridge in place, the valley of death has a very good chance of being successfully crossed.

OPTICAL/INFRARED, ATMOSPHERIC ABSORPTION/TRANSMISSION, AND MEDIA SPECTRAL PROPERTIES

Gian Luigi Liberti
 CNR/ISAC, Rome, Italy

Definitions

Optical and infrared. Wavelength range 0.2–20 μm within which main contributions in terms of radiative

processes at the basis of current optical and infrared remote sensing techniques occurs in the Earth atmosphere.

Absorption and transmission are the volume properties that describe the overall effects, of single radiative processes, within a given atmospheric volume, interacting with propagating radiation.

Introduction

Radiative transfer simulations, for example, for remote sensing applications, need to summarize the complexity of radiative processes in a given atmospheric volume due to interaction between propagating radiation and single molecules, aerosols, and hydrometeors, introducing macroscopic or volume properties of the media, such as transmission and absorption (see “[Radiative Transfer Theory](#)”).

Processes responsible for each of the media properties considered are reviewed. The relationships between macroscopic properties and variables describing single components radiative processes are reported. For some case references and links to related codes and/or database will be also given.

Absorption

Absorption is the property of the media that describes the interaction between a propagating electromagnetic (e.m.) wave at a given wavelength and the media characterized by the transformation of the energy associated to the propagating wave into another type of energy (e.g. heat) including e.m. energy at wavelengths different from the original one.

In the atmosphere, due its composition, absorption occurs through two main processes: molecular absorption and absorption by scatterers (aerosols and hydrometeors). In the considered wavelength range, absorption by atomic components can be neglected due both to the reduced energy of photons and to the low concentration of radiatively active pure atomic components in the atmosphere. The most relevant difference in the spectral characteristics of the two absorption processes is due to the fact that molecular absorption is strongly selective (i.e., characterized by large spectral variability), while absorption by condensed matter has smoother spectral features. An example commonly encountered in optical/infrared remote sensing application is the absorption of H_2O that can be found as gas, liquid, or solid in the same optical path. Absorption bands, in addition to the difference in the spectral dependence, are shifted in wavelength; this characteristic allows, for example, the development of remote sensing techniques for cloud particle phase classification in the 1.6 and 10 μm window regions (e.g., Baum et al., 2000).

Absorption due to atmospheric scatterers can be obtained as part of the computation of single-scattering optical properties (see “[Optical/Infrared, Scattering by Aerosols and Hydrometeors](#)”). This section specifically

deals with absorption from molecules and with the relationship between media and single-element (molecule, scatterers) optical properties and the relationship between media optical properties.

Molecular absorption

In the most general case, a molecule in the atmosphere has a total energy E that can be written as the sum of different terms:

$$E = E_{rot} + E_{tr} + E_{vib} + E_{el} \quad (1)$$

where the terms are written in the order of increasing associated energy and refer to the following:

- E_{rot} is the energy associated to rotation of the molecule as a unit body. It depends from the symmetry of the molecules through the number of moments of inertia needed to describe the rotational characteristics of the molecule. Associated energy falls in the far infrared and in the microwave.
- E_{tr} is the translational energy associated to the motion of the molecules. It depends on the temperature of the media (atmosphere) and for typical tropospheric temperatures. For typical temperatures of the Earth atmosphere it falls in the infrared.
- E_{vib} is the energy associated with the vibrational mode. A molecule with N atoms has $3N$ degrees of freedom, of which 3 correspond to the translation. A molecule with N atoms has $3N$ degrees of freedom, of which 3 correspond to the translation of the molecule center of mass and 3 or 2 to the rotation, for a nonlinear or a linear molecule respectively. As a result the remaining degrees of freedom associated to vibrational energy are $3N-6$ (nonlinear molecule) or $3N-5$ (linear molecule).
- E_{el} is the electronic energy. Levels of energy associated to the electronic status are derived from the electronic levels for the atoms forming the molecules decomposed in sublevels due to the influence of the molecular electric field (Stark effect). Associated energy is in the range of the UV and visible.

With the exception the translation energy E_{tr} , the remaining energy terms can take only discrete values that correspond to the transitions between a quantized status of energy to another allowed one. These transitions are regulated by selective rules. Transitions between energy levels associated to a higher form of energy are, in general, associated to transitions between levels of the lower form of energy. A typical example is given by the roto-vibrational absorption bands in the infrared.

Excessive vibrational or electronic excitation results in the dissociation or ionization of the molecule, respectively. Similar unquantized transitions generate continuous absorption spectra that typically occur in the UV region.

For the atmospheric conditions, in addition to the spectra due to transitions between energy levels allowed for a molecule as an isolated entity, collision-induced and

polymer bands should be considered. Collision-induced spectra occur when, for example, a homonuclear diatomic molecule, such as O_2 or N_2 , that has no dipole moment in an isolated state may have, as a consequence of collisions, an induced dipole moment and consequently allowed dipole transitions. Alternatively, depending upon the interaction potential, colliding molecules may form a dimer or larger complex that can survive a few collisions. Such a complex is, from a radiative point of view, a new species with its own vibration-rotation characteristics responsible for the observed polymer spectra. An example is the O_2 - O_2 dimer in the atmosphere.

Line absorption/emission occurs when the energy of a photon ($h\nu$) is equal to the energy required to have an allowed transition from two quantized energetic levels of the molecule, E_1 and E_2 :

$$h\nu = |E_1 - E_2| \quad (2)$$

where h is the Planck constant and ν is the frequency (s^{-1}) of the photon.

According to this definition, absorption (emission) spectra should be formed by strictly monochromatic absorption lines, that is,

$$\sigma_a(\nu) = S\delta(\nu - \nu_0) \quad (3)$$

where σ_a is the absorption cross section, S is the line intensity, and δ is the δ -Kronecker function. Due to the line broadening absorption lines have a finite width, as a consequence:

$$\sigma_a(\nu) = Sf(\nu - \nu_0) \quad (4)$$

where $f(\nu - \nu_0)$ is the generic line shape function that respects the condition:

$$\int_{-\infty}^{+\infty} f(\nu - \nu_0) d\nu = 1 \quad (5)$$

Line broadening occurs due to the following different physical processes:

- *Natural broadening.* Strictly monochromatic absorption is not possible either from the point of view of classical radiation theory due to the damping of any emitted energy or from the quantum theory due to the finite width of quantized energy levels. Resulting line width is, however, from the point of view of current remote sensing applications, negligible being of the order of 10^{-11} cm^{-1} .
- *Collisional broadening.* It depends from the deformation of the molecules, and consequent shift of the energy levels, due to collisions among them. From the kinetic theory of gases it can be derived that the number of collision per unit time is proportional to the ratio $p/T^{1/2}$ where p and T are the pressure and the temperature of the gas volume respectively. Collisional broadening is often referred to as *pressure broadening* because of the direct dependence from pressure.

The characteristics of the collisional broadening depends from the nature of the interacting molecules. It is important to distinguish between: self-broadening due to collisions among molecules of the same species (e.g., $\text{H}_2\text{O}-\text{H}_2\text{O}$) and foreign broadening due to collisions between molecules of different species (e.g., $\text{H}_2\text{O}-\text{N}_2$). This process dominates the line broadening in the troposphere with typical values for line width of the order of 10^{-2} cm^{-1} .

- **Doppler broadening.** It is due to the molecular thermal motion for which a photon emitted by a molecule moving with respect to an observer with a speed V will have a Doppler shift in the frequency proportional to the ratio V/c where c is the speed of light. From Maxwell distribution of velocities, a dependence from the gas temperature $T^{1/2}$ can be derived. In the terrestrial atmosphere at sea level even if temperature can have large values, collisional broadening dominates, and the Doppler half-width is approximately 100 times smaller than the collisional one. At approximately 30–40 km of altitude, depending on the molecule, Doppler broadening equals the collisional one becoming the dominant line broadening process at higher levels.

Line shape, that is, the functional form used to describe the line broadening, is an important issue particularly for the computation of molecular absorption outside the line center wavelength. In particular, the contributions of the far wings sum up in the *continuum*, that is, a sort of very smooth spectral dependence absorption outside the absorption bands. Commonly adopted functional forms are (e.g., Lenoble, 1993) the *Lorentz profile* (for natural and collisional broadening), the *Doppler profile* (for Doppler broadening), and the *Voigt profile* (a combination of the previous two, used to describe the line broadening in for pressure and temperature conditions where Doppler and collisional broadening have comparable values).

In the most general case, remote sensing applications require the computation of the average *absorption (transmission)* $\bar{A}(T)$ within a given spectral interval v around a wavelength value v . For molecular absorption from a single absorbing gas with a density a within the optical path, this can be written as

$$\bar{A}(v) = 1 - \bar{T}(v) = \frac{1}{\Delta v} \int_{v-\Delta v}^{v+\Delta v} [1 - \exp(-a\sigma_a)] dv \quad (6)$$

where if L lines contribute to the absorption in the spectral interval v then

$$\sigma_a(v) = \sum_{j=1}^L \sigma_a^j(v) = \sum_{j=1}^L S^j f^j(v - v_o^j) \quad (7)$$

The above computation can be done using several approaches and corresponding numerical models, depending on the specific application. Relevant

parameters in the selection of the method can be spectral resolution (e.g., radiometry vs. spectrometry) and range (e.g., UV vs. IR), geometry of the observation (limb vs. zenith), objective of the observations (remote sensing of cloud properties, profiling of minor constituents, atmospheric correction for surface remote sensing applications, etc.), and finally logistic considerations (creation of Lookup Table, design of new sensors characteristics, etc.).

Highest spectral resolution computations are obtained with the line-by-line (LBL) approach that is based on considering the contributions, at a given wavelength, from each single absorption line within a certain wavelength range (e.g., the LBLRTM code (Shephard et al., 2009) available at www.rtwweb.aer.com/ or for a review and intercomparison of LBL's models, Tjemkes et al., 2003). Line-by-line computations require detailed information on single-line characteristics (intensity, central wave number, broadening parameters, etc.) that are collected in line atlas. The most widely used and well-documented line atlas is the HITRAN (Rothman et al., 2009), available at www.cfa.harvard.edu/hitran/. The current version of the HITRAN database includes spectral characteristics of 47 molecules including many of their isotopologues. For some molecules or in a certain region of the e.m. spectrum (e.g., UV), absorption properties are given not in terms of single-line properties as derived from spectroscopy but as experimentally derived (i.e., in laboratory inverting the Beer-Bouguer-Lambert law) cross sections.

Computation of molecular absorption through the LBL approach is demanding in terms of computational resources and time. Even considering the increasing availability of computational resources, remote sensing applications that do not require to solve for the single absorption line contributions, as for example radiometry, can apply other methods to compute the effects of molecular absorption. Apart for experimentally based approaches, lower resolution approaches are based still on LBL computations, applied at least once, to compute or to validate the absorption parameters used in the model.

Several solutions have been proposed (see for a review Goody and Young, 1989), for example:

- **Regular models.** These models are based on the assumption that the band is formed by lines spaced at regular intervals of constant (e.g., Elsasser) or variable intensity (e.g., Curtis). With this assumption it is possible to find analytical solutions to the integration over a given wavelength range.
- **Random models.** With this approach lines are assumed to be distributed, in the wavelength range of interest, randomly, with respect to the frequency, following a probability distribution function whose analytical properties allow for a solution to the integral effect of all lines.
- **K-distribution (KD).** The KD method (e.g., Fu and Liou, 1992) is based on the fact that, within a given spectral interval v , radiative variables related to

scattering and thermal emission processes, because of their relatively low spectral variability, can be considered constant. On this basis the integration over frequency [Equation 6](#) is operated changing the variable in distribution of line intensity. Examples of KD-based codes can be found at www.rtwweb.aer.com/rtrtm_frame.html or at <http://snowdog.larc.nasa.gov/cgi-bin/rose/flp200503/flp200503.cgi>.

Finally, the total atmospheric volume absorption, that is, due to the combined effect of molecules and scatterers, is computed, assuming the independence among processes, by summing the absorption cross sections for each species.

Emission

In conditions of *Local Thermodynamic Equilibrium (LTE)*, *Absorption* and *Emission* properties have the same spectral characteristics according to *Kirchhoff's law*. More complex relationships linking absorption to emission properties must be adopted for remote sensing applications strongly based on radiative transfer in the upper stratosphere or higher atmospheric levels (e.g., limb sounding in the upper stratosphere), where *Non Local Thermodynamic Equilibrium (NLTE)* conditions occur (see "[Trace Gases, Stratosphere, and Mesosphere](#)").

Transmission and reflection

For a non-scattering medium (e.g., an atmospheric volume with negligible scattering as a cloud-free layer in the IR) absorption and transmission are related by [Equation 6](#).

In the most general case, in the optical/IR range to fully describe the properties of an atmospheric volume, it is also necessary to introduce the concept of reflection that occurs in the presence of scatterers including molecules. For this reason from the point of view of radiative processes, reflection in the atmosphere depends from elastic scattering, and, in conditions of single scattering (i.e., optically thin layer), it is possible to express the reflection of the layer as a function of single-scattering optical properties.

Absorption deals with the radiative processes that transform the energy of the radiation interacting with the media into other forms of energy including radiation at different wavelengths, for this reason the only relevant geometrical parameter is the optical path of the incoming radiation within the media. Transmission and reflection, dealing with radiation emerging somehow from the volume, need to take into account of the more complex geometry of propagation described by the incident and by emerging radiation. Therefore, the concepts of *direct/specular* and *diffuse* are often introduced to specify particular cases of geometry.

Summary

Radiative processes responsible for the atmospheric volume properties of absorption and transmission have been shortly reviewed, giving examples of methods to

practically account for, in radiative simulation studies. Finally, for some wavelength, in the Optical/IR range and/or remote sensing applications (e.g., optical lighting detection techniques), stimulated emission processes such as *Raman scattering*, *Excited emission*, and *Fluorescence* are the basis for remote sensing techniques.

OPTICAL/INFRARED, RADIATIVE TRANSFER

Knut Stamnes
 Stevens Institute of Technology, Castle Point on Hudson,
 Hoboken, NJ, USA

Definition

Radiation. Electromagnetic energy in the solar and terrestrial part of the spectrum.

Short-wave radiation. Electromagnetic energy in the solar part of the spectrum.

Long-wave radiation. Electromagnetic energy in the terrestrial part of the spectrum.

Radiative transfer. Transport of electromagnetic energy in a scattering and absorbing medium.

Blackbody. A cavity, filled with matter of any kind, that absorbs all radiation incident upon it and emits radiation in accordance with Planck's spectral distribution law.

Introduction

Remote sensing relying on optical/infrared radiation depends on the transport of radiation through a scattering and absorbing medium. For example, remote sensing of the Earth from space requires interpretation of the electromagnetic signal either backscattered or emitted from the atmosphere and the underlying surface. Successful retrieval of surface properties is hampered by the presence of atmospheric molecules and aerosol particles that contribute significantly to the measured signal. To retrieve atmospheric and surface parameters from space, realistic simulations of the radiative transfer process in the coupled atmosphere-surface system are required.

Sources of atmospheric radiation: atmospheric windows

The bulk of the Earth's atmosphere (99 % by mass) consists of molecular nitrogen and oxygen, which are radiatively inactive (homonuclear, diatomic) molecules that have negligible impact on absorption and emission, but are responsible for molecular (Rayleigh) scattering or radiation. Trace amounts of polyatomic molecules are responsible for atmospheric absorption and emission of radiation in several hundred thousands of individual spectral lines arising from rotational and vibrational transitions (Goody and Yung, 1989; Liou, 2002; Thomas and Stammes, 1999). The atmospheric contribution to the top-of-the-atmosphere radiance depends on scattering and absorption by molecules and aerosol particles. As shown in Figure 1, there is little overlap between the radiation spectra of the Sun and the Earth. Therefore, except for applications where the region of overlap (3–4 μm) is of special interest, we may treat the two spectra separately.

The gaseous absorption is strongly wavelength dependent, whereas the aerosol effect varies smoothly and relatively slowly with wavelength. Figure 1 demonstrates that there are certain "atmospheric windows" in which gaseous absorption is very small. Thus, radiances measured in these window regions are suitable for retrieval of aerosol and surface properties, and satellite instruments are usually designed to take advantage of them.

Radiative processes and the radiative transfer equation

The spectral radiance I_ν is the energy d^4E per unit area, per unit solid angle, per unit frequency, and per unit time:

$$I_\nu = \frac{d^4E}{\cos\theta dA dt d\omega dv} [\text{W} \cdot \text{m}^{-2} \cdot \text{sr}^{-1} \cdot \text{Hz}^{-1}]$$

where θ is the angle between the surface normal $\hat{n}$ and the direction of propagation $\hat{\Omega}$.

Absorption, scattering, and extinction by molecules and particles

A beam of light incident on a thin atmospheric layer will interact with matter, and if the layer has thickness ds , then the light is attenuated so that the differential loss in radiance is $dI_\nu = -kI_\nu ds$, where k is called the extinction coefficient. Integration along the beam path through the layer yields

$$I_\nu(s, \hat{\Omega}) = I_\nu(0, \hat{\Omega}) \exp[-\tau_\nu(s)]. \quad (1)$$

Here $\hat{\Omega}$ denotes the propagation direction of the beam, and the dimensionless extinction optical path or opacity along the path s is given by $\tau_\nu(s) \equiv \int_0^s ds' k(\nu)$. Attenuation of a light beam in a specific direction can be caused by either absorption or scattering.

Angular scattering by molecules and particles

The scattered power per unit area per steradian in a particular direction of observation divided by the power per unit area of the incident beam is called the angular scattering cross section, $\sigma(\Theta)$. The angle Θ between the directions of incidence $\hat{\Omega}'$ and observation $\hat{\Omega}$ is given by $\cos\Theta = \hat{\Omega}' \cdot \hat{\Omega} = \cos\theta' \cos\theta + \sin\theta' \sin\theta \cos(\phi' - \phi)$. Thus, in spherical coordinates θ' and ϕ' are the polar and azimuthal angles of the incident beam and θ and ϕ those of the scattered beam. We define the phase function as the normalized angular scattering cross section:

$$p(\cos\Theta) = \frac{\sigma(\cos\Theta)}{\int_{4\pi} d\omega \sigma(\cos\Theta)}$$

which has the normalization $\int_{4\pi} d\omega p(\cos\Theta)/4\pi = 1$.

Long-wave absorption and emission by the surface and the atmosphere

The Earth's atmosphere is in contact with land and ocean surfaces. Their strong continuous absorption in the IR allows them to be treated as blackbodies, which emit radiation according to Planck's law:

$$I_\nu^{BB} = B_\nu(T) \equiv \frac{m_r^2}{c^2} \frac{2h\nu^3}{(e^{h\nu/k_B T} - 1)}$$

where h is Planck's constant, c is the speed of light, m_r is the real index of refraction, and k_B is Boltzmann's constant.

The spectral *directional emittance* is defined as the ratio of the energy emitted by a surface of temperature T_s to the energy emitted by a blackbody at the same frequency and temperature $\in(\nu, \hat{\Omega}, T_s) \equiv I_{\nu_e}^+(\hat{\Omega}) \cos\theta / B_\nu(T_s) \cos\theta d\omega = I_{\nu_e}^+(\hat{\Omega}) / B_\nu(T_s)$. A surface for which $\in$ is unity for all $\hat{\Omega}$ and ν , is a *blackbody*, by definition. Similarly, we define the *spectral directional absorptance* as the ratio of

Optical/Infrared, Radiative Transfer, Figure 1 Spectral distribution of solar (shortwave) and terrestrial (longwave) radiation fields. Also shown are the approximate shapes and positions of the scattering and absorption features of the Earth's atmosphere.

absorbed energy to incident energy of the beam $\alpha(v, -\hat{\Omega}', T_s) \equiv I_{v\alpha}^-(\hat{\Omega}') \cos \theta' d\omega' / I_v^-(\hat{\Omega}') \cos \theta' d\omega' = I_{v\alpha}^-(\hat{\Omega}') / I_v^-(\hat{\Omega}')$. Kirchhoff's law states that for an opaque surface $\alpha(v, -\hat{\Omega}, T_s) = \epsilon(v, \hat{\Omega}, T_s)$, whereas for an extended medium the thermal volume emission coefficient j_v^{th} is

$$j_v^{th} = \alpha(v) B_v(T).$$

Short-wave surface reflection and transmission

For an angular beam of radiation with radiance $I_v^-(\hat{\Omega}')$ within a cone of solid angle $d\omega'$ around $\hat{\Omega}'$, the energy incident on a flat surface with normal $\hat{n}$ is $I_v^-(\hat{\Omega}') \cos \theta' d\omega'$, where θ' is the angle between $\hat{\Omega}'$ and $\hat{n}$. Denoting by $dI_{vr}^+(\hat{\Omega})$ the radiance of reflected light leaving the surface within a cone of solid angle $d\omega$ around the direction $\hat{\Omega}$, we define the *bidirectional reflectance distribution function*, or BRDF, as the ratio of the reflected radiance to the energy in the incident beam $\rho(v, -\hat{\Omega}', \hat{\Omega}) \equiv dI_{vr}^+(\hat{\Omega}) / I_v^-(\hat{\Omega}') \cos \theta' d\omega'$. Adding the contributions to the reflected radiance in the direction $\hat{\Omega}$ from beams incident on the surface in all downward directions, we obtain the total reflected radiance

$$I_{vr}^+(\hat{\Omega}) = \int dI_{vr}^+(\hat{\Omega}) = \int_{2\pi} d\omega' \cos \theta' \rho(v, -\hat{\Omega}', \hat{\Omega}) I_v^-(\hat{\Omega}').$$

The BRDF, or in short the *reflectance*, plays a central role in the remote sensing of planetary surfaces and is important for the correct assessment of their albedo.

Purely diffuse reflection occurs at microscopically irregular surfaces, while purely specular reflection occurs when the surface is perfectly smooth, like a mirror. If the reflected radiance from a surface is completely uniform, i.e., independent of the angle of observation, it is called a *Lambert surface*. The BRDF for a Lambert surface is independent of both the direction of incidence and the direction of observation. Then the reflectance simplifies to $\rho(v, -\hat{\Omega}, \hat{\Omega}) = \rho_L(v)$, where ρ_L is the *Lambert reflectance*. Specular reflection from and transmission through a smooth dielectric surface can be calculated from *Snell's law* and *Fresnel's equations*, given the optical constants of air and the dielectric material.

The equation of radiative transfer

For an atmospheric layer of thickness ds that not only attenuates but also emits radiation, we find that the differential change in radiance becomes $dI_v = -kI_v ds + j_v ds$ or $dI_v/d\tau_s = -I_v + S_v$ where the source function, S_v , is the sum of two terms: $S_v = j_v^{th}/k(v) + j_v^{sc}/k(v) = S_v^{sc} + S_v^{th}$. Here the volume emission coefficient for scattering is $j_v^{sc} = \sigma(v) \int_{4\pi} (d\omega/4\pi) p(\hat{\Omega}', \hat{\Omega}) I_v(\hat{\Omega}')$, while (from Kirchhoff's law) that for thermal emission is just $j_v^{th} = \alpha(v) B_v(T)$. Thus, the complete radiative transfer

equation, which includes both multiple scattering and absorption, becomes (Thomas and Stamnes, 1999; Zdunkowski et al., 2007)

$$\frac{dI_v}{d\tau_s} = -I_v + [1 - a(v)]B_v(T) + \frac{a(v)}{4\pi} \int_{4\pi} d\omega' p(\hat{\Omega}', \hat{\Omega}) I_v(\hat{\Omega}') \quad (2)$$

where $a(v) = \sigma(v)/k(v)$, the *single-scattering albedo*. Equation 2 has a simple physical interpretation: the term on the left-hand side is the change in the radiance along the path ds , the first term on the right-hand side is the loss of radiation due to extinction, the second term is the gain due to emission, and the third term is the gain due to multiple scattering.

Conclusion

Solutions of the radiative transfer equation allow for computation of the radiance that would be measured by a remote sensing instrument. They also allow for computation of weighting functions required in classic inverse methods designed to retrieve atmospheric and surface properties from remote measurements (Rodgers, 2000).

OPTICAL/INFRARED, SCATTERING BY AEROSOLS AND HYDROMETEORS

Gian Luigi Liberti
 CNR/ISAC, Rome, Italy

Definitions

Optical/infrared range of wavelengths $0.2 \div 20 \mu\text{m}$ where the range somehow takes into account of the probability, referred to the Earth atmosphere, to have scattering of natural radiation (i.e., solar or from Earth-atmosphere-ocean thermal emission) from particulate suspended in the atmosphere.

Elastic *scattering* of electromagnetic (e.m.) radiation occurs when the propagating e.m. wave traverses an inhomogeneity in terms of propagation properties. Only elastic scattering is considered in this entry.

Hydrometeors are used for particulate solid and liquid formed principally by water, while *aerosols* include all remaining (i.e., nonwater) liquid or solid particles suspended in the atmosphere.

Introduction

Elastic scattering of electromagnetic (e.m.) radiation occurs when the propagating e.m. wave traverses an inhomogeneity (scatterer) in terms of e.m. propagation properties. The effect of the scatterer depends on the length (relative to the wavelength in the propagating medium) of the portion of path, within the discontinuity, of the propagating e.m. wave and on the propagating properties of the scattering medium. In the atmosphere the propagating medium is the vacuum, therefore, atmospheric particulate acts by delaying the propagation of the e.m. wave.

Within the optical/infrared ($0.2 \div 20 \mu\text{m}$) range of wavelengths, molecules are small compared to the wavelengths and therefore their elastic scattering effect either is negligible or can be described by the Rayleigh scattering (Rayleigh, 1871). Because of the relative stability of atmospheric composition and the weak dependence from the nature of the scattering molecules (e.g., Snee and Ubachs, 2005), scattering from molecules is often assumed as known or dependent only from the density or pressure. This allows to use it as background/calibration signal in some remote sensing application. Examples are Mie-Rayleigh lidar calibration (Fiocco and Grams, 1964), aerosols extinction profiling (Ansmann et al., 1990), cloud detection (Buriez et al., 1997), and detection of absorbing aerosols in the UV (Herman et al., 1997). Quantitative information, through remote sensing techniques, can be retrieved for liquid and solid particulates in the atmosphere for which, for some wavelength in the range of interest, the effect of scattering depends on the physical and chemical characteristics of the scattering particulate. This condensed matter is generally divided into two major classes according with the dominant composition:

- *Hydrometeors* that include condensed water vapor particulate both in liquid as well as solid form. Hydrometeors represent the basic components of clouds and precipitation.
- *Aerosols* that include the mixture of micron-sized liquid or solid particles, except water, suspended in the air.

Because of the processes of cloud droplet nucleation and of aerosol hygroscopic growth, there is obviously an overlap in the two classes of atmospheric particulate. A typical example is the transition from haze, considered as a type of aerosols, to fog that is a type of cloud. In addition to the dominant particle composition, another relevant

aspect in terms of scattering properties is that hydrometeors are in general larger than aerosol particles.

From a historical point of view, most of the optical phenomena that occur in the atmosphere such as rainbows, halos, glories, and coronas are generated by scattering by hydrometeors, and their observation and interpretation have been documented since the antiquity (e.g., [Aristotle ~350 BC](#)).

Physical parameters from which scattering properties depend

In order to be able to describe the set of basic single-scattering optical properties (SSOPs, e.g., extinction coefficient, single-scattering albedo, and scattering matrix) at a given wavelength for a single-particulate element, the following properties need to be known:

Size/shape (or habits) and orientation to allow the computation of the physical path, within the particulate of the e.m. radiation. Two main classes are defined to describe these physical properties of the particulate: *spherical* (for which a single parameter, i.e., the radius a , is sufficient to describe the whole physical aspect of the particulate) and *nonspherical*. Distinction between optical properties of spherical and nonspherical constitutes the basis, in some cases, of remote sensing techniques to identify the nature of the scattering particulate, as for example, the analyses of lidar backscatter ratio (for a review, see Sassen, [2005](#)) or POLDER cloud phase algorithm (Goloub et al., [2000](#)). Liquid particulate is generally considered as spherical. This assumption holds up to the size of precipitating droplets up to a radius of about 140 μm above which the deformation becomes large, and droplets are better approximated by oblate or oblate with a flat bottom spheroids.

Particularly important is the description of particle habit for ice hydrometeors. In fact, although the basis of solid water is hexagonal, the overall shape depends on a combination of factors (temperature, available humidity, rate, and process of growth). This means that ice crystal habit contains useful information on the characterization of the observed cloud volume but, on the other hand, it makes it difficult to develop remote sensing inversion algorithms, for example, for the estimation of optical thickness and cloud microphysical properties (e.g., Baum et al., [2005](#)).

A minimum set of variables to quantitatively describe size and shape of particles is based on the following parameters:

- *Size parameter*: $x = 2\pi a/\lambda$ where λ is the wavelength of e.m. radiation in the surrounding medium and a is, for spherical particles, the radius while for nonspherical can be another characteristic particle size (e.g., semi major dimension, radius of surface, or volume equivalent sphere).
- *Aspect ratio*: ratio of the maximum to the minimum particle dimensions.

With reference to orientation (obviously relevant only for nonspherical particles), most of quantitative applications assume randomly oriented particles. This is the case when atmospheric turbulence dominates the internal motion of particles in a given atmospheric volume. In some case, as, for example, in the upper troposphere, intense laminar air fluxes can be responsible for orientation of particles. Similarly, orientation of hydrometeors (i.e., plates, snowflakes) in absence of strong atmospheric motion can be determined by the aerodynamic properties of the particles (e.g., Breon and Dubrulle, [2004](#)). The optical phenomenon of sun dogs, for example, is due to orientation of ice particles.

Chemical composition from which the propagation properties of the electromagnetic wave depends

This is represented at a given wavelength by a value of the complex refractive index where the real part is responsible for the delay of the e.m. wave, while the imaginary part is responsible for the absorption of energy from the e.m. wave. The complex refractive index also shows dependence from the temperature that can be already relevant for the range of possible atmospheric temperatures, for example, when focusing on particular cases of particulate as, for example, supercooled water droplets. Taking correctly into account of temperature dependence may be even more important for remote sensing applications for the study of planetary atmospheres. If the refractive index is different for different states of polarization, the composite medium is birefringent and/or rotates the plane of polarization. Examples of birefringent media that can be found in atmospheric particulate are ice (Takano and Liou, [1989](#)), quartz (SiO_2), and hematite.

An up-to-date compilation of tabulated complex refractive indices and relevant documentation for basic components of atmospheric particulate can be found in the HITRAN (Rothman et al., [2009](#)) package (www.cfa.harvard.edu/hitran/). As an example, the 2008 version (V13.0) includes refractive indices of water, supercooled water, ice, sodium chloride (NaCl), ammonium sulfate $(\text{NH}_4)_2\text{SO}_4$, sea salt, water-soluble aerosol, carbonaceous aerosol, volcanic dust, meteoric dust, dust-like aerosol, aqueous sulfuric and nitric acid, solid hydrates (i.e., nitric acid mono-, di-, and tri-drates), organic nonvolatile aerosol, crustal material (e.g., quartz, hematite, and sand), and ternary $\text{H}_2\text{SO}_4/\text{HNO}_3/\text{H}_2\text{O}$ droplets at low temperatures as components of polar stratospheric clouds (PSCs).

Single-scattering optical properties (SSOPs) of single particles

SSOPs for single-scattering particles can be computed with *numerical methods* based on the exact or approximate solution of Maxwell's equations of the wave propagating within the discontinuity or can be measured experimentally.

Several numerical methods to compute the SSOP have been developed. They can be classified in terms of:

- Size (or more correctly, size parameter) of the particle
- Shape of the particle, for example, spherical, regular solid, combination of regular solids, axially symmetric, and irregular shape
- Difference between the real part of the refractive index of the medium and of the scatterer (often referred as soft and hard particles)
- Whether it is an approximate or an exact solution

Basic textbooks dedicated to methods to compute SSOP for a large set of cases are Van de Hulst (1957), Kerker (1969), Bohren and Huffman (1983), Mishchenko et al. (2002), and Quinten (2011). A specific review of numerical and experimental methods for computation of SSOP for nonspherical particles is in the book edited by Mishchenko et al. (2002).

Programs to perform computation of SSOP have been developed and distributed even before the existence of the Web (e.g., (Dave, 1968), MIEV0 (Wiscombe, 1980), BHMIE and BHCYL (Bohren and Huffman, 1983)). Libraries containing source programs, executable programs, or online computations are now widely diffused. The SCATTERLIB Web site (atol.ucsd.edu/scatlib/scatterlib.htm) by Piotr Flatau contains links to a large set of codes for SSOP computation. In some cases, radiative transfer model packages (e.g., LIBRADTRAN www.libradtran.org, Mayer and Kylling, 2005) include libraries of programs for the computation of SSOP.

The selection of the method/package used to compute SSOP, apart for the applicability to the class of particles of interest, can be driven by the output parameters generated by the computation and in particular the possibility to compute the whole set of elements of the scattering matrix.

Measurement of SSOP is an alternative method to characterize optical properties of aerosols and hydrometeors or can be used to validate results obtained by numerical models. Because of the complexity of experimental setup to perform such type of measurements, relevant literature is by far less rich than literature on theoretical and numerical methods. In the optical/infrared range, two possible approaches have been used:

- *Direct measurement.* The experimental setup includes a light source, polarization devices for the incident and for the scattered radiation to select the scattering matrix element, a detector of the scattered light, and a scattering volume where the scattering particulate is illuminated. Due to their reduced dimension of scatterers of interest in this wavelength range, it is difficult to accurately characterize the size and shape of scattering particles. Another strong limitation of this approach is that the arrangement of light source and detector precludes scattering angle measurements close to 0° and 180° scattering angle with the consequence that the estimation of the scattering coefficient, obtained by

integrating over the whole range of scattering angle, needs extrapolation or integration with numerically obtained results. Similarly, the extinction coefficient in case of small particle is difficult to be measured with finite aperture detectors because of the presence of forward-scattered light. A review on direct measurements can be found in Hovenier (2000).

- *Analog microwave (MW).* Owing to the fact that scattering properties, for a given refractive index, depend uniquely by the size parameter, difficulties in characterizing the scattering particles can be reduced by using larger wavelengths (i.e., MW) for which the scattering object becomes a few order of magnitudes larger than for direct measurement, allowing for easier technical solutions to control size, shape, and orientation. Another advantage of the analog MW approach is that the range of allowed scattering angle can include the exact forward direction. A limitation of this technique is that measurements can be done only for one particle size, shape, and orientation at the time with consequent large effort to obtain more commonly required results for polydispersions or other kind of ensemble-averaged results. A review on MW analog to light-scattering measurements can be found in Gustafson (2000).

SSOP of polydispersion, mixtures, and atmospheric volumes

Processes responsible for the presence in the atmosphere of aerosols and hydrometeors generate particles with different size (*polydispersion*), even in the case of homogeneous chemical composition. The concept of *size distribution* (SD) is introduced to describe the population of a polydispersion of atmospheric particulate as a function of the size. SDs of atmospheric scatterers are generally expressed with a single or with a combination of analytic functions (e.g., Deepak and Box, 1982). More commonly used are lognormal (Davies, 1974), power law (Junge, 1963), Gamma and Modified Gamma (Deirmendjian, 1964, 1969), and exponential (Marshall and Palmer, 1948). The SD for a given atmospheric scatterer depends on the process generating it; for this reason differences among the functions are mostly due to the type of scatterer: aerosols, ice/water nonprecipitating hydrometeors, and ice/water precipitating hydrometeors. In addition, the numbers of parameters needed to fully describe the SD (typically ranging from 2 to 4) is another important factor in the selection of the SD function. In general, the analytical function is asymmetric with respect to the average being bounded inferiorly by allowing only positive values of the particle size, while most of atmospheric processes of interest allows for a small probability of having large particles. SD may be expressed in terms of radius, surface, or volume according to the application. For example, for computation of mass transport, the volume representation gives a more direct information.

In principle, to describe the optical properties of atmospheric particulate in a given air volume, it is necessary

to know size, shape, orientation, and chemical composition of each single particle. With a similar approach, the knowledge of optical properties is clearly a problem with a huge number of unknowns. In order to be able to practically take into account the direct radiative effects of aerosols (a similar approach, apart for the chemical composition, is done for clouds), basic *aerosol components* have been identified, on the basis of experimental observations that are directly linked with the source processes responsible for generation of particulate in the atmosphere. A generic atmospheric volume is then assumed to contain a mixture of single aerosol components. On the basis of observations, *aerosol models* are defined as typical combinations of aerosol components that represent both the presence of sources and the effects of atmospheric processes (i.e., transport, aging) on the particulate generated by the sources.

A first well-documented and widely diffused review and summary of previous results on aerosols and fog optical properties in terms of models is due to Shettle and Fenn (1979). The developed database derived from this review activity has been the basis for aerosol database input in the set radiative transfer models (RTM) developed by the Air Force Geophysics Laboratory (LOWTRAN, MODTRAN, FASCODE) as well as from other RTMs.

Successively, a reference publication for aerosol models has been the book from D'Almeida et al. (1991) that in addition, to the Shettle and Fenn (1979) models, contained in an updated review of aerosol components and models. Moreover, one of the objectives of the volume was to define a global climatology of aerosol scattering properties for a set of given wavelengths. The information contained in D'Almeida et al. (1991) has been used to produce database and packages for computation of SSOP for mixture of components and/or models, for example, OPAC (Hess et al., 1998a) or Levoni et al. (1997).

Aerosol components are often classified on the basis of the interaction with atmospheric water vapor in:

- Hygroscopic particles (e.g., NaCl, nitrates, sulfates) which act as nuclei for the condensation of water vapor responding to changes in atmospheric relative humidity (RH) by absorbing and releasing water vapor as RH changes
- Nonhygroscopic particles (e.g., dust, carbon soot, hematite) which are relatively passive components responding to a wet ambient by accumulating a film of water at the surface

Such classification is important for the computation of optical properties because it determines the kind of mixing. *External mixing* implies that each component of a given aerosol class is represented by a different substance with its own size distribution and complex refractive index. The resultant SSOPs of the mixture are obtained as appropriate weighted averages of the SSOP of each component. *Internal mixing* implies that a single particle is a result of mixture of components, for example,

in a solution. In this case, the refractive index of the resulting mixture and the size of the obtained particle must be computed to compute the SSOP. Other kinds of mixing are, for example, *coated particles* (e.g., water droplet condensating over a soot particle) or touching or aggregated particles, that is, where the particle resulting from the mixture is formed by single particles with their own composition but physically in contact.

Similar to what is available for aerosols, database of optical properties for clouds has been also developed and distributed (e.g., COPE, Hess et al., 1998b).

Summary

Elastic scattering by aerosols and hydrometeors in the optical/infrared range of wavelengths is at the basis of a wide set of remote sensing techniques, both active and passive as well as ground based or from flying platforms. Further improvement of our knowledge of the radiative effects of scatterers in the atmosphere requires a better characterization of the angular distribution of scattering from nonspherical particles, the absorption properties of atmospheric scatterers in the wide range of wavelengths of interest for Earth radiation budget. This improves the capability of remote sensing techniques, particularly in terms of profiling and estimating size distribution parameters at a global scale. It is reasonable to expect, in the near future, an increase of occurrence of active remote sensing instrumentation on satellite missions. Nevertheless, because of the nature of the scattering process, the angular- and polarization-derived information measurable from passive remote sensing instruments has not yet been fully exploited.

Definition

The classification of remote sensing images and the corresponding generation of land cover maps are perhaps the most common applications in remote sensing. In general, the aim of a land cover classification is the assignment of each pixel within the imagery to a specific information class (e.g., forest areas). In general, this is performed by methods of machine learning and pattern recognition. Pattern recognition can be defined as a technique to classify data (patterns) based either on a priori knowledge or statistical information extracted from the patterns.

Introduction

During the last decades, remote sensing became a valuable and important tool to monitor the Earth. Overall it had a significant impact on the acquisition and analysis of environmental data, and the manner how the planet is observed was revolutionized (Rosenqvist et al., 2003). Nowadays remote sensing imagery and corresponding products, such as land cover maps, are helping to support environmental monitoring systems and decision making in the context of different multilateral environmental treaties, such as the Kyoto Protocol and the European initiative Global Monitoring for Environment and Security,

GMES (Peter, 2004; Rosenqvist et al., 2003; Backhaus and Beule, 2005).

The classification of remote sensing data and, thus, the generation of land cover maps are the most common applications. Consequently, the development of adequate classification methods is an ongoing research topic. This entry briefly reviews well-known image classification methods as well as other state-of-the-art methods. However, a detailed discussion of all available algorithms and concepts, which are introduced in the field of pattern recognition and remote sensing, would be beyond the scope of this entry. The interested reader is referred to one of the several textbooks, e.g., Richards and Jia (2006) and Duda et al. (2002). An overview to the classification of multisource remote sensing data is given in Chapter x (Waske and Benediktsson 2014).

Classification of remote sensing data

General definitions

The data, the remote sensing imagery, consist of pixels (i.e., picture elements) and provide different characteristics at different wavelength (in case of multispectral and hyperspectral imagery). When dealing with land cover classifications, we aim at the differentiation between several land cover classes, and a classification algorithm is used to differentiate the types of patterns.

A pattern can be assumed as a unique structure or attribute (e.g., the pixel values), which is capable to describe a specific phenomenon (e.g., a land cover type). During the classification, unknown patterns (i.e., pixel) are assigned to a predefined class or they are combined to unknown clusters, depending on their similarity. An n -dimensional pattern (or pixel) in the context of remote sensing is represented by an n -dimensional random

variable or feature vector X , where n denotes the number of available features (e.g., image bands):

$$X = \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix} \quad (1)$$

where x_i , $i = 1, \dots, n$ corresponds to the i -th measurement (the measurement from the i -th wavelength band or sensor channel) on a given ground resolution element. The classification is usually done in a so-called *feature space* (Richards and Jia, 2006).

The field of pattern recognition and classification is highly linked with the area of machine learning. Machine learning refers to the development of methods that optimize their performance iteratively by learning from our data. When performing a land cover classification, we are usually dealing with descriptive models, which enable to distinguish between different classes of patterns. Various classifier concepts have been introduced, which can be sorted into different groups, such as supervised, unsupervised, parametric, and nonparametric methods (Waske and Benediktsson 2014).

Most approaches belong to the group of supervised classification, where a set of labeled samples is available. The objective is to predict y , the class membership of a new and unknown sample x , using the mapping function f . Machine learning theory aims at estimating the functional f from some prior data as the labeled training data.

In contrast to this, in *unsupervised* classification, only the data are available, without any class membership information. In this case, the classification algorithm describes how the data are clustered within the feature space and is enabled to identify unknown structures, such as natural groups within the feature space. Consequently, pixels that belong to different clusters are more dissimilar to each other compared to pixels within the same clusters (Jain et al., 2000). In addition to unsupervised and supervised approaches, *semi-supervised* techniques have been introduced (Shahshahani and Landgrebe, 1994; Jackson and Landgrebe, 2002). In this case, the learning is based not only on the training samples but also on some additional data without any ground truth knowledge. With that, the classification accuracy has been showed to increase, compared to a supervised classification. Besides the dichotomy of supervised and unsupervised, classifiers can also be grouped into *parametric* and *nonparametric* techniques. The widely used supervised maximum likelihood classifier is a parametric approach. This approach is based on the assumption that the probability density function for each class is multivariate, and often a Gaussian distribution is assumed. Contrary to this approach, nonparametric methods are not constrained to any assumptions on the distribution of input data. Hence, techniques such as neural networks, decision trees, and

support vector machines can be applied, even if the class-conditional densities are not known or cannot be estimated reliably. Thus, in the context of multitemporal and multisource data sets or high-dimensional imagery with a limited number of training samples, such techniques can be more adequate in terms of the classification accuracy.

Unsupervised techniques

In general, unsupervised techniques or cluster algorithms assign pixels to specific classes without having a prior knowledge of the classes, by measuring similarities between different pixels in a learning process which most often is iterative. After measuring the similarity between pixels, the algorithm merges the individual pixels to groups. Although different, similar measurements have been introduced in the literature, the Euclidean distance is perhaps the widely used measure when remote sensing data are clustered.

It is worth to underline that the clustering of a particular data can result in different potential cluster combinations, e.g., if the algorithm is initialized with different values. Thus, some kind of evaluation is required to assess the quality of the generated clusters, such as the squared error measure (Richards and Jia, 2006). The cumulative distance of each pixel to its cluster center is determined individually within each cluster and finally the total sum over all clusters is calculated.

In contrast to supervised methods, unsupervised approaches have the advantage that they enable the image classification without having prior knowledge (i.e., training data). On the other hand, the algorithm does not provide any final membership decisions, and in general, the analyst must assign a specific class label to each cluster. Thus, the quality of the final classification might be affected by the knowledge and experience of the analyst.

Well-known cluster methods include the k-means and the ISODATA (e.g., Duda et al., 2001; Richards and Jia, 2006). The latter optimizes the individual clusters during the learning process by splitting and merging operations. Both approaches assign each pixel to only one group, whereas concepts such as fuzzy c-mean clustering provide a degree of membership to all clusters for each pixel.

Supervised methods

As mentioned above, a pixel (or pattern) in the context of remote sensing is represented by an n -dimensional vector X . This representation in the feature space $\mathcal{R}^n$ is used by a classification algorithm to assign unknown pixels to one of c land cover classes $\Omega = \{\omega_i\}$, for $i = 1, \dots, c$, using training data. The differentiation between individual classes is based either on the similarity to a certain class or by decision boundaries, which are constructed in the feature space.

Maximum likelihood classification

In the statistical framework, a two-class classification problem can be formulated as

$$P(\omega_i|x) \underset{\omega_j}{\overset{\omega_i}{>}} P(\omega_j|x), \quad (2)$$

with $P(\omega_i|x)$ being the *posteriori* (or conditional) *probability* that the true class of x is ω_i . Following Equation 2, the sample x is classified to class ω_i if $P(\omega_i|x) > P(\omega_j|x)$. Equation 2 provides the basic concept for the well-known maximum likelihood classifier (MLC).

However, this requires the knowledge of $P(\omega_i|x)$, which is generally unknown and needs to be estimated from the training data. Following the well-known Bayes theorem, the posteriori probabilities can be described by prior and the class-conditional probabilities and Equation 2 can be rewritten as follows:

$$p(\omega_i)p(x|\omega_i) \underset{\omega_j}{\overset{\omega_i}{>}} p(\omega_j)p(x|\omega_j), \quad (3)$$

with $p(x|\omega_i)$ as the *class-conditional* probability density function and $p(\omega_i)$ the prior probabilities. The prior probability describes the probability that class ω_i is present in our image. Let us assume that it is known that 40 % of the image to be classified is covered by class ω_i . Then, the prior would be $p(\omega_i) = 0.4$, indicating that in this case, we would have a 40 % probability of finding a pixel x belonging to class $p(\omega_i)$.

The approach assumes that our different feature vectors have specific probability densities $p(x|\omega_i)$, which are conditioned on the observed land cover classes. Therefore, a pixel x belonging to class ω_i is assumed to be an observation, which is taken randomly from the class-conditional probability density function $p(x|\omega_i)$. Consequently, differences between two classes ω_i and ω_j result in differences between the corresponding likelihoods (density functions) $p(x|\omega_i)$ and $p(x|\omega_j)$ (Duda et al., 2001).

To determine the likelihoods from the training data, it is usually assumed that the distributions follow the form of a multivariate normal (Gaussian) model. It is important to note that other models can be assumed, but many processes can be described by a normal model. Moreover, this type of model simplifies the approach, because the model only has two parameters and is described by the mean and the covariance matrix of the training samples:

$$p_i(x|\omega_i) = \frac{1}{\sqrt{(2\pi)^n |\Sigma_i|}} \times \exp \left[-\frac{1}{2} (x - \mu_i)^T \Sigma_i^{-1} (x - \mu_i) \right] \quad (4)$$

with μ_i as the mean vector from class ω_i , covariance matrix Σ_i , and the inverse Σ_i^{-1} , and T as transpose

operator. By taking logarithms of both sides in Equation 3 and following Equation 4, the (Gaussian) maximum likelihood classifier can be finally described by

$$(x - \mu_i)^T \Sigma_i^{-1} (x - \mu_i) + \ln |\Sigma_i| \underset{\omega_j}{\overset{\omega_i}{>}} (x - \mu_j)^T \Sigma_j^{-1} \times (x - \mu_j) + \ln |\Sigma_j|, \quad (5)$$

under the assumption that all classes have equal prior probabilities.

Decision tree classifiers

Decision trees (DT) are a nonparametric method, which can handle different data sets, including categorical variables. The relative structural simplicity of DT and the relatively short training time (compared to computationally complex approaches) are some advantages of a DT classifier (Friedl and Brodley, 1997; Pal and Mather, 2003). In addition, the DT classification scheme allows a direct interpretation of class membership decisions with respect to the impact of individual features. Although a standard DT may be considered limited under some circumstances, the general concept is interesting and the classifier performance in terms of accuracies can be further increased by classifier ensembles or multiple classifier systems (Briem et al., 2002; Gislason et al., 2006; Waske and Braun, 2009).

A general introduction on DT is, e.g., given by Safavian and Landgrebe (1991) and a brief overview is given below. During the construction of the DT (i.e., the classifier training), the training set is successively separated into an increasing number of smaller, more homogenous groups. A DT consists of a root node, which includes all samples, internal nodes with a split rule, and the final leaf nodes, which refer to the different classes. This hierarchical concept is different from other classification approaches, which usually use the entire features space at once and make a single membership decision per class. Moreover, the training process may lead to a splitting of thematic classes (i.e., land cover classes) into several final nodes (Figure 1).

Most applications are based on binary DT, which use, contrary to a multivariate DT, only one feature for the construction of each split node. To determine the split rule, the classifier aims at generating the descendent nodes as pure as possible. A node is assumed to be pure, when all pixels within that node belong to the same class, resulting in an (im)purity value of 0. In contrast, the maximum (im)purity value is reached, if all samples are equally distributed over the classes. A common measurement criterion in this context is Breiman et al. (1984), *Gini index*, which is described as follows (Duda et al., 2001):

$$Gini(S) = \sum_{i=1}^c p_{oi}(1 - p_{oi}), \quad (6)$$

Pattern Recognition and Classification, Figure 1 Schematic flowchart of a decision tree, for a three-class example. At each internal node, there is a split rule S to successively separate the data into smaller groups. Finally, the data ends up in one of the leaf nodes, which refer to a specific land cover class.

with c as the number of classes and $p_{\omega i}$ as the probability of class ω_i at node S :

$$p_{\omega i} = \frac{l_{\omega i}}{L}, \quad (7)$$

where $l_{\omega i}$ the number of samples belonging to class ω_i and L as the total number of samples within the training set. The Gini index is used to determine the largest homogeneous group within the training data and discriminate it from the rest. The impurity of all potential groups is summed, and the split rule that causes the maximum reduction in impurity, i.e., which generates the most homogenous node, is selected.

To avoid complex tree structures and thus over-fit the training data, different approaches are considered when dealing with DT. Pre-pruning methods stop the tree induction, e.g., when the number of samples within a node becomes very small or the improvement in the accuracy is too low. Post-pruning methods, on the other hand, are applied after a DT is fully grown. They eliminate inefficient and weak branches and consequently generate a more compact classifier (Esposito et al., 1997).

Neural networks

Neural networks have been used for diverse remote sensing applications, including the classification of

Pattern Recognition and Classification, Figure 2 Schematic diagram of a neural network, with one hidden layer.

multisource data sets and high-dimensional imagery (Benediktsson et al., 1990, 1995; Paola and Schowengerdt, 1995; Bruzzone et al., 2004). As other machine learning approaches, e.g., support vector machines and decision trees, neural networks have the advantage that they are not based on any underlying statistical model of the data, the Gaussian maximum likelihood classifier, for example.

A neural network can be considered as an interconnection of neurons, where each neuron receives input signals, representing the activity at the input or the momentary frequency of neural impulses delivered by another neuron to this input (Bishop, 1995). The function at a neuron o_i can be described as:

$$o_i = Cf(w_i x - \vartheta_i), \quad (8)$$

where C is a constant, x a vector of inputs, and f a nonlinear function, the threshold function, which takes the value 1 for positive argument and 0 for negative arguments. The w_i are weights and ϑ_i are thresholds, with $i = 1, \dots, c$, where c is the number of (land cover) classes.

An adaptive training process is used to determine the weights, using a set of training samples as input. For each sample, the network gives an output response, which is compared to the desired and known output. This information is used to modify the weights in the neural network. When the accuracy cannot be increased any further or the error is reduced to a predefined threshold, the adaptive process ends. A neural network with one hidden layer can be used to differentiate linearly separable data, whereas two or more layers enable the definition of more complex decision boundaries. A schematic overview of a fully connected feedforward neural network is shown in Figure 2.

The backpropagation algorithm (or the multilayer perceptron network) is the best-known neural network algorithm in the context of classification of remote sensing data (for a review see Paola and Schowengerdt, 1995). This multilayer network enables the discrimination between classes, which are not linearly separable. Nevertheless, the approach has some serious drawbacks, such as among others the slow convergence of the algorithm. In contrast to this, radial basis function (RBF) networks can overcome some of the problems with the backpropagation and have a much faster training time (Bishop, 1995; Bruzzone and Prieto, 1999).

Support vector machines

Support vector machines (SVM) have been used for successfully for the classification of diverse remote sensing data sets (Huang et al., 2002; Foody and Mathur, 2004; Melgani and Bruzzone, 2004). The nonparametric approach is particularly interesting for classifying multisource and high-dimensional data sets (Pal and Mather, 2006; Waske and Benediktsson, 2007).

The SVM differentiates two classes by fitting an optimal separating hyperplane to the training samples of two classes in a multidimensional feature space. It can be assumed as an approximate implementation of Vapnik's structural risk minimization principle (Vapnik, 1999). In different remote sensing studies, the SVM has performed efficiently with small training sets, even when classifying high-dimensional imagery (Pal and Mather, 2006). Nevertheless, a sufficient number of training samples are required to ensure the availability of adequate samples for the classifier training (Foody and Mathur, 2004). Moreover, the classifier performance of the SVM can also be affected by the curse of dimensionality in high-dimensional feature spaces and with small or suboptimal training sets (Waske et al., 2010).

The SVM is able to separate complex (e.g., multimodal) class distributions in high-dimensional feature spaces by mapping the data with nonlinear kernel functions. Thus, for linearly not-separable cases, the input data are mapped into a high-dimensional space, wherein the newly distributed samples enable the fitting of a linear hyperplane. Whereas the SVM was originally developed as a supervised classifier, the concept was extended by semi-supervised concepts (Chi and Bruzzone, 2007; Ghoggali et al., 2009) and used for classifier ensembles (Waske et al., 2010).

A detailed introduction on the general concept of the SVM is given in Burges (1998); an overview in the context of remote sensing can be found, e.g., in Huang et al. (2002), Melgani and Bruzzone (2004), and Plaza et al. (2009).

For a binary classification problem in a n -dimensional feature space $\mathcal{R}^n$, the training vectors are given by $x_i \in \mathcal{R}^n, i = 1, 2, \dots, L$, with L training samples and a vector $y \in \mathcal{R}^L$ with the corresponding class labels

$y_i \in \{+1, -1\}$. The SVM aims to solve the following primal problem:

$$\begin{aligned} \min_{w, b, \xi} \quad & \frac{1}{2} w^T w + C \sum_{i=1}^L \xi_i \\ \text{subject to} \quad & y_i (w^T \phi(x_i) + b) \geq 1 - \xi_i \\ & \xi_i \geq 0, i = 1, \dots, L. \end{aligned} \quad (9)$$

Its dual is

$$\begin{aligned} \min_{\alpha} \quad & \frac{1}{2} \alpha^T Q \alpha - e^T \alpha \\ \text{subject to} \quad & 0 \leq \alpha_i \leq C, \quad i = 1, \dots, L \\ & y^T \alpha = 0, \end{aligned} \quad (10)$$

with e as the vector of all ones, C as regularization parameter, Q is an L by L positive semidefinite matrix, and $Q_{ij} = y_i y_j K(x_i, x_j)$ and $K(x_i, x_j) = \phi(x_i)^T \phi(x_j)$ are the kernel. Thus, the training vectors x_i are implicitly mapped into a higher-dimensional feature space by ϕ . The class membership is based on the sign of the final decision function $f(x)$:

$$f(x) = \sum_{i=1}^L y_i \alpha_i K(x_i, x_j) + b. \quad (11)$$

The kernel strategy enables to work within the newly transformed feature space, without explicitly knowing ϕ , but only the kernel function. A widely used kernel in remote sensing applications is the Gaussian RBF kernel:

$$K(x_i, x_j) = \exp(-\gamma \|x_i - x_j\|^2), \quad (12)$$

where γ denotes the width of the Gaussian RBF.

Besides the standard kernel functions, some specific kernels have been introduced for spectral-spatial classifications (Camps-Valls et al., 2006) and multisource and multitemporal applications (Camps-Valls et al., 2008).

The training process requires the estimation of the γ and the regularization parameter C . Many approaches have been introduced, which use a leave-one-out cross-validation procedure for an automatic model selection (Chapelle et al., 2001; Chung et al., 2003).

The output of a SVM classifier is different from other algorithms. Whereas classifiers such as a decision tree directly provide a final class label and the MLC results in probability measures, the SVM provides distance measures between each pixel and the separating hyperplane.

Due to the binary nature of SVM, a multiclass decomposition strategy is necessary to handle multiclass problems. Although it is possible to solve multiclass problem directly (Foody), two main strategies exist for solving multiclass problems: A c -class problem is divided into several binary problems. Following a one-against-one (OAO) strategy, classification problem with c classes is separated into $c(c-1)/2$ subproblems, and $c(c-1)/2$

SVM classifiers are trained, one for each possible pair of classes ω_i and ω_j , with $1 \leq i < j \leq c$. In contrast to this, the one-against-all strategy (OAA) is based on a set of c classifiers and separates each class ω_i from the rest $\Omega - \omega_i$. The maximum decision value $f(x)$ determines the final class membership.

In contrast to the above strategies, it is possible to transfer the original outputs into class probabilities (Lin et al., 2003; Wu et al., 2004). Thereby, probability values can be used to determine the final class membership. However, the reliability of these pseudo probabilities can be questioned (Foody, 2008; Roscher et al., 2012b) and the use of alternative probabilistic models, such as import vector machines (e.g., Roscher et al., 2012a), is interesting.

Summary

Land cover classification is perhaps the most widely used application in remote sensing image analysis. In this entry, some well-known and state-of-the-art classifier algorithms were presented. Regarding recent and upcoming Earth observation missions, the availability of remote sensing data will increase and a variety of diverse data types can be expected for the future. Due to enhanced missions with increased revisit times and better spatial resolutions, the potential of the use of these approaches is increasing further and thereby remote sensing applications will become even more attractive. Thus, the classification of remote sensing data is and will continue to be an important research topic in the field of remote sensing.

POLAR ICE DYNAMICS

James Maslanik
Department of Aerospace Engineering Sciences,
University of Colorado, CCAR, Boulder, CO, USA

Synonyms

Glacier motion; Ice drift; Ice rheology; Ice sheet motion; Ice transport; Sea ice motion

Definition

Polar ice. Ice cover found in the polar regions, with “polar” typically defined as locations north or south of the Arctic and Antarctic Circles, respectively (latitudes of 66.56083 °N and 66.56083 °S). The definition includes ice that forms on the oceans (sea ice), glaciers, and ice sheets.

Ice dynamics. Motion of ice cover, including large-scale patterns of ice transport, fine-scale movement of ice floes, and the interactions of ice and forcings such as winds and ocean currents.

Introduction

To many, the “polar ice caps” are viewed as areas of permanent, relatively static, and stable ice cover. In fact, all areas of ice on the oceans and land move at different rates, ranging from the relatively fast transport of sea ice of typically between 5 and 20 km/day (e.g., Emery et al., 1997; Heil and Allison, 1999) to the movement of glaciers and ice sheets (as much as 30 m/day for the fastest advancing glaciers (Joughin et al., 2004) to 1 m/year for inland ice sheets). The dynamics of sea ice is driven by the combination of winds, ocean currents, and, to a lesser degree, tides and ocean tilt (McNutt and Overland, 2003; Leppäranta, 2004; Feltham, 2008). These forcings can vary substantially over periods of hours to days. Studies of ice floe interactions, such as the production of open water areas within the ice pack (leads and polynyas), require remote sensing observations at daily or even hourly intervals, while investigations of seasonal variability in large-scale patterns of sea ice drift involve mapping ice motion on weekly or monthly scales. In contrast, the accumulated mass in glaciers and ice sheets advances under the influence of gravity, with the rate of movement controlled by slope, friction with underlying or adjacent rock, and by the mechanical properties of the ice, and require measurements over years.

There are two main aspects to the study of ice dynamics using remote sensing: direct measurement of ice displacement over time (ice motion mapping) and the analysis of specific features of the ice cover (geophysical classification) such as sea ice ridges, ice leads, crevasses, and glacier calving associated with ice motion. The former approach describes patterns and speed of ice motion, while the latter approach provides information on geophysical characteristics of the ice, such as strength, thickness, and age, without direct measurement of displacement.

The basis for observing ice movement using remote sensing methods involves the detection of the position of particular ice surface features or characteristics through comparison of images acquired at different times. The goal is to detect the position of specific surface features or general ice characteristics in each image and then to calculate the displacement of the features from one image to the next. The expected rate of ice movement, the particular characteristics of the features or characteristics to be tracked, and the spatial resolution and geolocation accuracy of the remotely sensed data determine the required image spatial resolution, the time difference between images, and the particular analysis methods that are applied. In contrast, analysis of geophysical characteristics of specific ice features does not necessarily require sequential imagery. The discussion here focuses on remote

sensing methods to measure ice displacement. Examples of methods to study geophysical ice features in remotely sensed data are described by Carsey (1992) and Lubin and Massom (2006).

Applicable data types

Any remotely sensed data that are capable of depicting ice surface features and, for ice motion mapping, cover the same area with sufficient elapsed time between data acquisitions can be used to study ice dynamics. For investigations of sea ice dynamics, visible- and thermal-band imagery from medium-resolution sensors such as the Moderate Resolution Imaging Spectroradiometer (MODIS) and Advanced Very High Resolution Radiometer (AVHRR) (Ninnis et al., 1986; Maslanik and Barry, 1990; Meier et al., 1997) provides a good combination of spatial and temporal resolution for ice motion detection. However, due to the limiting effects of frequent cloud cover and the long polar night, microwave imagery is the most common data type used for sea ice dynamics studies. Microwave data typically used include synthetic aperture radar (SAR) imagery (Fily and Rothrock, 1987; Carsey, 1992; Haarpaintner et al., 2000; Kwok et al., 2003), passive microwave imagery (Agnew et al., 1997; Emery et al., 1997; Kwok, 2008), and radar scatterometer data (Haarpaintner, 2006; Haarpaintner and Spreen, 2007). Due to the slower movement of glaciers and ice sheets, less frequent temporal sampling is required; so higher-resolution imagery such as that provided by Landsat and ASTER are effective for measuring ice movement (Kaab et al., 2005; Dowdeswell and Benham, 2006). If sufficiently geolocated, any other data types that can be used to detect surface features, such as laser altimeter products (Abdalati and Krabill, 1999), can be used to map displacement of ice features. In turn, ice motion information can be used to calculate additional geophysical information such as ice age (e.g., Maslanik et al., 2007).

The most commonly used approaches for ice motion detection are feature-based tracking, correlation-based tracking, and flow measurement using interferometry.

Feature tracking

Feature tracking involves detecting distinct surface features present in the ice cover and then following the displacement of these features from one sequential image to the next. It is particularly effective compared to correlation methods when some aspect of the features, such as rotation of ice floes or opening and closing of crevasses, tends to change rapidly relative to the time spacing between images. A variety of digital preprocessing steps including spatial resolution enhancement, filtering and edge detection to accentuate features, image thresholding, and classification can help simplify the detection of features from one image to the next. A range of feature-detection methods has been applied to ice mapping. Commonly used approaches include wavelet mapping (Liu et al., 1999; Zhao et al., 2002; Zhao and Liu, 2007) and suites

of hierarchical steps to identify individual features based on radiometric or geometric characteristics (e.g., Kwok et al., 1990; Luckman et al., 2007). Other methods such as optical flow analysis (Gutierrez and Long, 2003) can be effective but are less commonly used.

For individual case studies and situations where relatively few images are involved, visual interpretation is an effective approach for mapping ice dynamics (e.g., Lucchitta and Ferguson, 1986). The interpreter can apply a variety of image enhancement techniques such as edge detection and noise removal to highlight features, switch rapidly back and forth between images to visually highlight change, and manually adjust geolocation of each image using features that are fixed in location between the two image dates.

Image correlation

This approach, also referred to as hierarchical correlation or maximum cross-correlation, involves determining the spatial correlation between segments of sequential images. It can be considered a method of feature tracking (Pritchard et al., 2005) but is better viewed as a means of tracking aggregate characteristics of combinations of surface features. The approach is commonly applied to sea ice tracking using passive microwave and SAR imagery (Fily and Rothrock, 1987; Holt et al., 1992; Emery et al., 1997; Agnew et al., 1997; Kwok et al., 1998; Thomas et al., 2004; Kwok, 2008) and scatterometer data (Liu and Cavalieri, 1998; Zhao et al., 2002; Haarpaintner, 2006) but has also been used to map glacier motion (e.g., Bindenschadler and Scambos, 1991; Scambos et al., 1992). The latter application is sometimes referred to as speckle tracking when SAR imagery is used (e.g., Joughin et al., 2004), since it compares correlations in patterns of SAR backscatter speckle.

Interferometry

Lateral displacement of ice surfaces can also be mapped using interferometric methods applied to phase information available in sequential SAR imagery combined with elevation data (Goldstein et al., 1993; Kwok and Fahnestock, 1996; Smith, 2002; Dietrich et al., 2007). Interferometric SAR (inSAR) methods are most commonly applied to glaciers and ice sheets (e.g., Joughin et al., 1996; Rignot et al., 2004; Rignot and Kanagaratnam, 2006) but are also applicable to sea ice in some cases, such as for the study of subtle changes in relatively stable shore-fast ice that would otherwise be too small in scale to be detected using feature extraction or correlation methods (Dammert et al., 1998).

Summary

Applications of remote sensing methods to the study of ice dynamics are widespread and highly effective. Techniques used range from tracking of individual features in the ice surface to use of interferometry to extract patterns of ice transport. Nearly every type of imagery, as well as some

non-imaging data such as laser altimetry, has been applied to the important task of observing and understanding the dynamics of sea ice, glaciers, and ice sheets.

POLAR OCEAN NAVIGATION

Lawson Brigham
University of Alaska, Fairbanks, AK, USA

Synonyms

Ice navigation; Polar ship routing; Sea ice monitoring

Definition

Polar ocean navigation. Ship navigation through waters in the Arctic and Southern oceans covered with sea ice and icebergs.

Introduction

Modern remote sensing is critically important to ship navigation in all polar seas. With its broad array of sensors and applications, the field of remote sensing has revolutionized the ability of ships to effectively and safely navigate in ice-covered waters. Expanded use of remote sensing technologies has also enhanced polar marine safety and marine environmental protection. The application of remote sensing to ship navigation began with the development of radar. Early marine radars from the Second World War provided evidence of their ability to detect ice edges, small ice floes, and icebergs. As shipboard radars advanced, sea ice features could be detected several nautical miles from the ship, although a key limitation was that the return of sea ice could be masked by the normal sea return (the high-intensity echoes or clutter) on many systems. Small sea ice features could be lost in the sea return and escape detection; however, larger icebergs and ice

floes could generally be detected by most shipboard radar systems. Enhanced radar processing technology (producing high-quality, low-intensity radar video images) has recently been developed to greatly improve conventional marine radar for use in ice navigation.

The potential ice-monitoring capability of meteorological satellites was realized with the launch of the US satellite TIROS I in April 1960. The early visible sensors were limited to daylight and cloud-free conditions, and therefore, useful ice information from visible images for ship operations was infrequent. Since the polar regions are characterized by long periods of winter darkness and cloudy conditions, researchers recognized that microwave observing systems might be more advantageous since microwaves can penetrate clouds and are independent of light conditions (Rees, 2006). Satellite microwave sensors were developed by the Soviet Union and United States, and these were flown in the late 1960s and early 1970s, opening a new era of synoptic and all-weather observations for polar navigation. Satellite passive microwave radiometers have become the backbone of global sea ice monitoring since the late 1970s, providing daily information on sea ice coverage in the Arctic Ocean and around Antarctica. This large-scale ice information has been incorporated in sea ice charts developed at the national ice centers which pass their ice products to marine operators in both polar regions. Active microwave systems – real-aperture side-looking radar (SLR) and synthetic aperture radar (SAR) – were used during the 1970s to the early 1990s for aircraft ice monitoring of Arctic regions with marine traffic (Falkingham, 1991). Satellite SLR systems were also used by the Soviet Union to monitor sea ice along the Northern Sea Route during the 1980s and 1990s (Alexandrov et al., 2004; Johannessen et al., 2007). However, it has been the successful development of satellite SAR in the 1990s that has provided the ice centers and polar navigators with high-resolution ice imagery. A series of satellites with SAR sensors – ERS-1 (1991) and ERS-2 (1995) of the European Remote Sensing program, the Canadian RADARSAT-1 (1995) and RADARSAT-2 (2007), and the European ENVISAT (2002) – have provided high-resolution SAR images that have enhanced ice charting and onboard ice information (Bertoia et al., 1998; Tsatsoulis and Kwok, 1998).

Levels of ice information for polar navigation

Ship navigation through ice in polar seas generally requires two basic levels of information aboard ship: tactical, or information required for immediate navigation such as course alteration and maneuvering, and strategic, or information required for daily track planning and course decision-making. Tactical and strategic ice information can come from the ship's radar systems and from satellite data (passive microwave data, not SAR) which can be transmitted and received directly aboard ship in near real time (within minutes of the satellite passing the ship). A third level of information can be considered operational

planning which includes information of both short and long time scales. This type of information, heavily dependent on remotely sensed imagery, is typically developed ashore in ice or weather centers that provide polar mariners with forecasts and generate predictions for ice conditions (days, weeks, and season ahead of transits), weather conditions, transit difficulty, and even optimized routes. These three categories of ice information needs for navigation in both polar regions are broadly defined, and there can be considerable overlap of sea ice spatial scales and remote sensor performances among the three.

Key sea ice and climatological parameters that are critical to ice navigation and drive sensor requirements include the following:

- Topography (ice ridges, rafts, leads): tactical and strategic information
- Thickness: tactical, strategic, and operational planning
- Concentration: tactical and strategic
- Ice Floe Size and Small-Scale Features: tactical
- Snow Cover: tactical
- Strength (ice age, first- and multi-year ice): tactical, strategic, and operational planning
- Ice Drift: strategic and operational planning
- Regional Climatology (especially wind velocities): operational planning

Each of these parameters has varying spatial and temporal scales (Hutchings and Bitz, 2005). Thus, several remote sensing instruments may be required to provide adequate information about a particular sea ice characteristic. The challenge for the shipboard ice navigators and the shore-based ice centers is to combine an integrated strategy of remotely sensed observations (across multiple spatial and temporal scales) with ice forecasts that are based on sea ice models.

Observing systems

Table 1 is a summary of the general categories of observing systems used early in the twenty-first century for ice

navigation. All are based on the remote sensing capabilities of satellite sensors, airborne sensors, and shipboard radars. Included are selected key characteristics on coverage, image resolution, scale, and delivery issues. Data transmission remains one of the key challenges or constraints on remote sensing information used for ice navigation. The ultimate timeliness of sea ice images and product analyses is crucial to their effective use in tactical navigation. Low-resolution satellite images, both passive microwave and optical (visible and infrared), have been received directly aboard icebreakers and other polar ships since the mid-1980s. Onboard receivers track polar orbiting satellites and download multiple, daily (and twice daily) images from passive microwave and optical sensors; most of this information (12–25 km spatial resolution) has limited use for tactical or immediate navigation, although it is of significant value for planning and regional understanding of weather and sea ice conditions. In contrast, high-resolution raw data (from active microwave sensors such as SAR) – with high information content to 10 m resolution including ice concentration, ice topography, and ice types – must be received by ground stations in the high latitudes and then passed to ice centers for processing. The ice centers then transmit ice analysis products and processed imagery to polar ships.

During 1991–2005 Norwegian and Russian researchers of the Nansen Center conducted a series of pioneering demonstrations applying the use of satellite SAR images for summer and winter navigation along Russia's Northern Sea Route. ERS-1/ERS-2, RADARSAT-1, and ENVISAT images were successfully used to assist winter convoys (Alexandrov et al., 2000; Johannessen et al., 1997), including a major expedition (ARCDEV) exploring the potential for year-round tanker traffic from the Ob River to Europe (Pettersson et al., 1999). The SAR images were used onboard by icebreaker navigators to select favorable sailing routes based on the high-resolution ice imagery; the images could also be inserted into the ship's electronic chart display system.

Polar Ocean Navigation, Table 1 Selected observing systems for ice navigation

Observing system	Coverage/image resolution	Scale/delivery issues
Satellite systems: low resolution	Large-scale: 10–50 km	Large-scale information Daily delivery
Passive microwave and scatterometers	Sea ice edge, concentration, ice drift	Real-time delivery aboard ship No thickness data
Satellite systems: high resolution Synthetic aperture radar (SAR), optical and infrared (IR)	Regional and local scale: 50 km down to 10 m Ice floes, surface roughness ridges	Small-scale information Near-real-time delivery from ice and weather centers Ice thickness information limited
Airborne systems: high resolution SAR, LIDAR, and electromagnetic induction	Higher resolution Ice types, ice floes, ice roughness, ridges (height, freeboard, thickness)	Small-scale information along flight paths Near-real-time delivery
Shipboard radar	Local sea ice and iceberg coverage near ship	Small-scale information Real-time information

Role of the ice centers and commercial providers

Polar ocean navigation and remote sensing are closely linked through the national ice centers. These centers (such as the Canadian Ice Service, Russia's Arctic and Antarctic Research Institute, the Norwegian Meteorological Institute, the US National Ice Center, and other members of the International Ice Charting Working Group or IICWG) provide sea ice analyses and forecast products to a host of marine users operating in the Arctic and Antarctic. Most sea ice and weather information a polar ship mariner receives has been produced at an ice center or regional meteorology office, and most of these products are based on satellite imagery (from passive and active sensors) provided to the ice centers. Ice products are also based on aerial and shipboard observations, in situ sensors, and the use of computer modeling; however, satellite remote sensing remains the best means of observing remote, polar areas with extensive sea ice coverage. The operational ice service centers and the users are generally concerned with four requirements: the ice features to be measured, the spatial scale of the observations, the frequency of the observations, and the delivery time between the observations and when useful sea ice information will be received aboard ship.

Commercial providers have also developed services to provide satellite images and other products for tactical use by polar ship operators. For example, a commercial Norwegian enterprise, Kongsberg Satellite Services or KSAT (jointly owned by the government Norwegian Space Centre and the private Kongsberg Defence & Aerospace), can provide high-resolution satellite images of sea ice to an Internet connection or satellite phone anywhere in the world. KSAT can send European ENVISAT and Canadian RADARSAT SAR images which contain detailed and time-sensitive sea ice information that can be used for planning the safe and most effective route for a ship through the existing ice conditions. Commercial services will support polar ocean navigation more routinely in the future as more marine users require near-real-time and high-resolution imagery that may potentially include better sea ice thickness information.

Future challenges and requirements

Satellite remote sensing of sea ice and ocean climatology will play increasing key roles in polar ship navigation, especially in the Arctic Ocean where marine access is improving with the marked retreat of summertime sea ice. Increased repeat satellite coverage and data fusion (to fill spatial-temporal gaps) will be required so that higher-frequency ice information can be achieved. The greatest challenge, and perhaps the most pressing need by ice navigators, is for enhanced sea ice thickness measurements by satellite and airborne remote sensors. The CryoSat-2 satellite launched in 2010 by the European Space Agency carries an advanced radar altimeter capable of higher-resolution measurements of sea ice

thickness. The altimeter measures the freeboard of the ice, or the height of the ice above the ocean surface. Improved regional and local sea ice thickness maps will necessitate continued research into improving airborne electromagnetic measurements (Wadhams and Amanatidis, 2006).

Satellite C-band SAR sensors will continue to be improved resulting in the enhancement of daily and weekly Arctic sea ice charts (Johannessen et al., 2007). Higher-resolution SAR images should provide levels of detail for small sea ice features sufficient for ice centers to provide future charts with transit difficulty and route optimization information on a regional scale. The use of expert systems and other artificial intelligence technologies will assist in the improvement of sea ice features for multiple-scale, remotely sensed images. Current and future improvements for shipboard marine radars include requirements for enhanced radar image processing and high-resolution display systems. Real-time, tactical sea ice and iceberg information at the local scale should improve. In summary, the use of remote sensing in ship navigation throughout Arctic and Antarctic waters during the twenty-first century will be pervasive and ultimately indispensable to safe and efficient polar marine operations.

CIESIN, Columbia University, Palisades, NY, USA

Definition

Satellite remote sensing systems, particularly civil Earth observation systems, whether constructed in the public or the private sector, are generally governed by national policies. There are several reasons for this. Civil remote sensing satellites can be used to obtain observations in numerous areas of national importance, such as weather, climate, natural hazards, environment, and even international relations. As a consequence, control and management of these satellite systems is critically important to governments. This control is exerted through legislative, regulatory, and fiscal policies.

A second reason that governments are involved in policies for remote sensing is that these systems are extremely expensive to build and to operate. In most cases, governments initially became involved in remote sensing because of their need for specific types of remotely sensed data and their desire for technological expertise in this area. Over time, in their search for ways to defray some of the costs of building and operating satellites, many governments began to collaborate with private sector organizations under various types of public-private sector partnerships and government-to-government partnerships. These partnerships can involve the development, construction, or operation of remote sensing systems and generally also cover the release of the data. In most public/private sector partnerships, the government partner provides financial support to the private sector partner in exchange for participation in setting performance requirements and the retention of rights to the data under specified conditions. The private sector partner generally retains the right to commercialize the data after government requirements have been met.

In this section of the encyclopedia, entries discuss a broad range of economic, social, legal, and [data access](#) issues that, together with scientific and technical capacity, have contributed to shaping the satellite remote sensing systems in place today.

Synonyms

Farming by soils; Farming by the foot; Precision crop management; Precision farming; Site-specific agriculture; Site-specific management

Definition

Precision agriculture. A modern agricultural management paradigm that utilizes information technology to tailor crop management strategies according to inherent spatial and temporal variability within agricultural systems.

Information technology. Use of computer-based systems to collect, store, process, transmit, retrieve, and protect information.

Management zone. An area within an agricultural field that has a similar characteristic or that requires a similar treatment strategy for fertilizer or pesticide.

Decision support system. A software system that utilizes information about an agricultural system to predict the outcomes of various management alternatives and to aid in the decision-making process for agricultural crop management.

Precision management strategy. Any agricultural crop management decision that is made within a precision agriculture context.

Introduction

Before the advancement of agricultural mechanization in the previous century, the land area that an individual farmer could manage was relatively small. Without the aid of modern agricultural machinery, these earlier farmers relied on their experience and intuition to understand the spatial and temporal variability of soil characteristics and crop responses across the landscape, such that labor and other resources necessary for agricultural production could be most efficiently utilized. However, with agricultural mechanization came the ability of an individual farmer to manage larger areas of land, and farm management based on inherent soil and crop growth variability became secondary to the goal of increasing production by uniformly managing agricultural crops over larger land units (Morgan and Ess, 1997). Precision agriculture is a modern crop management paradigm that proposes to merge these dissimilar management objectives by utilizing information technology on

the farm. With agricultural computerization, farmers are able to use agricultural machines for managing large land units while accounting for inherent soil and crop spatial and temporal variability at the same time (Plant, 2001; Cox, 2002; Robert, 2002).

Spatial and temporal variability

Key to the concept of precision agriculture is the idea that many different aspects of agricultural systems, including soil properties, soil moisture, crop growth and development, crop stress levels, crop yield, crop residues, and pest infestations, are variable in space and time. If this variability can be appropriately measured, analyzed, and interpreted, then that information can be used to facilitate and improve the management decisions that ultimately govern the performance of agricultural systems. Pursuit of such an endeavor has potential to make our agricultural practices more productive, profitable, sustainable, and environmentally responsible (Zhang et al., 2002).

Remote sensing for precision agriculture

Remote sensing has been proposed as a viable source of information for understanding variability within agricultural systems, particularly in the spatial dimension (Frazier et al., 1997; Moran et al., 1997). Remote sensing images of appropriate spatial resolution have been useful for delineating management zones, which represent areas of the field that have similar characteristics or that require similar treatment strategies for pest infestations, crop stress, crop disease, soil tilth, or soil water deficit. Because of its raster nature, image-based remote sensing permits the division of an agricultural scene according to the spectral variability within the image, such that certain areas of the field can be managed differently from others.

Developments in remote sensing technology have improved our ability to monitor crop growth, development, and yield and to assess the effects of physical and biological stresses on crop productivity (Hatfield and Pinter, 1993). Within a precision agriculture context, these remote sensing techniques are applied with the objective to understand how various crop characteristics change in space and time, such that crop management can be adjusted accordingly. For example, since plant nitrogen contents have been linked to canopy reflectance measurements in the green, red, and near-infrared portions of the electromagnetic spectrum, remote sensing has been useful for delineation of field areas that have a nitrogen deficiency and require additional fertilizer. Infrared remote sensing has been used to quantify crop water stress, and infrared thermometers are currently being tested as a decision aid for precision water management with center-pivot irrigation systems. Use of remote sensing to detect abnormal canopy responses or to identify different plant species offers potential for delineation of weed infestations, such that herbicides can be applied only where necessary. Remote sensing indices can also be used to locate areas of abnormal crop growth caused by crop disease or insect infestations. Remote sensing-based

assessments of crop growth and development throughout the growing season are useful for monitoring the overall vegetative vigor of the plant canopy and for identifying the time at which the crop enters resource-sensitive developmental stages. In addition to being a useful aid for spatial and temporal crop management decisions, such assessments have also shown promise for forecasting and mapping the final crop yield.

Other precision agriculture objectives can be addressed by collecting remote sensing data over fallow fields (Moran et al., 1997). Spectral reflectance measurements over bare soil surfaces have been related to variation in soil physical and chemical properties, including soil nutrient contents, soil organic matter contents, soil salinity, soil texture, and soil compaction. Variability in these soil characteristics has also been directly related to variability in crop productivity. As a result, remote sensing has been proposed as a tool for mapping soil variability with the idea that zones for precision crop management could be established based on these soil maps. Variability in crop productivity is also highly dependent on soil moisture. Various types of instruments have been used to monitor soil moisture variability, including synthetic aperture radar and passive sensors for reflectance in the microwave, infrared, near-infrared, visible, and gamma portions of the electromagnetic spectrum. In the context of precision agriculture, remote sensing has been proposed as a tool for understanding the influence of topography on field-level soil moisture regimes. In addition, remote sensing of soil moisture has been suggested as a means to map the location of artificial subsurface drainage lines that were installed prior to the existence of modern mapping techniques. Spectral reflectance from bare soils is also affected by soil surface roughness and surface residue cover, which makes remote sensing a valuable tool for precision crop residue management. On a regional scale, remote sensing has been proposed as a tool for mapping variation in tillage practices, such that farmer compliance with erosion control guidelines could be verified.

Current obstacles

Robert (2002) reasoned that widespread adoption of precision agronomic practices is currently limited by socioeconomic, agronomical, and technological obstacles. Socioeconomic obstacles involve the cost of implementation and a lack of computer and technological skills among the majority of farmers worldwide. Agronomic barriers include the lack of basic information on variability within soil and crop systems, misuse of the information that is available, lack of qualified agronomic consulting services, and lack of a methodology for generating accurate site-specific management recommendations. Further technological developments in farm machinery, instrumentation, global positioning, computer software, and remote sensing are also necessary.

Several factors currently limit the usage of remote sensing technology in precision agriculture

(Moran et al., 1997; Robert, 2002). Some of these limitations, including cloud obstruction, partial canopy reflectance issues, instrument calibration needs, and data preprocessing requirements, are common in many applications of remote sensing. Other limiting factors are related specifically to the implementation of remote sensing within the precision agriculture context. For example, further investigations are needed to identify the precision agriculture objectives for which remote sensing is best suited and to understand the spatial, spectral, and temporal image resolution requirements for effectively addressing these objectives. Standardized methodologies for proper analysis and interpretation of remote sensing images are also necessary to insure that appropriate strategies for precision crop management are developed and disseminated in a timely fashion. Finally, there must be trained specialists in rural areas to coordinate remote sensing data collection, processing, and interpretation.

Importance of unified technologies

The technical success of precision agriculture will ultimately depend on the coordinated utilization of several different technological tools for designing and implementing precision management strategies. Required technologies include remote sensing, geographic information systems, spatial statistics, computer simulation models, global positioning equipment, and machine-based sensors, instrumentation, and control systems. Within this framework, the strength of remote sensing is its ability to rapidly and cost-effectively capture the spatial variability of reflectance from agricultural fields, which can subsequently be used to estimate the spatial variability of several important crop and soil characteristics. However, translation of spectral reflectance and spectral indices into justifiable management decisions has proven to be more difficult. One proposed solution has been to couple remote sensing with crop growth simulation modeling, where remote sensing would provide spatial information for model calibration using data assimilation strategies. Model simulations within a precision agriculture decision support framework would then be used to derive strategies for precision management of agricultural systems.

Conclusion

Precision agriculture is a modern agricultural management paradigm that promises increased agricultural productivity, profitability, sustainability, and environmental responsibility by utilizing information technology in every aspect of farm management. Remote sensing is an important component of the precision agriculture concept, because it can be used to rapidly estimate the inherent spatial and temporal crop and soil variability that exists within all agricultural systems. Continued advancements in precision agriculture technologies will help to improve agricultural production efficiencies, promote natural resource conservation, and secure the production of our food, feed, fiber, and fuel needs for many generations in the future.

PROCESSING LEVELS

Ron Weaver
 National Snow and Ice Data Center, Cooperative
 Institute for Research in Environmental Sciences,
 University of Colorado, Boulder, CO, USA

Definition

Processing levels. A means of describing the way remote sensing digital data are processed from raw or engineering units to informational geophysical products. These are typically differentiated by numeric (or sometimes alphabetical) hierarchies, from Level Zero, indicating engineering units or the data from the actual sensor system, to Level Four indicating geophysical products. Typically processing levels are applied to satellite data streams, but they have been utilized in other forms of remote sensing data.

Introduction

Processing levels as used in remote sensing activities are a methodology for differentiating raw (low) from more highly processed forms of digital data, typically collected

Processing Levels, Table 1 Processing levels as defined by CODMAC

Definitions of space science data levels and types

Data level or type	Definition	Utility
1. Raw data	Telemetry data with data embedded	Little use to most of science community, except for radio sciences
2. Edited data	Corrected for telemetry errors and split or decommuted into a data set for a given instrument. Sometimes called Experimental Data Record. Data are also tagged with time and location of acquisition. Corresponds to NASA Level 0 data	Wide use, especially for researchers familiar with instrumentation
3. Calibrated data	Edited data that are still in units produced by instruments but that have been corrected so that values are expressed in or are proportional to some physical unit such as radiance. No resampling, so edited data can be reconstructed. NASA Level 1A	
4. Resampled data	Data that have been resampled in the time or space domains in such a way that the original edited data cannot be reconstructed. Could be calibrated in addition to being resampled. NASA L1B	
5. Derived data	Derived results, as maps, reports, graphs, etc. NASA Levels 2 through 5	General way in which information is transferred
6. Ancillary data	Nonscience data needed to generate calibrated or resampled data sets. Consists of instrument gains, offsets; pointing information for scan platforms, etc.	Needed to be able to convert edited data to calibrated, resampled, or derived data sets
7. Correlative data	Other science data needed to interpret spaceborne data sets. May include ground-based data observations such as soil type or ocean buoy measurements of wind drift	Crucial data in many cases to provide ground truth calibration for spaceborne data
8. User description	Description of why the data were acquired, any peculiarities associated with the data sets, and enough documentation to allow secondary user to extract information from the data	Important aspect associated with the data that will be even more important for facility-class instruments and for secondary users of data

by satellite systems. The practice of defining processing levels originates from the space physics research community early in the 1970s civilian satellite research era. First references to processing levels within the US remote sensing community are traced to the Committee on Data Management and Computation (CODMAC) of the National Research Council (NRC, 1982, 1986). These reports codified the practices within NASA and NOAA, which predate the CODMAC effort (see Table 1). The CODMAC hoped that, by providing standard definitions, semantic confusion within the research community would be alleviated. This in fact has come to pass. Today, a search of the Web for “Data Processing Levels” reveals many current programs within NASA, NOAA, and other agencies which employ these definitions (Kobler, 1995; EOS, 2006; Chandra, 2008).

Other systems have been devised throughout the satellite era. For example, the World Climate Program (WCRP) follows a system originally devised for the Global Atmospheric Research Program (GARP) in the 1970s. GARP divided processing into three levels or groups: (1) primary instruments, (2) retrieved geophysical parameters, and (3) analysis fields. These categories roughly match the NASA/CODMAC levels 0–3. This WCRP classification has been used as is or in slightly modified form by WCRP programs such as Tropical Ocean and

Processing Levels, Table 2 Data processing levels from NASA Earth observing system

Data processing level definitions

Processing level	definition
Level 0	Reconstructed, unprocessed data at full resolution; all communications artifacts have been removed
Level 1	Level 0 data that has been time-referenced and annotated with ancillary information, including radiometric and geometric calibration coefficients, and geolocation information
Level 2	Derived geophysical variables at the same resolution and location as the Level 1 data
Level 3	Variables mapped on uniform space-time grids, usually with some completeness and consistency
Level 4	Model output or results from analyses of lower-level data

Global Atmosphere (TOGA), Global Energy and Water Cycle Experiment (GEWEX), or the International Satellite Cloud Climatology Project (ISCCP) (Gutman et al., 1995, 1997).

Processing Levels, Figure 1 Schematic data processing flow (Robinson, 2004).

It is important to differentiate from processing levels as defined in this section and levels of service (LOS). The data management community is increasingly active in the process of defining levels of service for data sets, which help prioritize resource allocations to existing data sets (Hunolt, 2003). Higher LOS means a data set might be housed in a more responsive data system or with more extensive metadata. LOS is complementary to processing levels but is clearly not the same. In the Internet-web serving environment, another related term has emerged. Quality of Service (QoS), or the ability to prioritize web information delivery by a predefined set of rules, has become a necessary part of data delivery systems and implementation of LOS for data.

Defined processing levels

The definitions presented here follow NASA practices. Table 2 presents the generally accepted definitions in use today by multiple NASA and NOAA missions. A more descriptive work flow diagram was developed by Robinson (2004, p. 99) and is presented in Figure 1. Others have identified processing steps and these contribute to processing level descriptions. For example, Kobler (1995) lays out the following science data processing requirements:

- Time ordering of data and removal of duplicate packets
- Repackaging of satellite instrument data with additional spacecraft and engineering data
- Calibration of data to correct for instrument drift

- Conversion of data to environmental variables
- Resampling of data to convert to gridded Earth patterns
- Generation of higher-level science analysis and modeling products

These steps generally follow the processing levels of Table 2.

Implementations of processing levels

Since the early 1970s, NOAA polar orbiter data has been labeled with processing levels. Those familiar with the NOAA data streams will recognize the L1A and L1B designations of AVHRR data. Level 1A (see Figure 1) refers to processing raw telemetry or L0 data to a time-sequenced but not decommutated format. Typically L1A data remain internal to NOAA archives. L1A processing is generally reversible to L0. Level 1B are discrete instrument-specific data sets derived from L1A and retain full resolution but are time-referenced and annotated with ancillary information including data quality indicators, calibration coefficients, and georeferencing parameters (NOAA, 2001).

NASA Earth remote sensing satellites have utilized the processing level concepts for many missions. The Earth Observing System (EOS) from its inception in the early 1990s to present designates data sets and products using processing levels (EOS, 1992).

Outside of the US National efforts by NOAA and NASA, the Committee on Earth Observing Satellites (CEOS) has developed a similar processing level descriptive hierarchy. The CEOS classifies data products by how they are processed and secondarily by their expected use (Gutman et al., 1997).

Summary

Use of processing levels in descriptions of remote sensing data and data processing over the past 40 plus years has been helpful to both data producers and data users. Many variations of level definitions exist internationally, with most deriving from the early usage within the NASA and NOAA remote sensing communities. In the United States remote sensing community, the most commonly applied definitions may be found on the NASA Earth Observing System documentation (EOS, 2006).

PUBLIC-PRIVATE PARTNERSHIPS

William Gail

Global Weather Corporation, Boulder, CO, USA

Definition

Partnership. A formal relationship or association between two or more organizations established to pursue business opportunities.

Public-private. A collaboration between a government entity and a private sector company.

Introduction

Public-private partnerships are a formal relationship between a government organization and one or more private sector companies. They are typically formed to pursue a specific objective of interest to the government entity for which the private sector partners present an efficient means of accomplishing that objective and involve a contractual relationship that defines the roles and responsibilities of each partner along with the ownership share. The relationship often takes the form of a single-purpose joint venture, sometimes referred to as a special-purpose vehicle (SPV). The government

may provide direct support such as one-time capital contributions or indirect support such as tax subsidies. Ideally, a public-private partnership provides goods and services at a higher quality and lower cost than either the government or private sector could do alone.

The most common examples of public-private partnerships occur in infrastructure development. These include roadways, hydroelectric projects, airports, and similar facilities. Development of pharmaceutical products for otherwise neglected illnesses in the developing world is also sometimes accomplished through public-private partnerships, enabling greater availability of vaccines and other medical resources than might otherwise be achieved through traditional for-profit markets.

General history and issues

Public-private partnerships have been in use for more than a century. An early example is the Scottish railway developer Robert Gillespie Reid who built numerous railway lines and bridges for both the USA and Canadian Governments in the late 1800s. His partnerships specified that his company would build railway facilities and operate them for 50 years, at which time it would own them. As a result, he was able to turn limited capital investment into significant land rights.

The advantage of such partnerships to the government is the ability to leverage skills and resources of the business sector while retaining a strong say in how an activity is pursued. The advantage to the private sector entity is the financial opportunity that arises from a relatively stable, long-term business.

A common criticism of public-private partnerships is that the government partner bears the primary risk while the private sector partner accrues most of the financial benefit. For example, financing risks such as interest rates and international exchange rates represent a risk that can be borne by either the government or the private sector entity. A well-defined partnership carefully addresses this balance between risk and reward to the benefit of all involved parties.

Partnerships and remote sensing policy

Within the remote sensing sector, public-private partnerships have been used by various nations to build, deploy, and operate Earth observation systems. In most cases, these systems are intended for dual-use purposes, such as joint military and civilian applications. Commercial sales of imagery are often an important objective; they may represent only a small element of the data use or can be the system's primary purpose. Within these partnerships, it has become increasingly difficult to distinguish between public and private entities (Gabrynowicz, 2007). In part, nations have different definitions of "commercial" or "private," and organizations are often linked in subtle ways through subsidies and other means. In Europe, for example, "commercial" generally refers to any entity that generates

revenue, whether privately owned or state owned. State-owned organizations are sometimes even organized similar to and operate like private corporations.

Public-private partnerships are governed by a combination of policy and law. Nations such as the USA and Canada have transparent policies and laws concerning commercialization of remote sensing. Others address the issue through less-open internal policies. Some have policies but no corresponding law. In nearly all instances, however, the greatest interest in partnerships occurs for high-resolution imagery, for which the overlap between commercial and national security interests is strongest and thus most policy sensitive.

In the USA, public-private partnerships for remote sensing are governed in part by the *Land Remote Sensing Policy Act of 1992*, created largely to resolved problems within the Landsat program. This act states that "commercialization of land remote sensing should remain a long-term goal of United States policy." It also notes that "development of the remote sensing market and the provision of commercial value-added services based on remote sensing data should remain exclusively the function of the private sector." One of the breakthrough provisions in this policy and its 1984 predecessor is a means for licensing fully commercial remote sensing systems: "In consultation with other appropriate United States Government agencies, the Secretary is authorized to license private sector parties to operate private remote sensing space systems for such period as the Secretary may specify and in accordance with the provisions of this subchapter."

Both public-private partnerships and commercial remote sensing are closely tied to national industrial and national security interests. In the USA, this aspect of land remote sensing policy was clarified in the 1994 Presidential Decision Directive 23, which stated that "the fundamental goal of our policy is to support and to enhance US industrial competitiveness in the field of remote sensing space capabilities while at the same time protecting US national security and foreign policy interests. Success in this endeavor will contribute to maintaining our critical industrial base, advancing US technology, creating economic opportunities, strengthening the US balance of payments, enhancing national influence, and promoting regional stability." This was reconfirmed by the 2003 National Security Presidential Directive 27 *US Commercial Remote Sensing Policy* stating a goal to "advance and protect US national security and foreign policy interests by maintaining the nation's leadership in remote sensing space activities, and by sustaining and enhancing the US remote sensing industry."

Outside the USA, the nature of public-private partnerships is often tied more openly to national interests, such as technology development and surveillance. The intermingling of commercial and security interests can present particular challenges, such as the need for bankers involved with investment in the partnership to hold security clearances.

Examples

Among the oldest public-private partnerships in remote sensing is for the French System pour l'Observation de la Terre (SPOT) satellite series. The Spot Image company was formed in 1982 as a public-private partnership between the French space agency Centre National d'Études Spatiales (CNES), the French national geographic center Institut Geographique National (IGN), and several French space companies to own and operate French commercial remote sensing satellite systems. As of 2010, EADS owned 99 % while IGN retained a 1 % minority interest. Spot Image has launched a series of increasingly capable satellites, starting with the 10 m resolution Spot-1 in 1986. The progression has continued with the Pleiades series of electrooptical imaging satellites launched starting 2011 and as part of a joint program called ORFEO in which Italy supplies radar satellites.

The US Landsat system has a long history of collaboration between the government and private sector entities. In 1985, the government-owned Landsat was partially privatized through a partnership with Earth Observation Satellite Corporation (EOSAT), itself a partnership of Hughes Aircraft and RCA. EOSAT was given a contract to operate the system for 10 years and build follow-on satellites, obtaining rights for commercial sale of the data. The Landsat Data Continuity Mission, initiated in the early 2000s as the follow-on to Landsat-7, was originally envisioned as a strong public-private partnership, but has since evolved into a more traditional system acquisition with the government retaining responsibility for data processing and distribution.

One of the earlier and most well-known examples of a purposely designed public-private partnership is the Sea-viewing Wide Field-of-view Sensor (SeaWiFS). It was built for NASA under partnership with Orbital Sciences Corporation and launched in 1997. ORBIMAGE (now part of GeoEye), a spin-off from Orbital Sciences, was given the responsibility for operating the satellite and for selling the data, with NASA itself purchasing data.

The intelligence community has been a significant partner in development of US commercial remote sensing capability. Through large data purchase contracts such as NextView, ClearView, and EnhancedView, the National Geospatial-Intelligence Agency (NGA) has provided anchor funding for commercial remote sensing companies. NextView contracts, for example, are service-level agreements (SLA) that specify requirements for imagery purchases from satellites still to be developed. They are designed to provide a long-term government partnership commitment that enables the private sector partner to finance and develop new satellites meeting the requirements. To motivate a commercial market, the agreements are nonexclusive, meaning that the companies can sell the same imagery to other customers.

In the mid-1990s, NASA initiated a public-private partnership called LightSAR. The objective was to develop

a dual-use synthetic aperture radar (SAR) satellite that served both scientific and commercial needs. Several teams were funded to study both the system and the market opportunity, but the final bid produced no team capable of satisfying the partnership's objectives. In this case, the scientific and commercial objectives required largely incompatible system requirements, so their combination did little to reduce costs over pursuing each independently. Dual use involving scientific-quality data also raises numerous challenges regarding open-data practices, calibration, metadata, and more. One of the teams involved in the LightSAR study included the German company Dornier as a major partner. Dornier (now EADS Astrium) subsequently built on the experience gained to form the German public-private partnership InfoTerra and launch the series of TerraSAR satellites.

Since the late 1980s, Canada has been building a public-private partnership for synthetic aperture radar (SAR) through the Radarsat series. The company Radarsat International was formed in 1989 by a consortium of Canadian companies with the purpose of processing and distributing the data from Radarsat-1, launched in 1995. One of the shareholders, Macdonald Dettwiler and Associates, bought out the others in 1999 and formed a deeper partnership with the Canadian Government to build and operate Radarsat-2, launched in 2007.

Many other nations utilize public-private partnerships for remote sensing systems. The Israeli EROS imagery satellites are owned and operated by an international company ImageSat International. Surrey Satellite Technology Ltd. (SSTL) developed a multigovernment collaboration that built and launched a series of small satellites called the Disaster Monitoring Constellation (DMC), each owned and controlled by a different government (Algeria, Nigeria, Turkey, Britain, China, Spain) and operated jointly through a wholly owned subsidiary of SSTL called DMC International Imaging. The German RapidEye satellite constellation, a five-satellite system designed for rapid refresh imagery, was developed with participation from the European Union and the German state of Brandenburg. In addition to space systems, aerial remote sensing operations can also leverage public-private partnerships.

Summary

Public-private partnerships are used extensively in remote sensing to develop and operate satellite systems. They are typically formed or supported to achieve a government-driven objective (such as surveillance or disaster monitoring) most efficiently accomplished through a private sector entity.

Definition

It is commonly understood that an altimeter is a down-looking radar device designed to measure relative altitude, thus to establish the height of the radar above the surface below. Although similar in form and function, the purpose of a remote-sensing altimeter is different, since usually it is mounted on a spacecraft whose orbital height is known. Remote-sensing altimeters are designed to retrieve certain geophysical parameters about the surface from the timing and shape of the radar reflections (waveforms).

Introduction

Since the first flight of an experimental altimeter aboard Skylab (1973), this class of radars has been developed primarily for observation of the oceans from Earth-orbiting satellites. Their data are comprised of a nearly continuous stream of waveforms, each one of which is the time history of the power backscattered from the surface below (thus from nadir) following each pulse transmitted by the radar. Over the ocean, sea-surface height, mean wave height, and surface wind speed can be retrieved, after averaging a sufficient number of waveforms to achieve the desired precision of the measurement (see “[Radars](#)”). These instruments usually are left “on” over their entire orbit, so that applications can be investigated regarding ice sheets, inland waters, or land forms. Since altimeters look

down, the resulting waveforms from large bodies of water are relatively simple and well understood. The altimeter’s response to surface topography is more complex, although useful results have been obtained, for example, from the ice sheets of Greenland and Antarctica, and the altimeter mode on the Magellan mission to Venus (Pettengill et al., 1991). Earth-observing altimeters usually perform first-order processing on board (including “tracking” of the time delay of the surface return) so that their mean data rate is on the order of only a few 10s of kbits/s.

Geophysical measurements

In the oceanographic application, a satellite-based altimeter systematically circles the Earth, generating sea-surface height (SSH), significant wave height SWH (significant wave height is the average height [trough to crest] of the one-third largest waves), and wind speed (WS) measurements along its nadir track. These measurements accumulate, providing unique synoptic data that have revolutionized knowledge and understanding of both global and local phenomena, from El Niño to bathymetry.

The driving requirement for oceanographic applications is determination of the local sea level relative to the Earth’s geoid. The average elevation relative to the Earth’s center of mass of the mean sea surface in the absence of dynamic perturbations is due to tides, winds, and currents. The reference for this measurement – the orbital height of the spacecraft – must be determined by means other than altimetry, such as GPS, Doppler tracking, or laser range finding (Chelton et al., 2001). The intended measurement – SSH – is given by the difference between the orbit height and the altimeter’s range measurement. The two other measurements made by a radar altimeter – SWH and WS – are retrieved from the shape of the return waveform.

Sea-surface height

Sea-surface height is a function of many geophysical parameters, such as current flow, the mean temperature in a column of water, or variations in the ocean's depth. Relatively small changes (on the order of cm) in mean sea-surface height may correspond to substantial differences in the corresponding geophysical parameters. It follows that accuracy and precision (see "*Radars*") are both required for useful measurements. An altimeter's accuracy depends to first order on precision orbit determination (POD) of spacecraft height and on correction of the propagation delays suffered by the radar's round-trip waveform. Accuracy is improved by "crossover" analysis (Luthcke et al., 2003), which is exploited to remove systematic height errors by extensive comparison of height measurements derived from intersecting ascending and descending orbits, under the assumption that the true sea level has not changed between observations. The precision of an ocean-viewing altimeter is proportional to the radar's range resolution and inversely proportional to the square root of the number of statistically independent measurements (looks) combined for each data point. Typical numbers for these key parameters are 0.5 m single-pulse post-compression range resolution and 1,500 or more looks averaged per second. Ocean-viewing altimeters in general benefit from the rather large signal ($3 \text{ dB} < \sigma_0 < 20 \text{ dB}$) reflected from the water's surface, which is quasi-specular when viewed vertically (see "*Microwave Surface Scattering and Emission*").

The SSH measurement objectives of space-based altimeters can be grouped into four broad categories: large-scale dynamic sea-surface topography, dynamic mesoscale oceanic features, static mesoscale sea-surface topography, and ice-sea ice as well as continental ice sheets. In the field of oceanography, mesoscale features have scales of several hundred kilometers, as opposed to the much larger basin scale (the North Atlantic ocean, for example). Each of these measurement themes implies narrowed constraints on preferred orbit and on the top-level instrument and mission design. Satellite altimeters dedicated to determining the ocean's large-scale dynamic surface topography are characterized by absolute sea-surface height (SSH) 1 s averaged measurement accuracy on the order of centimeters along tracks of more than 1,000 km and orbits at relatively high altitude that retrace their surface tracks in a stipulated number of days. These data when averaged over long timescales provide estimates of annual sea-level rise, known from radar altimetry to an accuracy of 1 mm per year (Nerem and Mitchum, 2001).

Wave height and wind speed

To extract SWH and WS from waveform data, finely tuned algorithms have been developed and validated against in situ buoy measurements (Fu and Cazanave, 2001). For example, the TOPEX Ku-band altimeter measured SWH to within 0.5 m up to more than 5.0 m

and WS within 1.5 m/s up to more than 15 m/s. These figures correspond to averages over 1 s, or about 7 km along the subsatellite path of the altimeter's footprint, which typically is 3–5 km wide, determined by mean sea state.

Mesoscale features

Important applications at the mesoscale include mapping of geostrophic currents [whose cross-flow SSH gradient is proportional to mean current velocity (Leeuwenburgh and Stammer, 2002; Stammer and Dieterich, 1999)] and tracking eddies (whose SSH relative to the surrounding area reflects the mean temperature of the underlying water column). Rather than absolute SSH accuracy, these shorter-scale applications require precision sufficient to sustain surface slope measurement accuracy on the order of $1 \mu\text{rad}$ (1 cm sea-level change over a 10 km distance), on spatial scales of less than several 100 km.

Oceanographic versus geodetic orbits

Both large-scale topographic and mesoscale missions are aimed at dynamic features whose SSH signals are on the order of only a few tens of centimeters and less and that remain relatively constant over time intervals up to several weeks. These signals must be distinguished from variations in SSH caused by the Earth's geoid, which is essentially constant on the scale of many years, in contrast to the dynamic signals set up by currents, volumetric temperature differentials, and the like. Globally the geoidal SSH signal spans a range of more than 100 m with respect to the reference ellipsoid of the mean Earth's figure. In order to see the dynamic topographic signals, the much larger geodetic signal has to be established, which then becomes the reference for the dynamic signals. The traditional strategy to establish this geoidal reference is to restrict the altimeter's orbit to an "exact-repeat" pattern. Once the geoid has been determined along such repeat tracks, then dynamic variations from that reference can be observed. The standard tolerance on "exact" is $\pm 1 \text{ km}$ on the maximum allowable deviation of every orbit's subsatellite locus relative to the nominal surface track; this requirement was derived from the height error induced by the mean sea-surface slope of the geoid. Exact-repeat orbits are the traditional standard for oceanographic radar altimeters, which as a consequence are characterized by track-to-track separations at the equator of several hundred kilometers. Altimeters in the TOPEX orbit, for example, have repeat tracks that are spaced apart at the equator by 316 km.

Geodetic signals are expressed as two-dimensional static topographic variations on the sea surface. To map these, orbits are required that have moderate inclination and generate dense track-to-track spacing, leading to nonrepeat (or long-period-repeat) orbits. Radar altimetric data from such orbits can be processed to measure deviations in both the N–S and the E–W planes of the local gravity vector ("deflection of the vertical") which is expressed as the local two-dimensional slope of the mean

sea surface, at scales on the order of 5–300 km. These data are sufficient to map the detailed structure of the local gravity field, which can be inverted to deduce bathymetry – the ocean’s depth (Sandwell and Smith, 1997; Smith and Sandwell, 2004). The prime example of a nonrepeat geodetic mission is the first 18 months of Geosat (MacArthur et al., 1989), for which the average orbit-to-orbit spacing was about 5 km at the equator.

Near-polar ice

Radar altimetric observation of ice-sheet surface elevations imposes its own set of requirements. Observation of near-polar ice requires high-inclination nonrepeat orbits, in contrast to altimeters in traditional oceanographic orbits, or sun-synchronous systems. Accurate mapping of continental ice-sheet elevations requires further that the altimeter have robust accuracy when viewing nonzero average surface slopes in the along-track and cross-track directions. CryoSat (URL/CryoSat, 2008), the first radar altimeter devoted to the Earth’s ice sheets, incorporate a cross-track interferometer and an along-track Doppler processing mode, both of which are designed to offset the surface slope problem. The CryoSat orbit is essentially nonrepeating at an inclination of 92°.

Range measurement accuracy

Given that the orbit’s height with respect to the Earth’s center of mass has been well determined, conversion of the altimeter’s range measurement into accurate sea-surface height is threatened by many sources of potential error, which must be estimated and then offset. There are two classes of corrections required: to compensate errors imposed by electromagnetic propagation and by the sea surface itself. After the range measurement errors are corrected, the residual accuracy usually is dominated by imperfect knowledge of the radial orbit.

Propagation delay corrections

An altimeter (like any radar) actually measures round-trip delay, not distance. For useful oceanographic radar altimeter data, the deceptively simple proportionality of range to delay time must take into account the small but significant retardation of the radar’s microwaves as they propagate. The cm-level SSH accuracy required of these instruments is much smaller than the ranging errors introduced by delays through the ionosphere and the atmosphere. The ionosphere imposes delays that are a function of frequency. In practice, these can be estimated and then corrected if the altimeter measures round-trip time delay at two different frequencies (Keihm et al., 1995). The atmospheric propagation delays (Goldhirsh and Rowland, 1982) are due to two components: the dry atmosphere and water vapor. The dry atmosphere component is relatively well known and stable at long spatial scales; in practice the resulting delay is compensated by recourse to model predictions. Delays due to water vapor in the atmosphere are variable down to scales of several

hundred kilometers (and much smaller when traversing a storm front). Standard practice is to measure the integrated water vapor contribution in the vertical column below the altimeter by a microwave radiometer, for which two or three frequencies are required. The method works well over the open ocean, but breaks down near land, whose microwave radiance corrupts the atmospheric signal.

Sea-surface corrections

The mean sea-surface elevation varies in response to the mass of the atmosphere above it. The implied (inverse) barometric correction is of the order of centimeters. Further, radar reflections at vertical incidence favor the wave troughs over their crests, leading to a SSH estimation error known as sea-state bias. This bias increases as significant wave height increases. The resulting correction (Chelton et al., 2001; Zanife et al., 2003), deduced empirically after many controlled measurements and comparisons to independent SSH and SWH measurements, is a function of the altimeter’s measurement of SWH (Hayne et al., 1994).

Measurement precision

Measurement precision is improved by more incoherent averaging. The lower limit usually is determined by the intrinsic precision of the radar. Figure 1 shows a summary history of these factors. The data, consistent with theory (Walsh, 1982), show that 1 cm instrument precision is close to the lower limit for conventional altimeters. The delay-Doppler instrument, which introduces waveform processing strategies adapted from synthetic aperture radar techniques (Raney, 1998) that allow increased averaging, provides approximately a factor of two improvements in precision (Jensen and Raney, 1998) to 0.5 cm.

Centimeter-scale SSH precision is supported in the oceanographic application by averaging over the range response of many returns. The resolution of each return waveform is typically on the order of 0.5 m (which is a constant of the instrument, proportional to the inverse bandwidth of the radar). As the altimeter progresses along its orbit, waveforms are accumulated and averaged pulse to pulse, whose shape converges on the flat-surface impulse response (Brown, 1977; Moore and Williams, 1957) (Figure 2). Sea-surface height is derived from the time delay to the midpoint of the waveform’s leading edge rise. About 1,500 or more such waveforms are averaged over 1 s, which corresponds to a mean range estimate whose standard deviation is on the order of 1 cm for a calm sea. In practice SSH precision degrades with increasing significant wave height.

The brown waveform

Over a quasi-flat sea, a pulse-limited altimeter’s idealized mean waveform is a modified step function, whose rise time is equal to the compressed pulse length, and whose position along the time-delay axis is determined by the altimeter’s range (Brown, 1977). If the sea surface is

Radar, Altimeters, Figure 1 Evolution of accuracy and precision. The altimeter's precision is determined primarily by the number of statistically independent returns averaged to form each output waveform, for which the upper bound is determined by the radar's pulse-limited area. The delay-Doppler processing algorithm increases available averaging, hence improving precision by approximately a factor of 2.

modulated by waves, the altimetric depth of the surface increases, which reduces the slope of the waveform's leading edge. Hence, SWH is proportional to waveform rise time. If the sea surface is disturbed by the wind, the resulting fine-scale roughness scatters reflected energy over larger solid angles, hence decreasing the power of the reflection back to the altimeter. For wind speeds of more than about two knots, WS is inversely related to mean waveform power. In practice, the inflections of the idealized flat-surface response function waveform are softened by the pulse weighting, and the waveform is attenuated over time by the weighting of the antenna pattern and further by any mis-pointing of the antenna pattern toward nadir.

Flight systems

Selected attributes of satellite radar altimeters are summarized in Table 1. The Jason series of altimeters represent the state of the art in absolute sea-surface height measurement accuracy, due in no small measure to their high-altitude TOPEX orbits. Significant milestones since 1973 include S-193 and GEOS-3 (McGoogan et al., 1974; Hayne, 1980), proof of concept; Seasat (MacArthur et al., 1989), first full de-ramp pulse compression (full de-ramp – or simply de-ramp – is standard terminology in space-based radar altimetry; it is known more commonly to most radar engineers as the Stretch technique); *Geosat* (MacArthur et al., 1987; Sandwell and Smith, 2001; Smith and Sandwell, 1994), first geodetic mission;

Radar, Altimeters, Figure 2 Waveforms. The return waveform (averaged) of an ocean-viewing radar altimeter is a softened step function, whose position in delay time, steepness of initial rise, and peak power are processed to retrieve respectively sea-surface height, significant wave height, and surface wind speed.

TOPEX/Poseidon (Chelton et al., 2001; Goldhirsh and Rowland, 1982), first global dynamic topography mission, and the first two-frequency ionosphere correction; *ERS-1*, *ERS-2*, and *ENVISAT* (Fu and Cazanave, 2001; URL/ENVISAT, 2008; Zelli, 1999), sun-synchronous multipayload missions; *CryoSat-2* (Wingham et al., 2004), first ice-sheet radar altimeter (the original *CryoSat* was launched in October 2005, but unfortunately, the launch vehicle malfunctioned; ESA and its member states authorized a replacement); *AltiKa* (Vincent et al., 2006), first Ka-band altimeter; and *Sentinel-3* (Le Roy et al., 2007), conventional and delay-Doppler modes.

Ice-sheet radar altimetry

Pulse-limited space-based radar altimeters work best over relatively mild topographic relief of mean slope zero, such as the ocean's surface. Over ice sheets or terrestrial surfaces, their performance is degraded (beam-limited techniques, of which laser altimeters are extreme examples, circumvent these problems but imply their own set of disadvantages, including limited lifetime and the

Radar, Altimeters, Table 1 Earth-observing radar altimeters (primarily oceanographic objectives), 1973–2012

inability to penetrate dense cloud formations). Approximately 95 % of Antarctica, for example, has slopes less than $\sim 3^\circ$, which although small is sufficient to trick a conventional altimeter into very large height errors. An unknown one-degree slope would lead to a 120 m surface height error.

The CryoSat altimeter (Phalippou et al., 2001) is the first space-based radar altimeter designed to operate over ice. Its payload instrument is the SAR/Interferometric Radar ALtimeter (SIRAL), which has three modes: conventional, SAR, and interferometric. The conventional pulse-limited mode reflects its Poseidon heritage. The SAR mode is the first space-based embodiment of the delay-Doppler architecture (Raney, 1998), which offers advantages in precision, resolution, and along-track surface slope tolerance. The interferometric mode (Jensen, 1995) is designed to measure the cross-track surface slope component. Data from each of the three modes are processed in ground-based facilities. The conventional mode is used for the open ocean (for calibration and sea-surface height reference purposes) and the central continental ice sheets that are relatively level. The interferometric mode is reserved for the more steeply sloping margins of the ice sheets. The synthetic aperture mode is used primarily over sea ice, where its sharper spatial resolution and precision support measuring the difference between the sea level and the top surface of floating ice (freeboard). Since the density of ice is relatively well known, such freeboard measurements can be inverted to estimate ice thickness (Laxon et al., 2003).

Orbit considerations

Given an arbitrarily good radar altimeter, its orbit becomes the dominant factor that may limit sea-surface height measurement accuracy (Parke et al., 1987). Earth orbits of altimeters usually revisit a given surface location only about every 10–20 days. This low revisit rate is in distinct contrast

to tides that have approximately one or two cycles per day, driven primarily by the Earth's rotation through the lunar and solar gravity fields. As a result, all tidal signals sensed by an altimeter are under sampled in the Nyquist sense. Altimetric data retain the resulting aliases, which over the course of a year or so can be identified, quantified, and calibrated out. Altimeter orbits are favored for which the tidal aliases do not fall upon signals of geophysical interest. The state of the art (with respect to SSH accuracy and large-scale circulation studies) is the Jason series, operating in the orbit originally designed for TOPEX/Poseidon. The orbit parameters include repeat period 9.9156 calendar days (unfortunately, often stated as 10 days), inclination 66° , repeat track separation at the equator 316 km, and altitude 1,336 km. The radial component of precision orbit determination (POD) was on the order of 2 cm for T/P, and Jason results show POD to a level of 1.5 cm.

The geosat orbit

The first 18 months of Geosat (1985–1989) were devoted to geodesy, hence a nonrepeating orbit at an inclination of 108° . After its geodetic mission, Geosat was controlled to maintain an exact-repeat orbit of a period of 17.0505 calendar days (sometimes inappropriately abbreviated to 17 days). From this orbit, half of the principal tidal constituents alias into unwanted frequencies (near zero, one, or two cycles per year). In particular, the dominant tidal constituent, the common twice-daily lunar tide, is aliased to 317 days, which is close to the annual cycle (Ray, 2001).

Sun-synchronous orbits

Sun-synchronous satellites host European Space Agency (ESA) altimeters including RA-1 on ENVISAT. All share the same orbit: 35.00 calendar days repeat period, 98.5° inclination, and 781 km mean equatorial altitude. Radial knowledge of these sun-synchronous orbits is good to about 5 cm, based on the Delft model

(Scharroo and Visser, 1998). As sun-synchronous altimeters, the largest solar constituent (twice-daily) aliases to zero, and all tidal constituents that are primarily dependent on solar forces alias to frequencies close to zero.

Radar altimeter design

Conventional oceanographic radar altimeters are pulse-limited, in the sense that their instantaneous footprint on the surface is determined by the shortness of the (compressed) range pulse, not by the width of the antenna pattern. (The footprint of an altimeter that has an extremely narrow radiation pattern such as a laser usually is beam-limited.)

Figure 3 illustrates the pulse-limited condition (Chelton et al., 1989). The radius r_P of the area delimited on a quasi-flat surface by a pulse of (compressed) length τ seconds on the Earth of mean radius R_E seen from a relative altitude of h kilometers is

$$r_P = (c\tau h/\alpha)^{1/2} \quad (1)$$

where $\alpha = (R_E + h)/R_E$ is a consequence of the spherical observation geometry. For typical satellite radar altimeters, the pulse-limited footprint over a quasi-flat surface is on the order of 2 km in diameter. As the pulse continues to impinge and spread over the surface, the resulting pulse-limited annuli all have areas equal to that of the initial pulse-limited footprint. Hence, the received power tends to maintain the level corresponding to the peak of the initial response (Figure 2). The pulse-limited area expands in response to increasing large-scale surface roughness, which in the oceanographic context is expressed as significant wave height SWH. The height accuracy of a pulse-limited altimeter is much less sensitive to (small) angular pointing errors than is the case for a beam-limited altimeter. The classic analysis of a pulse-limited altimeter's waveform is due to Brown (1977). The waveform of a delay-Doppler altimeter (Raney, 1998) is pulse-limited in the across-track direction, but it is beam-limited in the along-track direction.

A satellite-based radar altimeter (Figure 4) needs to measure range accurately, but only for an essentially planar surface, oriented orthogonally to the radar's line of sight. Hence, ocean-viewing altimeters have a small range window whose position and gain adjusts the delay and gain of the radar (originally implemented as an alpha-beta tracker) in response to the timing and strength of the surface reflection (MacArthur et al., 1989). For certain applications it may be advantageous in subsequent processing to "retrack" the waveforms (Deng and Featherstone, 2006) for more accurate retrieval of waveform parameters.

Most satellite-based radar altimeters since Seasat use the Stretch technique (Caputi, 1971). The distinguishing feature of this method of pulse modulation and demodulation is a clever trade between the two key parameters in a large time-bandwidth product (TBP) signal

Radar, Altimeters, Figure 3 Pulse-limited geometry. In a pulse-limited radar altimeter the intersection of the compressed ranging pulse with the sea-surface determines the area of the effective footprint. The pulse-limited area increases with increasing SWH and is elongated along track in proportion to waveform averaging time.

(see “*Radars*”). After reception, demodulation is applied that transforms the “short time, large bandwidth” nature of the original pulse to “long time, small bandwidth” signals. Since the same TBP is maintained, the original resolution is preserved. The method is ideal for altimetry, since the range depth of the ocean's surface is very much smaller than the time available in the pulse repetition period. The full de-ramp technique offers a considerable savings in system bandwidth at all subsequent stages and at no cost in range resolution. The waveform bandwidth reduction can be considerable, being a factor of more than 200 for TOPEX, for example (Marth et al., 1993; Zieger et al., 1991). The data rate is reduced further by

Radar, Altimeters, Figure 4 Block diagram of the TOPEX radar altimeter, showing the essential attributes of pulse modulation and demodulation (the full de-ramp technique), range gate position and receiver gain adaptive tracking, and on-board waveform processing.

pulse-to-pulse incoherent averaging. Thus, a typical single-pulse resolution of 0.5 m, which requires a bandwidth of 300 MHz, is reduced to an average waveform data rate on the order of 10 kb/s after de-ramp demodulation, on-board tracking, and one-second averaging.

Conclusion

Radar altimeter measurements have become essential for a wide variety of applications in oceanography, geodesy, geophysics, and climatology. For retrieval algorithms and in-depth reviews of applications, the book to consult is Fu and Cazanave (2001). An excellent on-line entry point for oceanographic radar altimeter missions may be found at URL/AVISO (2008), and for geodetic applications, see URL/Geodesy (2003). A tutorial on radar altimetry may be found at URL/Altimeter_Tutorial (2008).

Although relatively mature, radar altimeters continue to evolve. Interest is increasing for extending altimetry to near-shore oceanic applications and inland waters, including surface hydrography. The constraint on repeating orbits for mesoscale oceanographic applications may be relaxed by use of the refined geoid data from GRACE and other space-based gravity measuring missions, thus opening the way for one orbit plan to satisfy both mesoscale oceanographic and geodetic requirements. Radar instrumentation is moving ahead, pioneered by the SAR mode (delay-Doppler) on CryoSat and Sentinel-3. More radical demonstrations are in store, including a Ka-band instrument. There is abiding interest in the principle of wide-swath altimetry, which would be the “perfect” instrument if the technique could extend current accuracy and precision standards to areas either side of nadir.

Microwave scatterometer; Spaceborne scatterometer;
 Wind scatterometer

Definitions

Radar scatterometer. A calibrated radar designed to measure the radar backscatter cross section of a target, generally an area on the earth's surface.

Wind scatterometer. A radar scatterometer designed to measure the ocean's surface backscatter at multiple azimuth angles in order to estimate the near-surface

vector wind. It is also used for ice melt/freeze, soil moisture, and vegetation remote sensing.

Spaceborne scatterometer. A wind scatterometer operating on an Earth-orbiting satellite. Currently operating examples: SeaWinds on QuikSCAT (USA) and ASCAT on MetOP (ESA).

Normalized radar cross section. Area-normalized radar backscatter which is the ratio of the incident and reflected radar signal power. Conceptually similar to “albedo,” but for radar backscatter.

Geophysical model function (GMF). An empirical or analytic relationship between ocean radar backscatter and wind direction and speed used for wind estimation from wind scatterometer measurements.

Signal-to-noise ratio (SNR). Ratio of the signal power (or energy) to the noise power (or energy).

Introduction

A radar scatterometer is a carefully calibrated remote-sensing radar designed to measure the radar backscatter cross section (usually as the normalized radar backscatter coefficient, denoted σ^0) of a target, which is generally a natural scene. Measurements of the backscatter coefficient are used to derive key scene properties. For example, a wind scatterometer is designed to measure backscatter cross section over the ocean from several azimuth angles. From the backscatter measurements, the near-surface wind speed and direction are estimated (retrieved).

Scatterometer fundamentals

In order to achieve high calibration accuracy, scatterometers are generally real-aperture radars. Microwave scatterometers operate by transmitting a microwave signal toward the target and measuring the reflected or backscattered power. Knowing the measurement geometry and radar parameters, the radar cross section is computed from the backscattered power. Key target characteristics, such as wind speed and direction over the ocean, are then estimated from the target cross section.

Due to thermal noise in the radar receiver and Rayleigh fading, the signal power measurements are corrupted by noise. Typically, a separate measurement of the receive-only noise power is made and subtracted from the signal-plus-noise measurement to yield a backscatter signal power measurement. The measurement signal-to-noise ratio (SNR) depends on the noise level, radar parameters, and the scene but may vary from very low (< -40 dB) to high (20 dB or more).

Scatterometers are generally used with distributed (areal) targets. For such a target the backscattered signal power P_s is related to the normalized radar cross section (σ^0) via the radar equation (Ulaby et al., 1981)

$$\sigma^0 = P_s P_t G^2 \lambda^2 A_c / (4\pi)^3 R^4 L \quad (1)$$

where P_t is the transmitted power, G is antenna gain, λ is the wavelength of the transmitted microwave signal, A_c

is the resolved target area, R is the slant range to the surface, and L is the net system losses. For a given target, the measured radar cross section depends on the observational geometry including the incidence angle and (possibly) the azimuth angle. The cross section is related to the dielectric properties, surface roughness, and volume scattering characteristics of the target. With careful calibration and careful design to ensure measurement stability, the normalized radar cross section can be very accurately estimated, e.g., to better than ± 0.1 dB. The measurements of the cross section are then used to estimate target characteristics of interest.

Scatterometer transmit signals can be modulated pulses or interrupted continuous wave (ICW) signals. Processing of the received signal can yield cross-sectional measurements at finer scale than the antenna footprint. Pulse compression or matched filtering is used for this when the transmit signal is modulated, while Doppler filtering is used for ICW signals. In either case, signal power measurements from several pulses are averaged into a signal power measurement.

The backscattered signal from the target scene consists of distance-attenuated, time-delayed, and frequency-shifted copies of the transmitted signal. The time delay arises due to the finite speed of light and the distance (sometimes referred to as the slant range) between the radar and the scene. Scatterometers can be designed for stationary operation or for operation from moving platforms such as spacecraft. The relative motion of the radar with respect to the scene introduces Doppler frequency shifts. This relative motion coupled with the coherent nature of radar results in Rayleigh fading (Ulaby et al., 1981) or signal scintillation due to self-interference of signal from different component areas of the target. Rayleigh fading introduces signal variability that is often treated as undesired “noise” in the signal power measurement.

Scatterometer applications

The primary application of radar scatterometers is satellite-based ocean vector wind measurement. Scatterometer-derived winds are operationally used in [weather forecasting](#) and scientific research. Winds blowing over the ocean generate small, centimetric-scale waves known as capillary-gravity waves. These interact nonlinearly to generate larger waves known as swell. For moderate-to-large incidence angles (15° – 60°), the ocean surface backscatter is dominated by Bragg scattering from the capillary-gravity waves. The Bragg scattering results in a strong wind-speed and direction-dependent variation in the radar backscatter which is exploited to estimate the wind from the backscatter measurements. The relationship between the radar backscatter and the wind speed and direction is known as the geophysical model function (GMF). The GMF at 14 GHz is shown in [Figure 1](#). By making multiple measurements of the surface backscatter from multiple

Radar, Scatterometers, Figure 1 A representation of the Ku-band (14 GHz) geophysical model function relating the near-surface wind over the ocean to the ocean's normalized radar cross section. (a) Radar cross section versus wind speed and incidence angle. (b) Radar cross section versus the direction difference between the wind and the radar azimuth angle.

azimuth angles, the near-surface wind speed and direction can be determined by inverting the GMF. This estimation process is often termed wind retrieval.

Unfortunately, the double cosine dependence of the radar cross section on the wind direction gives rise to so-called ambiguities, where two possible wind vectors “explain” the cross-sectional measurements. To resolve this ambiguity, ambiguity selection algorithms (also termed “dealiasing”) are employed. Such algorithms generally start with a first guess of which ambiguity to use and then apply wind field continuity considerations to select a unique wind vector at each observation point.

Wind scatterometers measure the radar cross section from multiple azimuth angles on a grid of wind vector cells (wvcs) that are typically 12.5, 25, or 50 km on a side. Typical coverage swaths are 500–1,600 km wide for spaceborne scatterometers and result in global coverage of most of the Earth's oceans from 1 day up to several days.

Scatterometer cross-sectional measurements are also used for scientific studies of vegetation and polar ice. In the case of vegetation, the radar cross section is dependent on canopy roughness, density, and moisture content. Unlike the ocean radar cross section, which is primarily due to surface scattering, the cross section of vegetation is dominated by volume scattering from individual leaves in the canopy. Volume scattering is also important for ice and snow sensing. In this case, backscattering mostly comes from buried ice crystals and structures. When liquid water is present in the snow, the radar cross section changes dramatically when compared to dry conditions. As a result, the primary scattering mechanism shifts from volume to surface scattering, significantly altering the backscatter dependence on incidence angle.

This sensitivity makes scatterometer measurements very useful for monitoring freeze and thaw cycles in the polar regions.

Spaceborne scatterometers

A number of scatterometers have flown onboard Earth-orbiting spacecraft. The first of these was the Seasat-1 Scatterometer (SASS) in 1978, which first demonstrated the utility of spaceborne scatterometers. SASS was followed by the ERS-1 and -2 Advanced Microwave Instrument scatterometer mode (ESCAT) in 1992 and 1995, the NASA scatterometer on ADEOS-I in 1996, the SeaWinds scatterometer on QuikSCAT and ADEOS-II in 1999 and 2003, respectively, and the Advanced Scatterometer (ASCAT) on MetOp A in 2007. SeaWinds on QuikSCAT ceased its primary wind mission in 2009. ASCAT continues operating as of mid-2012. SASS, NSCAT, and SeaWinds were developed by the USA and operated at Ku-band (14 GHz), while ESCAT and ASCAT were developed by the European Space Agency (ESA) and operated at C-band (5.4 GHz). The Indian Space Research Organisation (ISRO) launched a scatterometer similar to QuikSCAT on Oceansat-2 in 2009. The Chinese Space Agency also launched a scatterometer similar to QuikSCAT on HY-2A in 2010.

A summary comparison of the key features of various wind scatterometers is provided in Figure 2.

SASS, ESCAT, NSCAT, and ASCAT were fan-beam scatterometers, while the SeaWinds scatterometer employs a rotating dual pencil-beam antenna. In a fan-beam scatterometer, along-track resolution results from a combination of a narrow antenna pattern and the timing

Radar, Scatterometers, Figure 2 A comparison of key features of various spaceborne wind scatterometers.

of transmit pulses integrated into a single measurement cell. Cross-track resolution is obtained either by range gate filtering (ESCAT and ASCAT) or by Doppler filtering (SASS and NSCAT) and the narrow beam pattern. Multiple fan-beam antennas enable multiple azimuth observations over a variety of azimuth angles.

The helically scanning SeaWinds antenna makes measurements at fixed incidence angles but at a wide diversity of azimuth angles. Measurement resolution for the SeaWinds scatterometer is based on the pencil-beam antenna footprint. Doppler processing further refines the measurement resolution. The Oceansat-2 and HY-2A scatterometers operate similarly.

Reported backscatter resolution for these sensors varies from 6 km by 25 km (SeaWinds) to 50 km SASS. Backscatter measurements are grouped on to 12.5, 25, or 50 km wind vector cell grids, depending on the sensor, and winds are estimated for each wvc.

Conclusion

Though primarily deployed for ocean wind measurement, scatterometer backscatter measurements have also proven useful in studies of land, vegetation, and polar ice. Spaceborne scatterometers have proven to be very powerful remote sensing instruments with measurements that span multiple decades and long, nearly continuous global data sets of well-calibrated backscatter and derived products. Scatterometer thus provide a valuable data set for studying global change.

Radar polarimetry; Range radar; SAR

Definition

A synthetic aperture radar (SAR) consists of two logical functions: radar and processor. The *radar* is an active imaging sensor that looks to the side as it moves along its trajectory and collects reflections from transmissions pulse by pulse, storing these data in memory. An individual reflecting object contributes reflections so long as it remains illuminated by the radar's antenna pattern. The *processor* coherently integrates these data using an algorithm that emulates the action of an antenna whose along-track aperture length equals the length of the data record from an individual backscatterer. The data record encompasses the signals that would have been received by a very long real antenna aperture, which is the source of the term "synthetic (or synthesized) aperture." The along-track (or, equivalently, the cross-range or azimuth) resolution that results is comparable to half of the along-track dimension of the radar's actual antenna. The radar must be *coherent* – thus phase preserving – while it collects reflections, so that the phase structure of the signal ensemble in memory from each and every scatterer is equivalent to that of a wavefront that would result from a single transmission.

Introduction

In its original and simplest form, a synthetic aperture radar (SAR) is a radar whose output product is an image – a two-dimensional mapping of "radar brightness" that resembles a black-and-white aerial photograph. The signal's "phase history" is the essential input to the processor that generates SAR images. More elegant forms of SAR systems take further advantage of the phase structure embedded in the data records to extract quantitative geophysical information about the scene. This entry is designed to provide a glimpse into these basic capabilities of SAR systems and to highlight key aspects of the underlying physics. [Table 1](#) provides a brief list of pertinent historical milestones relevant to modern SAR. For more information on specific SAR systems, the reader is advised to follow the citations in the discussion and to consult the (reasonably) complete list in Raney (2008). The entry closes with suggestions for tutorials, treatises, and other tools specific to remote sensing SAR systems that may be of interest to the reader.

Radar, Synthetic Aperture, Table 1 Selected milestones (citations in the text) from the history of SAR, including early discoveries that helped to establish SAR's foundations

Year	Source	Accomplishment
1842	Christian Doppler	Effect of relative motion on light

Imagery

Magellan – the 1990 NASA mission to Venus (Johnson, 1991; Pettengill et al., 1991) – successfully mapped more than 98 % of that planet's cloud-shrouded surface at nominally 120 m resolution (75 m pixels). An example is shown in [Figure 1](#). In such imagery, white represents radar-bright backscatter, as opposed to darker (black) areas that have less radar backscatter. Over terrain such as this, radar-bright areas correspond to surface roughness whose scale is on the order of the wavelength, which for Magellan was about 12 cm (S-band) (see "[Radars](#)").

Radar, Synthetic Aperture, Figure 1 Magellan craters. The impact crater Golubkina on the surface of Venus imaged by the Magellan S-band, HH-polarized SAR. Rough ejecta give rise to strong radar return, a blessing for those interested in planetary geology (Image credit, NASA).

SAR imagery appears to be viewed from above, even though the radar illuminates the scene from the side. This perspective is markedly different from that of conventional optical sensors, virtually all of which may be classed as “angle-angle” imagers. In both dimensions of an optical system, there is a ray-trace relationship between objects in the field of view and their portrayal in the corresponding focal plane. In contrast, a SAR is an example of a range-Doppler imager. The along-range (“line-of-sight”) coordinate system is distance, proportional to the round-trip time delay of the illuminating pulse and the resulting reflections. The cross-range dimension of a (side-looking) SAR is set up by the sensor’s along-track velocity. The resulting imaging perspective (Figure 2) is equivalent to that of an observer located at right angles to the slant-range plane, which is the plane that contains the radar’s radiation toward the scene. Several consequences follow from this perspective, including elevation displacement and layover leading to apparent distortions of taller features in SAR imagery and the appearance of radar shadows (Henderson and Lewis, 1998).

Phase: the fundamental measurement

An optical imager such as a common camera “works” because its lens imposes a phase delay (proportional to its thickness) that converts the spherical divergence of the incoming EM wave field into a corresponding convergence of the outgoing wave field. The camera’s film (or CCD array) is placed at the focal point of that convergence. The lens’ shape is dictated by the desired phase delay – thicker in the middle where the incoming wave

components need to be retarded and thinner toward the perimeter where the wave components need less delay. Data redistribution in the focal plane is the Fourier transform of the data across the wave emerging from the lens (Born and Wolf, 1959; O’Neill, 1963). The operations of a SAR processor are the same in principle. The processor imposes phases onto wavefront constituents in memory according to their relative position along the synthetic aperture (which may be visualized as a virtual microwave lens) and then collects (by integral transformation) the result onto a virtual focal plane.

Figure 3 shows the wavefront phase history of an individual reflecting object. The controlling system parameters are radar velocity V and (minimum) range R , radar wavelength λ , and the along-track location x of an individual scatterer with respect to the radar’s minimum range. At all scatterer positions, the incremental range $\Delta R = x^2/2R$ (following a small angle simplification, which often is reasonable for SAR systems). In radar, phase and range are related by the proportionality $2k$, where $k = 2\pi/\lambda$ is the usual wave number. Then

$$\text{Phase_increment} = 2k\Delta R \quad (1)$$

which could be defended easily as the most fundamental equation in the theory of SAR! (If ΔR is evaluated using $x = Vt$, then an individual scatterer’s phase variation as it moves across the radar’s field of view is seen to be quadratic, for which its time derivative is linear in time, which is the traditional frequency characteristic of SAR.) Note that it is not necessary that the ΔR ensemble for a given scatterer corresponds to a spherical wavefront nor that samples of ΔR be uniformly distributed along the trajectory of the radar. All that is required is that the processor “know” the incremental phases and where they are located. This degree of freedom enables effective processing of SAR data from radars mounted on maneuvering aircraft for example.

Processor: the essential ingredient

A SAR processor has essentially two tasks: image focus and data product generation. Image focus always requires azimuth processing and usually requires range processing as well. SARs use some form of range pulse coding – often linear frequency modulation (FM) – to increase the effective energy transmitted, thus improving the system SNR (see “Radars”). Linear FM is one-to-one equivalent to the linear FM of the azimuth dimension of SAR data and so may be processed in similar fashion. This similarity was first pointed out by Emmett Leith in his brilliant conceptualization of optical processing for the first successful airborne SAR system (Cutrona et al., 1960; Leith, 2000; Leith and Upatnieks, 1965). However, other range modulation schemes may be used, such as the binary code of Magellan’s radar. No matter the range modulation method, however, the SAR processor must include range focus (unless the radar includes range compression, as is sometimes true). Range processing often is based on the

Radar, Synthetic Aperture, Figure 2 Image viewing perspective. The range coordinate independent variable for the image from a side-looking radar is proportional to round-trip time delay; hence, the viewing perspective appears to be at a right angle to the slant-range plane.

Radar, Synthetic Aperture, Figure 3 Range increment. As the SAR passes a given object in the scene, at every angle either side of minimum range, the range is larger by a small increment. The SAR measures the relative phase of this extra distance. The resulting phase history is the prime input to the SAR image processor.

matched-filter paradigm (North, 1963; Turin, 1960), according to which the data are Fourier transformed, multiplied by a conjugate phase operator, and then inverse Fourier transformed.

Azimuth processing must be matched to the phase histories of the data. This simple statement implies several significant consequences. In any practical setting, there are many scatterers at different range and along-track positions simultaneously illuminated by the radar. Hence, the all-important range phase increments associated with each

scatterer overlap, so they cannot be phase matched simultaneously in the time domain. One effective strategy to overcome this challenge is to perform along-track Fourier transforms, thus remapping the azimuth data of each such block of data into the corresponding Doppler domain. In this domain, the range phase increments are single valued in azimuth frequency, since all data have their “zero” positions aligned, relative to “zero Doppler.” In principle, the matched-filter approach applies again, noting that starting with data already in the Doppler domain, only the conjugate phase multiply and the inverse Fourier transform are required.

The processor must accommodate the fact that the Doppler FM rate of each scatterer depends on its range R . Further, if the range increment size exceeds the radar’s range resolution, then the processor must correct the resulting range curvature.

The Seasat SAR (Jordan, 1980) is a good example to illustrate several key points. At a range of 900 km, Seasat’s 10 m-long SAR antenna pattern width was about 20 km, sampled by the radar’s pulse repetition frequency (PRF) at spatial separations along track of about 5 m. It follows that there were 4,000 azimuth lines in each synthetic aperture data set, thus 4,000 individual phase increments to match. Seasat’s single-look azimuth resolution was about 5 m (half of the antenna length), thus corresponding to an azimuth compression ratio (see “*Radars*”) of 4,000. At the beam edge, where the scatterers would be located 10 km from their minimum range, the corresponding range increment was 1/18 km, or about 55 m, which was on the order of 4 times larger than the radar’s (slant-range) resolution. Consequently, processing Seasat’s SAR data required range curvature correction (typically implemented by integral shifts and phase multipliers).

Radar, Synthetic Aperture, Figure 4 High-level block diagram. A SAR consists of two parts: the radar and the processor. The processor focuses the data collected by the radar, known as the single-look complex (SLC) image. The processor may also detect the SLC (estimate its power pixel by pixel), then form averaged (multi-look) imagery, which is the usual visual product.

By convention, the result of two-dimensional focusing is denoted as single-look complex (SLC) data, which consist of digital numbers that represent the image's amplitude and phase at each picture element location (pixel). In principle, these data are a perfect linear transformation of the EM wave field excited by the radar's transmissions. SLC data is most useful for subsequent processing (e.g., interferometry) that depends on signal phase information. The second task of a SAR processor is to generate the data products, which usually are one of two types, as suggested in Figure 4. Multi-look imagery is the more familiar form of SAR data, such as the example from Magellan in Figure 1. Imagery is generated within the processor by (1) detection (usually magnitude squared) to transform the SLC data into radar brightness, thus destroying the phase information, and (2) multi-look summation. The radar brightness of SLC data has very poor precision (see "*Radars*"), since by definition, it is characterized by a mean-squared-to-standard-deviation ratio of unity. This is due to the coherent nature of the input data, which generates manifold self-interference within the resulting imagery; the resulting "noise" is known as SAR speckle. Speckle has its good aspects as well as bad (Raney, 1998). General practice is to reduce speckle either by averaging statistically independent versions of the same scene or by averaging adjacent areas of a detected SLC image. Typical standard SAR image products have four or more looks.

For many years, there has been interest in filters that suppress speckle. If linear techniques are used, then there always must be a trade-off between looks and resolution (Porcello et al., 1976). Nonlinear techniques promise to get around that fundamental constraint, but the results are mixed. Early versions imposed a bias on the local mean and had difficulty with bright point reflections. Lee et al. (2008) have developed a mean-preserving technique that manages bright targets well and which may be implemented with an efficient algorithm.

For more on SAR processing, see Curlander and McDonough (1991) and Data Processing, SAR Sensors.

SAR interferometry

A SAR image of terrain is a two-dimensional mapping of a three-dimensional surface. Unless more information is

available, there is no way to quantitatively estimate terrain height with respect to a datum plane. Of course, as with aerial photographs, a pair of SAR images, each taken at different incident angles, could be used as a stereo pair. Being a coherent system, however, SAR supports interferometry, which is a much more powerful tool.

The basic interferometric environment is one in which there is a pair of mutually coherent data ensembles having the same carrier frequency and two-dimensional phase modulations, but within which a subset of elements have different reference phases (Hanssen, 2001). Signal processing is designed to estimate those phase differences and to deduce geophysical parameters of interest from the resulting measurement. In its finest forms, SAR interferometry is able to generate high-quality elevation contour maps or to observe physical movements or other changes in the observed scene that are at scales smaller than the wavelength of the radar being used, regardless of the radar's resolution.

The interferometric signal model is simple in concept. For the SLC images from one scattering element, let the signal pair be described by:

$$\begin{aligned} s_1(t) &= \Gamma_1 \exp\{-j\varphi\} \text{ ("master")} \\ s_2(t) &= \Gamma_2 \exp\{-j\phi + j\Delta\varphi(t_2 - t_1)\} \text{ ("slave")} \end{aligned} \quad (2)$$

where the subscripts t_1 and t_2 suggest that the two signals may be obtained at two different points in time as well as from two different spatial perspectives. The objective is to estimate (usually by cross-correlation) the relative interferometric phase difference:

$$\text{Phase_difference} = \Delta\varphi(t_2 - t_1) \quad (3)$$

The phase difference may be due either to geometric or to temporal differences (at wavelength scales) between the two observations.

Any approach to phase difference measurement is subject to the fundamental 2π ambiguity characteristic of phase estimation algorithms. In many radar applications, knowledge of the physical constraints of the situation coupled with phase unwrapping algorithms is sufficient for the purpose. More on the phase unwrapping problem may be found in Zebker and Lu (1998).

Radar, Synthetic Aperture, Figure 5 Elevation baseline. Data gathered by a radar from two vantage points separated in the vertical plane are sufficient to estimate the range elevation angle as well as the range distance to each resolved scatterer. The sensitivity of this vector range measurement depends on the radar's wavelength, baseline B , and viewing angle θ_{EI} .

Successful interferometry requires at least some mutual coherence between the complex scattering coefficients Γ_1 and Γ_2 . Coherence usually is expressed in the classic form (Born and Wolf, 1959) as the normalized mutual coherence function γ_{12} . A map of coherence over a scene of interest frequently is a supporting data product for interferometric SAR, where $\gamma_{12} \sim 1$ indicates high coherence, therefore more robust interferometry, and smaller γ_{12} indicates less coherence.

Topographic contours

Consider two SAR images of the same scene taken by the same radar from the same aspect, but from different altitudes, as shown in Figure 5. The slight difference in range between the two views differs across the scene on the scale of the radar's wavelength, a difference that is expressed in terms of phase and, in particular, in the phase exposed by interferometric combination of the two (SLC) data sets. The phase distribution over the scene is known as an interferogram, which can be interpreted as a mapping of the elevation contours of the surface, once the systematic phase grid due to the elevated viewing geometry is removed, and the 2π (phase-wrap) ambiguities are sorted out. The first demonstration of this technique was from an aircraft, with two antennas, one mounted above the other (Graham, 1974). That antenna separation of a meter or so may be fine for an aircraft, but the optimal vertical separation is proportional to radar range, leading to a desired interferometric baseline of 50 m or more for an orbital system, which for most spacecraft would not be practicable. The Shuttle Radar Topography Mission (SRTM) provided a very nice

example of space-based single pass SAR interferometry (Bamler et al., 2003; SRTM, 2005).

In the mid-1980s, a brilliant innovation was proposed by R. Goldstein (Zebker and Goldstein, 1986) to circumvent the antenna separation problem for satellite-based radars, namely, to use the same radar but on different orbital passes to get the required master/slave data pair, under the constraint that the two data sets must be mutually coherent. This technique, known as repeat-pass InSAR, has become the mainstay of space-based SAR operations.

The constraint on mutual coherence is not trivial, with spatial and temporal implications. Assume at the outset that the scene reflectivity is the same for both passes of the radar, particularly at the detailed level of the radar wavelength. The spatial constraint applies to the effective baseline B between the two orbital passes. For full coherence, the radar wavelength projected onto each area of the surface must be the same from both orbits. Since the two orbits are separated, the surface is observed at a slightly different incident angle, so that the wavelengths projected onto the surface are proportionally different. Mutual coherence is supported only if the range bandwidth of the radar signal is sufficient to assure overlap of the spectra of the wave numbers as projected onto the surface. Loss of mutual coherence through increasing orbit spacing is known as *baseline decorrelation* (Gabriel and Goldstein, 1988; Zebker and Villasenor, 1992). One may show for reasonably level terrain that the upper bound on acceptable baseline is:

$$B \leq R\lambda \tan \theta_{EI} / 2r_R \quad (4)$$

where r_R is slant-range resolution (which is inversely proportional to range bandwidth) and θ_{EI} is the angle between the radar line of sight and vertical (toward nadir from the spacecraft).

The second consideration has to do with scene coherence. This requirement is more readily satisfied for short inter-opportunity intervals and for longer-wavelength radars. For many scenes, one can find the so-called permanent (or persistent) scatterers (Ferretti et al., 2001), features (such as corner reflecting shapes that are frequently seen in urban areas) that maintain their phase characteristics seemingly indefinitely.

Coherent movement detection

Now consider two images of the same scene taken at two different times, but from (exactly) the same vantage point. If there is movement of even one coherent scatterer within the scene between the two observations, this may be evidenced as a change in the reference phase of the corresponding signal and hence detectable. An element of the scene with velocity v_{rad} toward the radar over an observation time interval of δt seconds will result in:

$$\text{Movement_phase_difference} = 2kv_{rad}\delta t \quad (5)$$

Radar, Synthetic Aperture, Figure 6 Motion sensitivity. The sensitivity of multi-pass SAR data sets to coherently sensible motions in the observed scene varies over several orders of magnitude, as illustrated by the examples of glaciers, earthquakes, and land subsidence.

which becomes more sensitive to smaller velocities for shorter wavelength (recall $k = 2\pi/\lambda$) and longer observation time. This technique lies behind all reasonable SAR-based moving-target-indicator radars (Raney, 1971; Urkowitz, 1964) and has been demonstrated from space-based systems (Palubinskas and Runge, 2008).

There is a huge range of possibilities lurking in Equation 5, from relatively high-speed movements such as vehicles or ocean currents (which require observation time intervals as short as 1 ms) to glaciers (Venkataraman et al., 2005) or even land subsidence (URL/PSInSAR, 2008) (Figure 6). The resulting data products are maps that show the distribution and rates of movement of elements within the scene. The same technique also can display in graphic detail differential land movements caused by an earthquake (Massonnet et al., 1993), if a pair of suitable SAR data are available from passes before and after the event.

In practice, it usually is not possible to repeat the same measurement from exactly the same vantage point, so that there will be residual topographic signals in the interferogram along with coherently sensible displacement signals. The topographic component can be estimated and removed by using a third image in combination with one of the other two, creating a pair for which the temporal baseline is too short to be sensitive to slow small in-scene movement, yet whose spatial baseline is suitable for terrain elevation measurement.

SAR polarimetry

A polarimetric radar is one that measures certain parameters of the observed EM field that depend on the transmitted and/or received polarizations (see “*Radiation, Polarization, and Coherence*”). The first dual-polarized imaging radar

was the APQ-97, which offered photographic images at either HH or HV polarization. Since the 1950s, the variety of transmit and receive polarization combinations offered by SAR systems has expanded considerably, for which a road map (Figure 7) should be helpful. Single polarization is the simplest case, epitomized by the ERS-1/2 (Attema, 1991), Magellan (Johnson, 1991), and RADARSAT-1 (Raney et al., 1991) systems. Dual polarization usually refers to two receive polarizations following one transmitted polarization, in the same spirit as the APQ-97; hence, the relative phase between the received polarizations is not available. In this road map, “dual polarization” also includes two transmitted polarizations when they alternate noncoherently, illustrated by ENVISAT (URL/ASAR, 2008) and certain modes on ALOS/PALSAR (URL/PALSAR, 2008). The distinguishing feature of this class of polarimetric radars is that their primary data product is *imagery*, sufficient to calculate ratios of powers drawn from different polarization combinations. Conventional dual-polarized imaging radars do not measure relative phase between the two receiver channels.

As was shown by Stokes in 1852 (Stokes, 1852), any partially coherent quasi-monochromatic EM field can be fully characterized by four real numbers, known as the Stokes parameters. These may be derived from the 2×2 coherency matrix of the field or, equivalently, from its covariance matrix. This theme characterizes the polarization combinations of Figure 7 whose data products may be viewed as matrices. Evaluation of the elements in these matrices requires knowledge of the relative phase between the radar’s two receive channels. This class of radars makes polarimetric measurements, not just polarization-dependent images.

The most complete embodiment is fully polarimetric, in which the transmitted field alternates between two orthogonal polarizations at Nyquist rate (which assures that the Doppler bandwidth of the backscatter is sampled adequately by both polarizations) and the resulting backscatter is received on two orthogonal polarizations coherently [preserving the relative phase between the two channels]. The classic form (van Zyl et al., 1987) transmits H or V polarization, multiplexed, and receives H and V coherently after each transmission. It turns out that a hybrid-polarization architecture has several advantages over linearly polarized architecture (Freeman and Raney, 2008; Raney, 2007). Hybrid polarization denotes an architecture in which circular polarizations are transmitted (L or R) and linear polarizations are received (H and V). Independent of the polarization plan, the resulting data from a fully polarimetric radar are sufficient to calculate the 4×4 covariance matrix representation of the data, which in turn is sufficient to fully characterize the complex reflectivity coefficient of all resolved elements in the scene. Certain symmetries may be found in the 4×4 matrix, which when exploited under appropriate assumptions lead to a reduced 3×3 matrix, commonly accepted as the standard “quad-pol” data product (Zebker and Van Zyl, 1991).

Radar, Synthetic Aperture, Figure 7 Hierarchy of polarimetric SARs. There are many possible combinations of receive and transmit polarizations and associated terminology for SAR systems. This chart traces the relationship between the radar and its data products for a single-polarization system, and progressively more elaborate SARs, from dual polarization through compact to full polarization.

If only one polarization is transmitted and two polarizations are received coherently, then the natural data product is the 2×2 covariance matrix of the observed field. (The elements of the complex scattering matrix cannot be found, because the single transmit polarization is not sufficient to probe all possible transmit and receive reflectivities.) This type of coherently dual-polarized radar is known as compact polarimetry, since its objective is to enjoy many of the benefits of a quad-pol system without incurring its disadvantages (Dubois-Fernandez et al., 2007; Souyris and Mingot, 2002). The 2×2 covariance matrix can be expanded to a 3×3 pseudo-covariance matrix by postulating certain symmetry properties (Souyris et al., 2005). The trick with a compact-pol radar is to choose the transmit polarization to match the measurement objectives of the radar; two appealing options are $\pi/4$ (Souyris and Mingot, 2002), known as slant polarization in radar meteorology, and circular (Raney, 2007).

Elegant analysis tools have been developed for quad-pol data (Cloude and Pottier, 1996; 1997), based in large part on well-established matrix decomposition techniques borrowed from quantum mechanics. Similar methodology also may be applied to data from the newer compact-pol architectures. These techniques are successful in parsing the scattering characteristics according to several disjoint classes, including volume backscatter, single bounce (including Bragg reflection from a random surface such as the ocean), and double bounce (from certain geological

formations or volumetric ice deposits), all of which have value in specific applications. For an excellent online tutorial, see URL/Polarimetry_Tutorial (2008).

SAR design rules of the road

SAR systems must obey certain physical rules if they are to provide useful remote sensing data. The key issues are summarized in this section. For more on the theory of SAR design, see Curlander and McDonough (1991) and Harger (1974). More radar-specific issues may be found in Skolnik (2008).

PRF constraints

SAR is a sampled system; hence, the sampling – the pulse repetition frequency (PRF) – must satisfy the Nyquist rule. It follows that the PRF f_p be sufficiently high to sample unambiguously the Doppler spectrum of width B_{Dop} . A radar must receive as well as transmit. Thus, the PRF must also be low enough so that there is time between transmissions to receive the data backscattered from the intended swath of slant-range (time-domain) width T_R . The traditional form (Curlander and McDonough, 1991) for these bounds on SAR PRF is:

$$B_{Dop} < f_p < 1/T_R \quad (6)$$

In practice, sufficient margin must be included in both the upper and lower limits to account for the length of

the transmitted pulse and for the fact that neither the spectrum nor the antenna's elevation pattern has sharp cutoffs. Equation 6 implies an intimate relationship between swath width (in range) and resolution (in azimuth), with consequences of course on the top-level characteristic output data products.

The lower bound often is recast as:

$$B_{Dop} = \frac{2V}{D_{Az}} < f_p \quad (7)$$

which states that the PRF must be sufficiently high such that there are at least two transmissions per antenna aperture length D_{Az} as the radar moves along its trajectory at velocity V . Usually the PRF lower bound is set so that there is a margin of 25 % or more with respect to this constraint.

In an airborne SAR, the PRF constraint is derived to satisfy the bandwidth-limited lower bound, from which follows the maximum range that the radar can operate without introducing ambiguities. However, by default, the minimum range for a space-based SAR is its orbital altitude, usually 600 km or higher. The typical slant range to the intended scene may be 800 km and more. Thus, the upper bound on the PRF should not be set by the range to the scene, but rather by the range width of the area to be imaged. As a consequence, the resulting high PRF will generate a sequence of pulses at any moment that are distributed between the radar and the scene. The space between pulses must be larger than the intended swath width. For example, in certain modes, RADARSAT-2 (URL/RADARSAT, 2008) generates seven pulses "in flight" simultaneously. At the beginning of such a data collection, backscatter from the intended scene would arrive only after the seventh pulse had been transmitted.

Ambiguities

The PRF generates a two-dimensionally sampled space when the data are decomposed into "slow time" (in the azimuth direction) and "fast time" (in the range direction). In azimuth, the PRF creates aliased versions of the data illuminated by the main beam of the antenna. The spectra of these aliases are located at multiples of the PRF to either side of the centroid of the main beam. Of course, when sampled, they are folded back into the Nyquist passband. These aliases are azimuth ambiguities, which should be suppressed – hence not visible – in a well-designed system. This burden falls upon the antenna illumination pattern and frequency-dependent weighting in the processor, as well as on the choice of PRF. Azimuth ambiguities are relatively easy to identify because they are weaker (ghost) duplicates of image features that were collected through the main beam and, therefore, at earlier or later positions along the image strip. The azimuth shift of the ambiguities relative to the central image is an integral multiple of $\Delta X = R\lambda f_p/(2V)$, which is the spatial

offset corresponding to the PRF. Azimuth ambiguities, especially from point targets, have the same FM rate as scatterers within the main beam, and so their focus is preserved through the processor.

In the range direction, one of the consequences of having many pulses in flight at once is that there are echoes from several different ranges that arrive back at the radar at the same relative delay within the range gate as the reflections from the intended swath. If these extra echoes are sufficiently strong, the resulting image artifacts are range ambiguities. Their relative strength depends on the range side-lobe levels of the antenna pattern. Range ambiguities are not as easy to identify as azimuth ambiguities, because they arise from ranges outside of the nominal swath, hence not echoing features that are imaged elsewhere. Range ambiguities by definition arise from ranges that are different from those for which the processor is set, so that range-ambiguous point targets tend to be defocused.

Antenna area constraint

The principal means of suppressing ambiguities is to confine the main beam of the antenna so that the potential sources of azimuth or range ambiguities are not illuminated or at least are illuminated only very weakly through the antenna's side lobes. This requirement imposes a minimum area constraint on the SAR's antenna. The lower and upper bound PRF constraints of B_{Dop} and $1/T_R$ lead to:

$$D_{El}D_{Az} > 4RV(\lambda/c) \tan \theta \quad (8)$$

where the antenna area is the product of its length D_{Az} and height D_{El} , and θ is the mean incident angle in the imaged swath. The range-velocity product in this expression is determined by the parameters peculiar to the particular planet (or moon) about which the SAR is to operate (see Table 2 in "Radars").

Image quality

Engineering norms and geophysical information capacity are the two dominant aspects of image quality for data from remote sensing SARs. Engineering norms include the radar's additive signal-to-noise ratio (SNR) and its multiplicative signal-to-noise ratio (MNR) (see "Radars"). Good SNR means that areas of relatively weak backscatter appear above the radar's intrinsic noise level. Good MNR means that the data products are free of artifacts such as range or azimuth ambiguities.

Geophysical information capacity is equally important as an image quality indicator for remote sensing SAR systems, although it is a more subtle concept. Looks and resolution work together to determine this aspect of image quality, one that is particularly appropriate for SAR response to natural terrain composed of distributed

scatterers. The governing expression is the SAR image quality parameter (Raney, 1998):

$$Q_{SAR} = \frac{N_L}{r_{Rg} r_{Az}} \quad (9)$$

where N_L is the number of (statistically independent) looks and r_{Rg} and r_{Az} are the range and azimuth resolution, respectively, on the surface. The important lesson of this relationship is that a modest increase in number of looks can be applied to offset a corresponding degradation in range resolution. Both looks and resolution require support in bandwidth. It follows that Q_{SAR} is proportional to the product of the range and azimuth bandwidths and hence proportional to the (two-dimensional) information capacity of the radar in the Shannon sense (Shannon, 1948). This principle was applied with great profit to the Magellan SAR design. The image quality of Magellan data varied by no more than about $\pm 2\%$ pole to pole (Johnson, 1991), in spite of large variations in radar range, incident angle, and ground range resolution over that radar's elliptical orbit.

SpotSAR and burst modes

The baseline single-look SAR azimuth resolution is proportional to one over the bandwidth generated by the azimuth beamwidth of the side-looking antenna. The corresponding length of the synthetic aperture is equivalent to the along-track spread of the antenna pattern, which, of course, is proportional to range. Azimuth resolution may be sharpened only by increasing bandwidth, which can be done in one of two ways: increasing the antenna's beamwidth or increasing the spread of aspect angles within which the antenna illuminates a given portion of the scene. The latter is the basis for Spotlight SAR (Jakowatz et al., 1996; Walker, 1980), in which the antenna is steered to dwell on the intended area as the radar passes, thus creating a wider total bandwidth (and a longer synthetic aperture). The trade-off is that adjacent areas along track may not be imaged at all. Increasing azimuth resolution by broadening the antenna pattern, by either reducing the aperture length or spoiling the beam, has several disadvantages, especially reduced antenna gain, thus degrading SNR (see "Radars").

Going the other direction – smaller bandwidth – leads to more coarse azimuth resolution. The bandwidth of the original signal history from a given backscatterer may be reduced by the simple expedient of generating a shorter synthetic aperture than in the usual strip mode, for which the radar is "on" all of the time. This logic leads to the "burst mode," which figures prominently in two forms in space-based SARs. Burst mode means that the radar is operated only during limited periods, rather than continuously. Along a single imaged swath, this implies a reduced data rate, which may be necessary to meet the stringent data-rate requirements confronting planetary or lunar missions. Alternatively, the intervals between bursts may be used to illuminate several different range swaths, thus

expanding the area that may be imaged unambiguously. This is the principle behind the ScanSAR mode (Luscombe, 1988; Moore et al., 1981).

Ambiguity space trade-offs

The fundamental rule is that the image space (illuminated by the antenna) must be "underspread" if ambiguities are to be avoided. The underspread condition (Green, 1968) is that:

$$T_R B_{Dop} < 1 \quad (10)$$

where T_R is the (slant) range swath depth of the antenna pattern and B_{Dop} is the corresponding bandwidth. This constraint (which may be recognized as a rearrangement of the bounds in Equation 6) may be expressed in terms of the antenna's azimuth beamwidth β , the number of azimuth looks N_L , and the duration T_{Az} of illumination time (Raney, 2008) to read:

$$\frac{T_R \beta R N_L}{T_{Az} r_{Az}} < 1 \quad (11)$$

which shows how resolution and target illumination time may be traded against each other while still respecting the fundamental ambiguity avoidance constraints. The formal justification for SAR imaging modes – strip map, SpotSAR, burst, and ScanSAR – follows from this simple inequality.

Fundamental principles

Under certain reasonable assumptions, a SAR obeys several high-level principles (Raney, 1998) that prove to be helpful in analysis and offer insight into how the system works. The assumptions are as follows: (1) The radar uses only one transmit and receive polarity. (2) Input signals from the scene combine linearly within the radar and the processor prior to detection. (3) The system uses a magnitude squared method of detection. (4) Signal manipulations on the output are linear in power. The assumption of input linearity for a SAR is true outside of the radar and almost always true inside. Magnitude squared detection, one of several possible methods, is convenient for mathematical reasons and finds justification in nature as well. Following detection, additional averaging may be performed, known as incoherent integration since it occurs in the power domain, equivalently "multi-looking" in SAR parlance.

Principle 1. Coherent scene illumination

Input to a SAR is a linear summation of voltages from reflecting elements within the scene that are illuminated by a coherent EM wave field. In distinct contrast to typical optical systems, for most SARs, the illumination from each transmitted pulse is essentially monochromatic, emitted from a point source. This implies that the radiating field has structured phase fronts, which may be well represented for most purposes by spherical surfaces,

centered at the radar. Thus, the EM illumination incident on the scene is coherent. This means that the reflections from more than one scene element combine through vector addition.

Principle 2. Image power mapping

Image domain output from a SAR is a mapping of power, derived from scene reflectivity, and presented as a two-dimensional array of numbers. It is customary to think of a radar image as a visually observable entity, such as a photographic print, whose brightness (whiteness in a positive rendition) at each location is proportional to the strength of the corresponding radar echo. As was the case with the first principle, the statement seems obvious, but there are significant implications. For coherent fields, the power is given by the magnitude squared of the vector voltage sum, not by the sum of the powers of individual echoes. Constructive and destructive interference takes place between the members of the signal ensemble. This leads to substantial variations in the power estimates known as speckle, clearly seen in most SAR imagery.

Principle 3. Well-behaved transformation

The transformation from EM scene reflectivity to image data by a SAR may be characterized if and only if both the response to an isolated point scatterer and the response to a uniform Gaussian distributed scattering field are determined. This important principle applies to all partially coherent systems which can be represented with the mathematics of quadratic filters, a wide class that includes optical and radar sensors (Raney, 1969). The common feature of such systems is that they operate on an input signal field in voltage to produce an output data field in power, using linear filters and square law detection, combined according to the degree of coherence in use by the system, and by the prevailing coherence of the scene. It is well known that a linear filter may be characterized by its response to an arbitrarily short test signal, which produces its so-called impulse response function (Woodward, 1955). Application of the Fourier transform to the impulse response function produces a frequency domain description of the linear filter, known as its transfer function. It is also true that the frequency distribution of a linear filter may be determined by observation of its frequency response to white Gaussian noise. The impulse response and the system frequency transfer function are logical equivalents of each other for a linear system. This simple relationship is not sufficient for radar systems. For a SAR, as with all partially coherent systems, measurement (or specification) is needed of both the impulse response and the frequency function (Raney, 1985). The purpose of the impulse response test is to estimate the system imaging function, analogous to the point spread function encountered in optics. The purpose of the Gaussian response test is to estimate the extent of system partial coherence. The essential lesson in this principle is that a SAR is well behaved in the best sense of system theory,

even if its properties are less familiar than those of a system that is linear exclusively either in (complex) amplitude or in power (such as most optical sensors).

The following principles highlight two radiometric rules for the image radar brightness that follow from the well-behaved principle, combined with the benefits of the large time-bandwidth product that characterizes most SAR systems.

Principle 4. Conservation of energy

For any neighborhood, if the scene is a Gaussian field, and all available data are used in each case, then the tone of the corresponding area in the image is a constant, independent of system focus, system coherence, or scene coherence. A Gaussian field (mathematically speaking) is an important idealized scene for imaging studies (Goodman, 1976). A wheat field (from the point of view of a farmer) is the classic practical example, having spatial features that are far too small to be resolved by the radar and having a uniform average reflectivity over an area much larger than the resolution cell. The radar is to estimate the power reflected from the wheat field by observing the corresponding average brightness value, or tone, in the image. The Gaussian property in this case derives from the fact that for each element in the image, there are many individual scatterers, such as the heads of the wheat shafts, contributing to the total scattered signal. One might think that the tone would depend on the details of the field, including the number, size, and location of each scattering element. Even more tempting, one might think that an error in system focus, or a change in the degree of partial coherence used in the processor, would lead to a change in the image tone. Wrong on all counts! Within very broad constraints, image tone is robust even when certain parameters change, which is the point of the compact wording of this principle.

The principle of conservation of energy is very powerful. Among other things, it establishes a solid basis for radiometric calibration of a SAR whereby image brightness values can be transformed to scene reflectivity estimates. For a given SAR, conservation of energy provides assurance that image average brightness (tone) is preserved independent of the number of degrees of freedom (looks) in the image data. Furthermore, given the same viewing geometry, polarization, wavelength, and system bandwidth, two different (calibrated) radars should provide equivalent mean reflectivity estimates for the same scene. This fact allows measurements from scatterometers and other radars that are not "SAR systems" to provide reflectivity data that are directly applicable to SAR observations.

Principle 5. Conservation of confusion

For any neighborhood, if the scene is a Gaussian field, and all available data are used in each case, then the uncertainty associated with each corresponding area in the image is a constant, independent of system focus,

system coherence, or scene coherence. This principle is concerned with speckle, which is the second statistical moment of the radar brightness of a random field that has nominally constant tone. The expected uncertainty in radiometric response at each pixel usually is measured by its covariance. (The covariance often is called the variance in SAR literature, a source of potential confusion.) The covariance is defined as the square of the second moment with respect to the mean value. The normalized covariance, which is the covariance divided by the local mean squared, is a measure of the amount of averaging in the data. The statistical number of degrees of freedom (“looks” in SAR literature) is given by the mean, squared, divided by the standard deviation. Speckle radiometric variation at any image pixel is correlated with that at neighboring positions. The width of the covariance function is defined as speckle correlation length, which is equal to the inverse of the coherent bandwidth of the system (in both the range and the azimuth dimensions).

The *uncertainty* at each point is measured by the volume under the normalized two-dimensional image covariance function. The principle of conservation of confusion states that the uncertainty volume is a constant of the system, under a wide variety of circumstances. A corollary of this principle states that there is a trade-off between resolution and the amount of averaging that may be used to reduce speckle variance, which is the formal justification for the image quality of Equation 9. This consequence is an example of the uncertainty principle for energy conservative systems (Papoulis, 1968).

Principle 6. Conservation of coordinates

For a range/radar, the output mapping has constant range and azimuth coordinate locations on the imaged surface, independent of angular rotations of the sensor. This principle follows from the first and third principles, and the illumination geometry customarily used with SAR systems. It implies that there is a fundamental spatial mapping accuracy available from a range-Doppler radar such as a SAR that is inherently less sensitive to sensor pointing precision than for most other imaging systems. In range, the coordinate is proportional to time delay, which is not affected by sensor rotations. In azimuth, the coordinates are established by the frequency gradient across the scene, which in turn is determined by the vehicle along-track velocity and its instantaneous along-track position. In either dimension, an error in sensor pointing does not impact spatial location of the coordinate system with respect to the sensor.

Conclusions

SAR is a mature field, but still moving ahead. Spectacular results are now routine from such space-based systems as PALSAR, RADARSAT-2, and TerraSAR-X. There are excellent online tutorials available, including URL/SAR_Tutorial (2008). More specialized online reference materials may be found at URL/INSAR (2008) for

interferometry and URL/Polarimetry_Tutorial (2008) for polarimetry. SAR conferences and workshops worth considering include IGARSS, PolInSAR, and Fringe, among others.

Definition

RADAR, an acronym derived from *RA*dio *DE*tectioN *ANd* *R*anging, is an active sensor that transmits and receives electromagnetic (EM) waves. Remote sensing radars are designed to generate terrain maps or to measure a wide variety of geophysical parameters such as wind speed over the ocean, forest biomass, or annual sea-level rise.

Introduction

Radar was first field tested and patented in 1904 (Hulsmeyer, 1904) but did not attract serious attention at the time. Sir Watson-Watt, with his 1937 Chain Home coastal radars (20–30 kHz, 350–750 kW peak power), is generally credited (somewhat disingenuously) as the “father of radar,” due in large part to the spectacular success of this system in the Battle of Britain (Battle, 2008). Radar has evolved considerably since 1950, earning a major place in the suite of modern remote sensing instruments, which includes imaging radars (especially synthetic aperture – SAR – systems, both airborne and spaceborne), scatterometers, altimeters, and radar sounders (Raney, 2008). An outstanding early example is the Seasat satellite (Figure 1) launched in 1978, which (as its name suggests) was designed for oceanic observations. Three of its sensors were radars – a synthetic aperture radar, an altimeter, and a scatterometer. These three Seasat instruments established the initial paradigm for virtually all subsequent radars of their respective classes (Barrick and Swift, 1980; Evans et al., 2005).

Space-based synthetic aperture radar (SAR) systems capable of 1 m resolution have become the norm, with systems under development or launched by at least seven

countries. The (range) measurement precision of surface height change is on the order of 1 mm per year, as established by SARs (see “*Radar, Synthetic Aperture*”) and radar altimeters (see entry *Radar, Altimeters*). Several nations are sponsoring radars for exploration at the Moon and beyond.

Any radar system observes a scene within constraints established by the frequency, polarization, and illumination geometry of the emitted signals. After reception of an echo and subsequent processing, the observable parameters include position, reflectivity, polarization, and phase, from which geophysical information of the observed object may be retrieved. The various types of remote sensing radars are differentiated only by the design emphasis on one or more of their basic radar parameters. Military radars usually are optimized to respond to point objects (discrete targets). Such systems are characterized by fine resolution, frequency agility, moving target capability, and multiple target dynamic tracking. In contrast, the primary objective of most remote sensing radars is to measure the reflectivity of relatively large areas (distributed targets). This leads to systems characterized by moderate resolution, post-detection averaging to improve image quality, and constraints on the calibration and stability of the final image products.

Remote sensing radars (Ulaby et al., 1981) usually are classed according to their wavelength λ (related to frequency f by $\lambda f = c$, the speed of light). Most remote sensing radars use wavelengths (Table 1) that are comparable to the structural detail of many geophysical features of interest, an attribute that is a central aspect of radar data products. (International frequency allocation protocols limit the choice of frequency and usable bandwidth

Radars, Figure 1 Seasat (launched in 1978) carried a synthetic aperture radar, a scatterometer, and an altimeter, whose antennas ranged in size from 1 m (the altimeter) to 10 m (the length of the SAR antenna).

Radars, Table 1 Common radar band designations and their corresponding wavelengths and frequencies

Radar band	Wavelength (cm)	Frequency (GHz)
P	77–133	0.22–0.39
L	19–77	0.39–1.55
S	7.1–19	1.55–4.20
C	5.2–7.1	4.20–5.75
X	2.8–5.2	5.75–10.90
Ku	1.67–2.50	12–18
Ka	0.75–1.67	18–40
W	0.30–0.54	56–100

available to radars to be less than the letter designation definitions (see Table 1). Alert: “P-band” as used in radar remote sensing actually refers to the 70 cm wavelength band, thus technically at the high end of L-band. The so-called L-band remote sensing radars operate at 23 cm wavelength.) For any given system, the emitted polarization and wavelength are known constants over the scene, whereas the angle of illumination varies according to the relative position of each scatterer. For the radars of interest in this entry, the transmit antenna and the receive antenna are assumed to be in the same location, which is the monostatic configuration. (Certain radars rely on transmit and receive antennas that are separated, which is known as the bistatic configuration (Willis and Griffiths, 2007).)

The transmitting antenna determines the polarization of the emitted wave. Remote sensing radars usually use linear polarization (H or V), with the exception of Earth-based radar astronomical observatories, which invariably use circular polarization (Campbell et al., 2002), and certain meteorological radars (Bringi and Chandrasekar, 2005). As a rule, only one polarization may be transmitted at a time. Likewise, the receiving antenna selects one component of polarization of the reflected signal. If there is a change in the polarization of the transmitted wave during either reflection or propagation, then the polarization of the reflected wave will differ accordingly. This has practical implications for microwave remote sensing. The reflectivity dependence on polarization may be observed through a radar whose antenna and supporting systems are designed to handle more components and to process the data to derive polarization signatures, known in general as polarimetry (see “*Radiation, Polarization, and Coherence*” and “*Radar, Synthetic Aperture*”).

In addition to wavelength, polarization, and swath width, the radar system parameters determine the resolution and radiometric quality of the resulting image. Resolution is a measure of the radar’s sharpness, where “high resolution” means “small minimum discernable separation distance” between two closely spaced objects. “Closely spaced” is situation dependent: A good space-based SAR may offer 1 m resolution over a 5 km square image, in stark contrast to a wind-field scatterometer designed to parse the data onto a 25 km grid spanning

many hundreds of kilometers. Range resolution (along the line of sight of the radar beam) is inversely proportional to the transmitted pulse’s bandwidth. Resolution in the crossbeam direction – sometimes termed “azimuth” in certain geometries – is determined by the radar’s antenna beamwidth, unless multi-pulse signal processing schemes are applied. The radiometric quality of the radar data products usually is limited by the amount of noncoherent averaging. Such averaging, known in statistics as “degrees of freedom,” is expressed as “looks” in SAR data (see “*Radar, Synthetic Aperture*”) and as the “k factor” in scatterometry (see “*Radar, Scatterometers*”).

It often is said that radar is “all weather,” but this generalization clearly is not universally true. From space, the ionosphere and/or atmosphere may corrupt or even prevent radar wave propagation. Passage through the ionosphere may induce Faraday rotation, which is a change in the plane of polarization forced by a planet’s magnetic field. If more than a few degrees, this would degrade or even destroy the polarization properties of the transmitted and received signals (Pisacane, 2005). The Faraday rotation of a linearly polarized E-vector is proportional to $M\lambda^2$, where the rotation measure M is a function of ionospheric electron density. Clearly, Faraday rotation is more of an issue for radars at long wavelengths, such as L-band and P-band for Earth-orbital systems. The ionosphere also introduces dispersion and, under certain unfavorable circumstances, effectively cuts off propagation. Thus, for example, it was not possible for the 5 MHz MARSIS radar sounder to probe the Martian surface during daylight hours, because the cut-off frequency under those conditions increased to about 10 MHz. MARSIS was designed to work as a surface sounder during dark hours and as an ionospheric sounder during daylight hours (Gurnett, et al., 2005). The 12 cm wavelength of the Magellan Venus radar (see “*Radar, Synthetic Aperture*”) was chosen in response to the trade-off between propagation through Venus’ very dense atmosphere (for which longer wavelengths would be better) and synthetic aperture radar system considerations (for which shorter wavelengths would be better). Propagation speed is retarded along the path length from an ocean-viewing altimeter to the Earth by a very small fraction of the speed of light but sufficient nevertheless to impose range measurement errors of many meters. These errors must be estimated and compensated before the required cm-level accuracy can be achieved (see “*Radar, Altimeters*”). Atmospheric moisture is more of an issue for radars at shorter wavelengths, effectively limiting Ka-band systems, for example, under certain circumstances to a range of only a few km in terrestrial applications. In contrast, weather radars are designed specifically to observe atmospheric moisture.

Reflectivity

The information value of radar data products is conditional upon the backscatter collected by the instrument. Radar reflectivity falls naturally into two types, either

discrete (point) or diffuse (distributed), described, respectively, by radar cross section, sigma, and normalized reflectivity, sigma zero.

Sigma

Reflectivity is described by σ (sigma) if the backscatter is due to an isolated discrete scatterer – often called a point target (Skolnik, 2008). In this context, “point” usually means that the physical size of the reflecting object is smaller than the spatial resolution of the radar. A three-sided or trihedral corner reflector is a good example of a point target. Strong reflections also may occur from a simple plane surface when it is orthogonal to the line of sight of the radar. The effective area of a trihedral or dihedral is determined by the object itself and also for small flat planes. For extensive planar surfaces, such as a calm ocean surface illuminated at vertical incidence by a radar altimeter, the radar’s wavelength λ and height h above the surface determine the effective area. This is known as the (first) Fresnel zone, whose diameter is given by $(2h\lambda)^{1/2}$. The backscattered signal strength from these geometric shapes is relatively large, especially when the surface in question is smooth and is at least moderately conductive. Collectively, these are known as specular backscatter, as all the reflections tend to be in phase and directed back in the direction of the radar’s illumination. If two or more point scatterers are present in the same resolution cell of a radar, then the signals reflected simultaneously from them interfere, complicating their collective phase characteristics.

Sigma has units of area since the value of σ is equal to the surface area of the equatorial disk of a hypothetical, isotropically scattering sphere that would be large enough to cause the same reflected power observed at the radar as that seen from the target. From this equivalence, σ is known as the radar cross section (RCS). The “area” expressed by RCS (or σ) bears rather little resemblance to the size of an object; it is much more dependent on backscatter directivity due to the object’s shape and on its electrical properties. For example, at X-band, a human being and an F-18 aircraft both have (average) cross sections of about 1 m² or less, whereas a triangular corner reflector with sides 1 m long at their intersection has a cross section of about 4,500 m². Sigma may be expressed in dBm², which conveys the RCS of an object in decibels (dB) with respect to a standard RCS of 1 m². Thus, these two examples have cross sections of 0 dBm² and 36.5 dBm², respectively. (In contrast, the RCS of a stealth aircraft is on the order of 40 dBm².)

The properties of corner reflectors are reviewed extensively in Ruck et al. (1970) and summarized for remote sensing applications in Ulaby et al. (1982). As a rule of thumb, the RCS of a corner reflector or flat plate is proportional to A^2/λ^2 , where A is the effective area of the shape orthogonal to the incoming radar illumination. Carefully constructed corner reflectors are useful as calibration references.

Corner reflection also occurs in a natural situation. Dihedral reflection often is observed from the intersection between the side of an iceberg and the sea surface, or the combination of tree trunks surrounded by standing water. Trihedral reflection may occur from angular structures on a large vehicle such as a ship or from mutually orthogonal surfaces in a cluster of buildings.

Sigma zero

For distributed terrain features giving rise to diffuse scattering, the conventional description of radar reflectivity to be found in the literature is σ^0 (sigma zero, sometimes denoted sigma nought). Sigma zero represents the average reflectivity of a given surface, normalized with respect to the reflecting area on the surface, where the area is delimited by the range and cross-range resolution of the radar. Sigma zero sometimes is called the scattering coefficient (Ulaby et al., 1981), as in effect it quantifies the reflection efficiency of the terrain feature in question. It is a dimensionless fraction, usually expressed in decibels (dB) that describes the ratio of the (average) backscattered power compared to the power of the incident field. The value of σ^0 depends on the physical and electrical properties of the reflecting material and on the wavelength, polarization, and illumination’s angle of incidence. Typical values of terrain or oceanic reflectivity when viewed obliquely by a radar are much smaller than unity, on the order of –10 dB to –30 dB. In contrast, a radar such as an altimeter or (ice) sounder that looks down on a (radar-bright) horizontal surface may encounter strong reflectivities that are larger than unity, on the order of 10 dB or more. Certain large-area distributed scatterers such as the Amazon rain forest have been proven to have relatively constant normalized reflectivity of known value (see “*Calibration, Synthetic Aperture Radars*”). These are used routinely as calibration references for space-based remote sensing radars such as SARs (Luscombe et al., 2006) and scatterometers.

Sensitivity

The reflectivity observed by a radar is always in competition with noise, primarily additive receiver noise. For some types of remote sensing radars, additive noise is expressed as σ_{Neq}^0 or noise equivalent sigma zero (Ulaby et al., 1982). This number may be interpreted literally to suggest an equivalent hypothetical area whose scattering coefficient corresponds to the observed noise level, thus quantifying the inherent (additive) noise floor of the radar with respect to the span of reflection coefficients to be encountered in the radar’s application. A radar’s σ_{Neq}^0 always may be reduced (thus improved) by transmitting more power, in contrast to multiplicative noise, whose level is always proportional to the transmitted power, in the same way that the strength of the intended radar reflections is proportional to the power transmitted.

Wavelength

For a given wavelength and polarization, there are three significant factors that influence the strength of the signals reflected back toward the radar. These factors are surface roughness, local incident angle, and material dielectric constant. Surface roughness is the most important characteristic, followed by incident angle effects. Surface roughness, a qualitative norm, in the radar context always is in comparison to wavelength λ .

Typical remote sensing radars operate within a sector of the EM spectrum whose wavelengths span ~ 70 cm to less than 1 cm. Radiation at these wavelengths interacts with the detailed structural scales typical of natural and fabricated objects. The Rayleigh criterion (Rayleigh, 2008) defines a smooth surface to be one whose mean topographic height variation $h \lambda / (8 \cos \theta)$ where θ is the incident angle between the incoming ray and the normal vector of the mean surface. Radar backscatter is small from a smooth surface when seen obliquely, since most of the incoming energy is reflected in the forward specular direction, away from the radar. When illuminated at the same incidence, reflection from a rough surface will be more isotropic, reflecting a sensible portion of the EM energy back toward the radar. Within limits, greater roughness tends to increase the relative backscatter seen by the radar. Two radars that have different wavelengths may see the same object differently. Likewise, an increase in the angle of incidence may convert an extended object from “rough” to “smooth.” Of course, the Rayleigh roughness criterion is only a rule of thumb, as the point of transition between the two extremes is gradual. Nevertheless, it does provide valuable guidance on the interplay between key radar and object parameters.

The penetration of EM waves into a medium is proportional to radar wavelength and is suppressed by the material’s intrinsic dielectric losses δ . For low-loss media, such as dry sand or clean fresh ice, for which the loss tangent $\tan \delta \ll 1$, the penetration depth $D = \lambda / (\pi \tan \delta)$. This relationship is a major factor in wavelength selection for radar sounders.

Bragg scattering

There is another type of coherent scattering that occurs with certain rough surfaces having supposedly random features. If the scatterer positions are organized such that they are spaced periodically in range, then when viewed obliquely, their respective backscatters coherently reinforce each other when the several reflections are in phase. Phase agreement occurs when their range spacings r_B satisfy the Bragg scattering condition (Bragg, 2008):

$$r_B = \frac{n\lambda}{2 \sin \theta} \quad (1)$$

The relationship derives from the field of crystallography, in which the parameter n allows longer period structure to contribute to the coherent reflected component.

In microwave applications, only the lowest order case ($n = 1$) usually is dominant.

Bragg scattering, as with other forms of co-phase combination of individual reflections, leads to a total reflected power that is proportional to the square of the number of constituents, which is always greater than that from randomly phased scatterers for which the total power is proportional only to their number. Reflectivity from certain natural rough surfaces, such as the ocean, is predominantly Bragg scattering (Zebker and Van Zyl, 1991). This is a consequence of the inherent selectivity of coherent scatterer reinforcement: in an ensemble of randomly located scatterers, if there is a subset whose spacings satisfy the Bragg condition, then the probing wave will find them.

Accuracy and precision

Reflectivity measurements suggest that a direct relationship exists between σ^0 at each resolved location in the system’s data product and the radar brightness (power) derived from the scene’s echoes. Unfortunately, radars do not observe directly the power of each individual echo. As a result, the accuracy and precision of any radar measurement deserves careful attention. In the vast majority of remote sensing radars, at any given instant, many individual echoes from within a given resolution cell are presented simultaneously to the receiver. Each such backscatter constituent has its own amplitude and phase. These combine to form one signal (amplitude and phase) that represents the radar’s output at that particular resolution cell. This seemingly simple fact has many consequences; it is the smoking gun – and also the blessing in disguise – behind many subtle aspects of remote sensing radar performance. Because of this phase-sensitive summation at their front end, radars always must be respected as coherent sensors (the resulting radar measurements may or may not take advantage of signal coherence. Coherent radars do, in contrast to noncoherent radars, as reviewed in subsequent paragraphs), setting them apart from most other remote sensors.

To quote Wikipedia, “Accuracy is the degree of veracity while precision is the degree of reproducibility” (Accuracy, 2008). In other words, accuracy is the relative agreement between the average result of a measurement and the actual value of the intended parameter, whereas precision is the concentration of a distribution of measurements (described by standard deviation for example) with respect to their mean. (Alert: Standard deviation is denoted in most statistical references by the symbol σ ; potential confusion with a target’s radar cross section σ usually may be determined by context.)

Accuracy

For any remote sensing radar whose radiometric properties are stable over time, its accuracy may be “tuned up” by calibration, the objective of which is to minimize – even to drive to zero – any systematic residual difference

Radars, Figure 2 The probability distribution functions (normalized to unity maximum value) of the power estimated by a radar in response to distributed random scatterers (having $\sigma^0 = 1$) parameterized by the number of statistically independent looks. These PDFs belong to the family of gamma functions.

between the radar's mean measurement and the true value. For users, post-calibration accuracy is the radar's measurement characteristic that counts. Remote sensing radars have moved successfully into the realm of quantitative measurement, for which the norm is relatively small tolerance on acceptable error for their geophysical measurements. Effective calibration depends on preflight system characterization, calibration references built into the radar, and on external "end-to-end" references of known radar reflectivity, such as corner reflectors or large areas of distributed scatterers (see "*Calibration, Synthetic Aperture Radars*").

Precision

Most (remote sensing) radars are precision challenged when viewing distributed (diffuse) backscatter. This is the unavoidable consequence of combining within one radar resolution cell many individual echoes that have about the same frequency, but whose phase and amplitude are random. Precision reflects radar radiometric uncertainty, which in the wider world of radar is known as "fading." In SAR (see "*Radar, Synthetic Aperture*"), jargon for the same concept is "speckle."

Radar measurement precision in response to diffuse backscatter under most circumstances is well modeled by signals that are complex Gaussian. Consider the problem of measuring the radar backscatter of a scene whose normalized reflectivity is unity. This notional radar transmits one pulse, receives the backscatter, and after demodulation, amplification, and pulse compression (none of which are relevant to the present issue) forms an estimate of the received power by magnitude-squared detection. If this experiment is repeated many times, the results taken individually converge to an exponential probability

distribution function, as in Figure 2. Note that the most likely normalized reflectivity value is zero (!) for this $N = 1$ (one-look) case. The sample points are distributed widely from zero to several times the nominal value of unity, which is about as imprecise as the measurement can get. The variance (and standard deviation) of this example is 1. If the variance is viewed as noise, then this result implies for the $N = 1$ case an effective signal-to-noise ratio of 1. The alert reader will have noted that this "noise" is always proportional to the mean value of the normalized reflectivity, hence sometimes termed "multiplicative." (Single-look data have their own special value, examples of which may be found in the entry "*Radar, Synthetic Aperture*.")

Now, using the same data, average together four individual power responses to get a new estimate. Then, as shown in the figure, for the resulting $N = 4$ PDF curve, the sigma zero accuracy improves (as the mean of the PDF is closer to the actual value of 1.0), and the precision (the width of the PDF) also improves. The standard data product from most SAR systems is four-look imagery. Increasing the amount of incoherent (power-summed) averaging continues to improve measurement precision. The table cites the numbers typical of representative remote sensing radars. The examples include the following: $N = 16$, two hybrid-polarimetric lunar radars (see "*Radar, Synthetic Aperture*"); $N = 64$, typical of wind speed scatterometers (see "*Radar, Scatterometers*"); $N = 200$ and $N = 600$, representative, respectively, 1/10 s waveform averaging for a conventional noncoherent altimeter and a delay-Doppler (partially coherent) altimeter (see "*Radar, Altimeters*"). As a rule of thumb, precision (standard deviation) improves in proportion to the square root of the number of statistically independent samples in the average. Alternatively, the mean-squared-to-variance

ratio of the PDF equals the number of statistically independent constituents in the average.

Improved precision by incoherent averaging requires that two background conditions be met. First, the detected returns must be statistically independent (mutually uncorrelated). If not, then the results would be compromised by residual correlation within the ensemble of summed returns. Second, the backscatter must be wide-sense stationary from a statistical perspective. In other words, each of the individual measurements must “see” essentially the same scene during the interval over which the average is taken. These limits may be expressed more formally in expressions that are specific to each type of remote sensing radar.

Radars end to end

Traditional textbook treatments of radar systems usually start with the radar equation (Ridenour, 1947; Skolnik, 2008; Ulaby et al., 1982). The radar equation describes the peak power of the received signal in response to a single-pulse observation of an isolated, discrete scatterer. For simple radars, this equation is helpful as an introduction to the way radar performance depends on system parameters. One essential aspect of the radar equation is to quantify the performance of the system in the presence of additive noise, in terms of the observed signal-to-noise ratio SNR. However, the radar equation is just part of the story. Most remote sensing radars are comprised of two logical sections: the radar and the processor. This section closes with several ancillary comments.

The radar

The radar radiates a modulated electromagnetic (EM) frequency, often characterized by its mean wavelength, λ . For each transmission, the radar generates a pulse that is directed by the antenna’s pattern toward the scene. A fraction of the incident field is reflected back toward the radar where it is gathered by the receiving antenna. The received signal, being weak, is vulnerable to additive noise which accompanies the signal through the rest of the system.

There also are unwanted hitchhikers with the signal due to sidelobes in the antenna pattern, aliases due to sampling by the transmitted pulse sequence, analog-to-digital range sampling that may contribute quantization noise, and range ambiguities. Noise contributions of this kind are known collectively as multiplicative, since their level is always proportional to the level of the intended radar signal. This noise is quantified by the multiplicative noise ratio MNR, similar in principle to the additive noise ratio SNR. Unlike additive noise, multiplicative noise cannot be reduced by an increase in the radar’s transmitted power.

Both signal and noise are amplified in the receiver and demodulated from the carrier frequency to a low-pass or video frequency. In general, these video signals are written into memory. Radars that retain phase data for subsequent processing are known as coherent, with implications on the radar itself as well as the processor. At some stage

during processing, most radars estimate the power of the radar returns, an operation known as detection, the most common form being square law, for which the operation is magnitude squared, $|x|^2$.

After square-law detection, the radar (averaged) output is an estimate of reflectivity, with units of power. If the measurement is one dimensional, as it would be for an altimeter, then the output usually is in graphical form, with the horizontal axis proportional to time delay and the vertical axis proportional to radar reflectivity. For radars with two-dimensional output format, as is the case for air traffic control, wind-field scatterometers, or synthetic aperture radars, both spatial dimensions of the output are needed to represent radar brightness as a function of position. The single-pulse peak signal-to-noise ratio for a single target of radar cross section σ is given by:

$$SNR = \frac{P_T G^2 g^2(\theta, \varphi) \lambda^2 C_R \sigma}{(4\pi)^3 R^4 K_B T B F L} \quad (2)$$

The usefulness of a radar measurement must be judged in comparison to the relative noise level which competes with the desired signal observed through the same system. All electronic systems have inherent internal noise, due to the random motion of free electrons in conducting elements (Johnson, 1928). This receiver noise, although of extremely low level, competes with the very weak signals from radar backscatter in the front end of the radar, usually the low-noise amplifier (LNA). It is conventional in radar systems (Skolnik, 2008) to represent the average receiver noise power by $N_{rec} = K_B T B F$ where:

K_B = Boltzmann’s constant (1.38×10^{-23} J/K)

T = effective receiver temperature (Kelvin)

B = receiver noise bandwidth (Hz)

F = receiver noise factor

The receiver noise factor (or noise figure if stated in *decibels* (dB) as is customary) describes the noise performance of a given receiver compared to that of a perfect receiver. Naturally, a real receiver is always short of the ideal, so the noise factor is larger than unity. Typical receivers have noise figures of about 3 dB or somewhat more. The other three parameters describe the noise to be expected from an ideal receiver, having a given bandwidth and effective temperature. The product $K_B T B F = N_0$ is the noise per unit bandwidth (or noise spectral density) at the input to the receiver. From this stage on, all signals are amplified alike; hence, (at least to first order for the response to distributed targets) the SNR at the front end of the radar determines the SNR preserved in the output data products. In a multi-pulse radar, additive noise is statistically independent pulse to pulse.

The remaining parameters in the radar equation are determined by attributes of the radar, save for the target’s reflectivity σ . These parameters are:

P_T = (peak) transmitted power

G = gain of the antenna (one way, power)

$g(\theta, \phi)$ = one-way directivity (power) of the antenna, in azimuth and elevation, normalized
 λ = radar wavelength
 C_R = range pulse-compression ratio
 R = range from the radar to the target
 L = factor to account for losses in the radar

Peak power and compression ratio work together. Almost all remote sensing radars use some form of pulse modulation, so that more energy can be transmitted within a peak-power limit imposed by hardware constraints. For such pulses, pulse compression increases the peak power of the sharpened pulse, thus improving the SNR of point targets in proportion. Likewise, larger transmitted energy improves the average SNR of distributed reflections (characterized by σ^0) relative to the background additive receiver noise (characterized by noise equivalent sigma zero σ_{Neq}^0). The gain of the antenna usually is reciprocal, acting on both the transmitted EM field and the received field; hence, gain is squared in the round-trip radar equation. The same comment applies to the antenna's directivity. (Directivity and gain differ, in that directivity describes the shape of the antenna pattern, whereas gain includes losses or other imperfections imposed by the antenna as the microwave energy passing through it.)

The single-pulse radar equation of Equation 2 shows the classic R^{-4} dependence on range. This is due to the R^{-2} spreading loss of the radiated energy in traverse from the radar to the target and another R^{-2} spreading loss by the energy reflected back toward the radar. This range dependency depends on the radar's viewing geometry and the way in which a sequence of received pulses may be combined in processing. Side-looking radars usually are characterized by a multi-pulse radar equation with an R^{-3} range dependence (thanks to their antenna patterns whose width expands in proportion to range). Altimeters and sounders may have range dependence of R^{-2} in response to specular scattering from Fresnel-zone delimited areas on surfaces viewed orthogonally by these radars.

The smallness of the reflected signals in the radar's front end may be illustrated by the Seasat synthetic aperture radar. That SAR had an average radiated power of 55 W, about the same as the power consumed by a modest incandescent light bulb. Typical range for that radar was about 850 km, and the antenna had an area of approximately $10 \times 2 = 20 \text{ m}^2$. The effective power received by Seasat from an object having a radar cross section of 10 m^2 would be on the order of 10^{-17} W , about a factor of 1/1,000,000,000,000,000,000 smaller than the transmitted power. Even so, most Seasat imagery has very good average SNR, typified by $(-18 \text{ dB } \sigma^0 - 10 \text{ dB})$ with respect to the radar's σ_{Neq}^0 of -21 dB .

The processor

The discussion to this point has considered primarily the return from only one transmitted pulse. All radars of interest in remote sensing take advantage of processing over

many pulses. As transmissions are repeated, the resulting amplitude range lines constitute the input signal set for the processor. Cross-range (azimuth) processing depends on the relative phase relationship between pulses. In the simplest case, range processing and azimuth processing are orthogonal and may be considered as separate operations. In general, they are coupled, which must be accounted for in the processor. From a data processing point of view, the several types of radars used in remote sensing are distinguished primarily by the specific signal structures and processing strategies employed in each embodiment.

Most remote sensing radars depend on extensive signal processing. The more sophisticated systems, such as synthetic aperture radars, exploit the relative phases of a large number of individual single-pulse responses (see "*Radar, Synthetic Aperture*," and "*Data Processing, SAR Sensors*"). Simpler radars use only detection and video display in their signal processing. Signal processing includes detection and post-detection filter operations, such as data averaging, and transformation into the (Doppler) frequency domain, usually to sharpen the cross-range resolution of the system. The main message of this brief summary is that from a signal processing point of view, although remote sensing radars obey fundamentally similar rules based on common physical principles, they are distinguished by their respective processing strategies.

Pulse compression and bandwidth

Signal-to-noise performance of remote sensing radars is determined by the transmitted pulse's energy, even though the radar equation is usually stated in terms of peak power. Since transmitted energy is fundamental to a radar's performance, phase-modulated pulses much longer than the intended resolution are used so that the radar is better able to transmit a relatively large amount of energy while still satisfying a high resolution (i.e., short pulse) requirement. Following reception, the radar (or its processor) must compress the data, thus collapsing the long modulated reflection to the more familiar sharp impulse response from a point target. Range pulse modulation and compression is an excellent scheme used extensively in all classes of remote sensing radars.

The time-bandwidth product $TBP = \Delta t B_p$ is a parameter of fundamental importance for pulse-compression systems, where Δt is the length of the modulated (coded) pulse before compression and B_p is its bandwidth. Prior to pulse compression, values of $TBP > 100$ are typical in remote sensing radars and may be very much larger. Following compression, $TBP \sim 1$ since there is no remaining internal phase modulation, and the pulse width in time $\tau = 1/B_p$. The value of a pulse's TBP cannot be less than unity. This fact, analogous to the uncertainty principle of physics, is a consequence of a fundamental law of information theory (Woodward, 1955).

The theoretical resolution τ of any radar system is given by its inverse bandwidth. Interpretation of this rule in the

range direction is obvious, since the time-to-distance scaling is always by the factor $c/2$ (150 m per microsecond), where c is the speed of light, approximately 3×10^8 m/s. (Why divide by two? Because the radar's range measurement – and hence the scaling on all range-dependent parameters such as effective pulse length – is two-way which is logically equivalent to a one-way traverse at half the actual round-trip velocity.) Interpretation of the inverse bandwidth rule is situation specific, as it depends on a time-to-distance scaling that is determined by the geometry of the particular radar and viewing conditions. Note that in a perfect system, the bandwidths of the original modulated pulse and of the compressed pulse are the same. The azimuth resolution achieved through a synthetic aperture radar may be viewed as a pulse-compression operation, being described by mathematics that are essential identical to a linearly frequency-modulated pulse. In this case, the time-to-distance scaling is proportional to the radar's forward velocity rather than (half of) the speed of light.

Coherence

A coherent system is one for which signal phase structure is systematically retained so that it is available for signal processing. In comparison to an incoherent system, extra effort is required to make a radar coherent, motivated of course by the extra power phase structure affords the processor.

For the simplest form of radar, the phases of the transmitter ϕ_i^T and the local oscillator ϕ_i^{LO} are random values, uniformly distributed between zero and 2π , thus different for every i th pulse. This is characteristic of a noncoherent (sometimes “incoherent”) radar. In a noncoherent radar, each received signal following demodulation would have a reference phase ($\phi_i^{LO} - \phi_i^T$) which would be different for all returns. Given such randomness in the reference phase, there is no way to take advantage of systematic phase variations that might be inherent to the signal. In other words, it is impossible to do phase-dependent processing on data from a noncoherent radar. Conventional altimeters and laboratory scatterometers are examples of noncoherent remote sensing radars.

A given radar is coherent if, and only if, the reference phase difference ($\phi_i^{LO} - \phi_i^T$) in the post-demodulation data ensemble has the same value for all of the returns. To achieve this, the radar may be designed to lock the reference phase of both the transmitter and the receiver to a constant value. Alternatively, the local oscillator phase may be reset to match the phase of the transmitter on each and every transmission, in which case the system is said to be coherent on receive. In either case, the inter-pulse phase structure in the signal ensemble is stable, so that it may be used in processing. Synthetic aperture radar is the best known example of a coherent radar.

For many remote sensing radars, the concept of coherence is more broadly defined. If filter operations are

applied after signal detection, then the end-to-end performance of the radar becomes partially coherent (known as mixed integration in radar astronomy). This means that signal phase structure may be used in processing, but only within limits. Outside of the range of signal coherence, the phase structure is not used. Multi-look processing of SAR data is a typical example. Likewise, there may be forced departures from system coherence beyond the control of the two oscillator reference phases. These would occur, for example, if there were atmospheric phase perturbation of the propagating signal or if there were random and uncorrected motions of the radar platform. Under such conditions, the desired signal phase structure may not be fully accessible for processing. These effects lead to partial coherence of the system.

Multi-channel radars

Many remote sensing radars are designed to take advantage of systematic differences between the data streams through more than one channel. Ocean-viewing scatterometers are good examples of noncoherent multi-channel radars, as they rely on the backscattered power differences in polarization and viewing aspect to infer wind speed and direction (see “*Radars, Scatterometers*”).

Coherent multi-channel measurements take advantage of relative phase differences. For example, the interferometric mode on CryoSat uses differential phase to measure the cross-track slope of a continental ice sheet (see “*Radar, Altimeters*”). Polarimetric SARs (see “*Radar, Synthetic Aperture*”) depend on phase and amplitude differences between channels for orthogonal polarization components to measure the covariance matrix of the backscattered field (coherent dual polarization) or the complex scattering matrix (full or quadrature polarization).

In a more generalized sense of “multi-channel,” mutually coherent radar data may be gathered over a given scene on two time-separated occasions. If there are changes as small as a fraction of a wavelength between radar observations, these motions can be observed by differential phase processing (see “*Radar, Synthetic Aperture*,” and “*Microwave Radiometers, Interferometers*”). There are two cases: (1) time changes and (2) elevation variations. (1) If the two viewing positions along their respective radar passes are identical, then any observed differences are due to motion within the scene, either to moving objects such as vehicles or to very slow geophysical processes, such as land subsidence. (The optimum time interval between such measurements depends of course on the rate of change in the scene and the wavelength of the radar.) (2) If the two viewing positions of the radar are offset in the plane orthogonal to the line of sight to the scene, then the resulting phase differences may be interpreted as elevations in the scene.

Examples such as these illustrate the unique power of certain radar remote sensing systems to make measurements on the scale of their wavelength, regardless of their spatial resolution.

On space-based radars

Unlike an airborne platform that can go anywhere at any time (subject to fuel and air-space limitations), a satellite's position and velocity when in orbit about a planetary body are rigidly governed by orbital dynamics, summarized compactly by Kepler's laws. Further, access by a space-based remote sensing radar to a given area of interest depends on the rotation rate of the planet as well as the satellite's position along its orbit and the radar's viewing geometry.

The performance of radars is conditional upon the velocity of their host platform far more sensitively than other types of sensors. This is especially true for radars that use any form of range-Doppler processing, such as altimeters, sounders, or SARs. Hence, the performance of a range-Doppler radar depends to first order on the velocity and range of its host spacecraft, which in turn depends on where in the universe that spacecraft may be. The velocity V of a spacecraft in orbit at altitude h above a planet of radius R and mass M is given by:

$$V = [MG/(R + h)]^{1/2} \quad (3)$$

where G is the universal gravity constant (N is the standard symbol for Newton, force, with the units m kg s^{-2}) $6.67 \times 10^{-11} \text{ Nm}^2 \text{ kg}^{-2}$. Table 2 lists representative spacecraft velocities for bodies in the solar system that have been visited, or are likely to be observed, by range-Doppler radars. Feasible satellite altitudes are limited below by the prevailing atmospheric density. The final column of the table lists the altitude-velocity product hV corresponding to each entry. This product is a scaling factor that characterizes the range-Doppler space confronting a SBR intended to be deployed in that environment. There is approximately a 40-fold spread in the value of this parameter, from the Earth to Jupiter's moon Europa. It follows that radar designs that work in one situation may not be at all appropriate if migrated to a different planetary body.

Radars, Table 2 Spacecraft velocities and typical range-Doppler scaling parameters for a variety of planets and moons relevant to remote sensing radars (such as SARs, sounders, and altimeters), either already visited (e.g., the Moon, Mars, and Venus) or are interesting candidates

Body	Mass (kg)	Radius (km)	Altitude h (km)	V (m/s)	hV (km ² /s)
Earth	5.97 E + 24	6,380	800	7,466	6,000

Thumbnails of remote sensing radars

Synthetic aperture radar

In its most general form, an imaging radar is a device designed to provide a two-dimensional portrayal of the radar backscatter returning from the field illuminated in range and azimuth. Space-based microwave imagers are synthetic aperture radars (with the exception of certain early Soviet ocean-observing real-aperture systems). As with all imaging systems, SAR image products are rated according to their resolution, where "higher" is "better." Higher resolution always implies wider bandwidth, in both range and azimuth. Azimuth bandwidth derives from the Doppler signatures set up by the motion of the radar with respect to the illuminated field. Resolution by itself is not sufficient to determine the image quality of importance to most applications. SAR images are degraded by a multiplicative "self-noise" known as speckle, which is a direct consequence of the coherence required by the radar-processor combination to form the synthetic aperture and the resulting enhanced resolution. Speckle can be reduced only through supplemental incoherent processing, known in SAR jargon as multi-looking. Additional looks require proportionally more bandwidth. It follows that two-dimensional bandwidth (range and azimuth) is the driving requirement for this class of radar.

Space-based SAR systems have motivated fruitful specializations in quantitative applications in a wide variety of areas, comprehensively reviewed in *The Manual of Remote Sensing* (Henderson and Lewis, 1998). For an introduction to topics such as SpotSAR, ScanSAR, polarimetry, and interferometry, see "[Radar, Synthetic Aperture](#)."

Radar altimeters

The main objective of a space-based altimeter is to measure the distance between the radar and the surface and to deduce geophysical quantities of the surface from the reflected waveforms. Relatively small changes (on the order of cm) in mean sea surface height may correspond to substantial differences in the corresponding geophysical parameters. Sea surface height measurements have become essential for a wide variety of applications in oceanography, geodesy, geophysics, and climatology (Fu and Cazanave, 2001). With the exception of near-polar ice, Earth-orbiting oceanographic altimeters have seen relatively little application over nonaquatic surfaces.

A satellite-based altimeter systematically circles the Earth, gathering waveforms along track. The resulting data provide measurements of sea surface height, significant wave height, and wind speed. Although one might consider altimeters to be relatively simple one-dimensional (range measurement) instruments, their phenomenal accuracy and precision requires elegant microwave implementation and innovative signal processing. Since the mid-twenty-first century, coherent and interferometric radar techniques are being incorporated into innovative altimeter systems (see "[Radar, Altimeters](#)").

Scatterometers

Space-based remote sensing scatterometers measure the normalized backscatter with sufficient precision and accuracy to deduce the value of one or more parameters of geophysical significance. For example, the power reflected from the ocean back to a radar is a function of surface roughness at the scale of the radar's wavelength, which in turn is a function of the local wind (Quilfen et al., 2004). Estimation of wind speed and direction over the open ocean is the most common application for these instruments. In addition to open ocean observations, calibrated data from this class of remote sensing radar have been applied to a variety of large-area surface features, such as determination of sea ice coverage, mapping the boundaries between the principal ice zones of Greenland, or global estimation of tropical deforestation. In all such applications, the emphasis is on measurement of mean reflectivity over large areas, rather than mapping fine spatial detail. These radars typically have resolution no better than several kilometers, supported over swaths of 1,000 km or more.

In the ocean application, relatively small changes in radar backscatter may correspond to substantial differences in the retrieved wind information (Kerkmann, 1998; Moore and Fung, 1979). It follows that the dominant requirement for this class of radar is the accuracy and precision of the received power measurement. Since the geophysical interpretation of scatterometric data often depends on distinguishing between two similar values of σ^0 , the results depend critically on reducing the uncertainty in the estimated value as well as getting the average value right. However, the next step, vector wind retrievals – transforming the radar backscattered power into accurate estimates of wind speed and direction – is far from trivial. Indeed, the technique fails for the very low wind speeds that do not generate wavelength-scale surface roughness. In the limit, any side-looking radar will generate virtually no backscatter from the sea surface in the absence of wind-driven waves, even if there is a substantial swell in the region. For more on these and related topics, see “[Radar, Scatterometers](#).”

Radar sounders

The term “sounder,” usually associated with acoustic echo sounding, derives from many centuries of oceanic shipborne depth measurements using lead lines and the like. The extension from acoustic to electromagnetic methodology is a small step in comparison. In its most general form, a radar sounder is an active device designed to transmit pulses that penetrate the volume of a target medium, from which the waveform of the resulting backscatter indicates variations in dielectric contrasts as a function of distance. Remote sensing radar sounders may be used to probe the ionosphere, the atmosphere, or solid media such as ice sheets or planetary surfaces. (A system deployed on the surface such as ground-penetrating radar (GPR) is a closely related case.)

As a sounder passes over an illuminated region, the sequence of ranging waveforms generates a profile, which is a two-dimensional reflectivity cross section of the surveyed volume. Penetration depth in general increases with wavelength and also with radiated power. On the other hand, reflectivity depends on the dielectric contrasts between internal layers; a material's dielectric constant is also a function of wavelength. It follows that space-based radar sounders must choose a frequency and bandwidth that balance the often conflicting requirements of penetration, reflectivity, and resolution, under the constraints of available power and antenna aperture. For an overview of active (radar) sounders, see Raney (2008). Alert: Radar sounders should not be confused with certain spaceborne atmospheric sounders that are passive devices.

Conclusions

Radar is a vast subject, now spanning more than 100 years; drawing upon physical principles some of which go back more than 200 years. For comprehensive coverage of imaging radar applications and an introduction to theory, see Henderson and Lewis (1998). For a somewhat more technical radar discussion, the book to consult is Toomay and Hennen (2004). For an introduction to hardcore radar design issues, see Skolnik (2008). For highlights and an historical perspective into space-based remote sensing radars, see Raney (2008).

Definition

Natural electromagnetic radiation within the Earth's environment is a product of natural physical processes and can be used as a remotely sensed indicator of the conditions governing those processes and/or the media through which the radiant signal passes.

Natural radiation within the Earth's environment

The natural sources of electromagnetic radiation within the Earth's environment that are used for remote sensing can be conveniently classified by frequency. At frequencies below ~ 1 GHz, dominant sources are nonthermal and include lightning (sferics) and ionospheric synchrotron radiation. At frequencies between ~ 1 GHz (~ 30 cm wavelength, the lower end of the microwave spectrum) and 40 THz (~ 8 μm wavelength, the higher end of the thermal infrared (TIR) spectrum), natural sources are overwhelmingly the result of thermal processes. Beginning with near-infrared frequencies (or reflectance infrared frequencies), through visible frequencies, and to the upper limit of the UV frequencies, the Sun serves as the primary source for natural source, remote sensing techniques. Above UV frequencies, nuclear decay is a source of the gamma radiation used in well logging and in airborne sensing of Snow Water Equivalent (SWE). This section concerns thermal sources within the Earth's environment, i.e., natural sources at frequencies between 1 GHz and 40 THz.

Thermal radiation from elements of the Earth system that might be sensed from aircraft or spacecraft is a product of thermal energy of media at the Earth's surface or within the atmosphere. Although the span of relevant temperatures is nearly 100 K centered on ~ 275 K, it is convenient to think of the Earth as a 300 K source. The radiant brightness of a 300 K source decreases rapidly to insignificance at wavelengths shorter than 8 μm and is masked by nonthermal sources at frequencies below ~ 1 GHz. Atmospheric opacity at wavelengths between ~ 14 μm and ~ 1 mm effectively divides the thermal radiance spectrum into two classes of remote sensing techniques identified by their wavelength, TIR (8–14 μm) techniques and thermal microwave (1 mm to 30 cm) techniques. Concepts discussed in this section will be applicable to both ends of this 300 K thermal radiant spectrum and will be couched in the hybrid language of optical physics (e.g., Bohren and Huffman, 1983) and radio astronomy (e.g., Kraus, 1966).

The section is organized around six topics cast as assertions:

- (i) Planck radiation is a consequence of local thermal equilibrium.
- (ii) Brightness temperature is invariant along a ray traversing a nonabsorbing, scatterer-free medium.
- (iii) Emissive power equaling absorption is a condition of local thermal equilibrium.
- (iv) EM constitutive properties are most intuitive when expressed in the frequency domain.

Radiation (Natural) Within the Earth's Environment, Figure 1 Cartesian representations of a cubic resonant cavity whose edges are length a in physical space (a). For the condition that surfaces of the cube are Perfect Electrical Conductors (PEC), allowed standing waves are prescribed by all positive integers, p, q, r , and the wave vector, $\vec{k} = \hat{x} \frac{\pi p}{a} + \hat{y} \frac{\pi q}{a} + \hat{z} \frac{\pi r}{a}$ in wave number space (b). The wave vectors, $\vec{k}$, are normal to the corresponding wave fronts (planes of constant phase).

- (v) Real and imaginary components of frequency domain EM constitutive properties are related through Kramers–Kronig relationships.
- (vi) Emissive power is a consequence of the imaginary component of relative permittivity.
- (i) Planck radiation is a consequence of local thermal equilibrium

Thermal radiation is the thermal energy in a medium that is partitioned into radiant energy. Planck radiation is thermal radiation from a region that is in local thermal equilibrium. Planck's explanation of the process has not been improved upon (Planck, 1909). An abbreviated version is presented here because familiarity with the assumptions allows us to recognize where the assertion might break down.

Consider a dielectric cube whose edges have length a (Figure 1a), where a is much larger than any relevant electromagnetic wavelength, λ . For mathematical convenience, assume that the electromagnetic constitutive properties of the medium are locally isotropic. This limitation is readily removed once the expression for Planck, or "blackbody," radiance and its dependence upon the index of refraction is established.

Begin by identifying the electromagnetic modes that can be supported within this cube. Because $a \gg \lambda$, it is reasonable to assume that energy differences associated with the choice of boundary conditions for the cube's

electromagnetic modes are small with respect to the total energy of electromagnetic modes in volume v . For convenience, assign the boundary condition of a Perfect Electrical Conductor (PEC), so there can be no electric fields on the faces of the dielectric cube. Standing waves in the orthogonal $\hat{x}$, $\hat{y}$, and $\hat{z}$ directions shown in Figure 1a have spatial frequencies, or wave numbers, k_x , k_y , and k_z , that satisfy

$$\begin{aligned} k_x a &= \pi p \\ k_y a &= \pi q \\ k_z a &= \pi r, \end{aligned} \quad (1)$$

where p, q , and r are any positive integers. In wave number space, illustrated in Figure 1b, every allowed wave vector, $\vec{k}$, in the dielectric cube can be expressed:

$$\begin{aligned} \vec{k} &= \hat{x}(\pm k_x) + \hat{y}(\pm k_y) + \hat{z}(\pm k_z) \\ &= \hat{k} k, \end{aligned} \quad (2)$$

where $\hat{k}$ is a unit vector normal to the wave front and wave number, k , is

$$k = \sqrt{\left(\frac{\pi p}{a}\right)^2 + \left(\frac{\pi q}{a}\right)^2 + \left(\frac{\pi r}{a}\right)^2}. \quad (3)$$

Standing wave modes outside the first octant of Figure 1b are degenerate in that all distinguishable modes can be described by choosing the “+” options in Equation 2. The elemental volume, Δ_k , in wave number space associated with each standing wave mode is

$$\Delta_k = \left(\frac{\pi}{a}\right)^3 = \frac{\pi^3}{v}. \quad (4)$$

If $N(k) dk$ is the number of standing wave modes in the first octant of a spherical shell of thickness dk centered on the origin in Figure 1b, then

$$\begin{aligned} N(k) dk &= \left(\frac{1}{8}\right) \left(\frac{4\pi k^2 dk}{\Delta_k}\right) (2) \\ &= \left(\frac{k^2 v dk}{\pi^2}\right), \end{aligned} \quad (5)$$

where the “1/8” in the first parenthesis on the right of the first line designates the first octant of the spherical shell, the numerator in the second parenthesis is the volume of the spherical shell, the denominator is the volume associated with one mode, and the “2” in the third parenthesis represents the two possible polarizations of each standing wave mode.

Planck’s contribution, in addition to this formulation, was the assertion that the energy in each mode was quantized and could be expressed $m h f$ where m is an integer, h is Planck’s constant (6.6262×10^{-34} J s), and f is frequency. From Boltzmann and statistical mechanics (e.g., McQuarrie, 2000), the probability density of energy $m h f$ for an electromagnetic mode that is in thermal equilibrium with all other thermally excited modes, including non-electromagnetic modes, is

$$p(mhf) = C e^{\frac{-mhf}{k_B T}}, \quad (6)$$

where C is a normalizing constant, k_B is Boltzmann’s constant (1.3806×10^{-23} J K⁻¹), and T is temperature in Kelvin. The expected energy, $\langle U(f) \rangle$, in a particular electromagnetic mode having frequency, f , is then

$$\begin{aligned} \langle U(f) \rangle &= \frac{\sum_{m=0}^{\infty} m h f p(m h f)}{\sum_{m=0}^{\infty} p(m h f)} \\ &= \frac{hf}{e^{\frac{hf}{k_B T}} - 1} \text{ J.} \end{aligned} \quad (7)$$

If $N(f)$ is the number of modes in the cavity having frequency f , then cavity’s energy density at frequency f at thermal equilibrium becomes

$$w(f) = \frac{N(f) \langle U(f) \rangle}{v} \text{ J}^{-1} \text{ m}^{-3} \text{ Hz}^{-1}. \quad (8)$$

Radiation (Natural) Within the Earth’s Environment,

Figure 2 A pill-shaped volume within the resonant cavity of Figure 1. The faces of the pill (normal to the $\hat{z}$ axis) have area A_o , and the thickness of the pill is $\delta\ell$. Radiation escapes the pill in solid angle, $\delta\Omega$, integrated over the 4π solid angle of the sphere. The assumption is that the pill is sufficiently thin that the radiation escaping through its edge is negligible.

The independent variable in Equation 5 is k , while that in Equation 4 is f . The number of modes in terms of f equivalent to those in terms of k is obtained from the dispersion relation, $k = 2\pi f \left(\frac{n}{c}\right)$, where n is the refractive index. That is,

$$\begin{aligned} N(f) df &= N(k) dk \\ &= \frac{k^2 v}{\pi^2} dk \\ &= \left(\frac{2\pi f n}{c}\right)^2 \frac{v}{\pi^2} \left(\frac{2\pi n}{c}\right) df \\ &= \left(\frac{8\pi f^2 n^3 v}{c^3}\right) df. \end{aligned} \quad (9)$$

Equations 7 and 9 allow the energy density at thermal equilibrium, Equation 8, to be written

$$w(f) = 8\pi h \left(\frac{fn}{c}\right)^3 \left(\frac{1}{e^{\frac{hf}{k_B T}} - 1}\right) \text{ J}^{-1} \text{ m}^{-3} \text{ Hz}^{-1}. \quad (10)$$

This can be converted to spectral brightness using the concept of radiation escaping from a pill-shaped volume having thickness, $\delta\ell$, and area, A_o (Figure 2). The spectral energy in the pill $\delta W(f)$ is

$$\begin{aligned}\delta W(f) &= w(f) A_o \delta \ell \\ &= 8\pi h \left(\frac{f n}{c} \right)^3 \left(\frac{1}{e^{k_B T} - 1} \right) A_o \delta \ell \quad \text{J}^{-1} \text{ Hz}^{-1}.\end{aligned}\quad (11)$$

A strategy for identifying the Planck brightness spectrum is to equate the electromagnetic energy at frequency f stored as standing waves in the pill-shaped volume to the same energy as it leaves the volume as radiant energy. For sufficiently small $\delta \ell$, effectively all radiant energy leaves the pill-shaped volume through the faces, each having area A_o . That is,

$$\delta W(f) = 2 \int_{2\pi} \left\{ \left(A_o \cos \theta B_{fp}^b(\hat{k}) \right) \left(\frac{\delta \ell}{\cos \theta c} \right) 2 \right\} d\Omega \quad \text{J}^{-1} \text{ Hz}^{-1}.\quad (12)$$

The first “2” to the right of the equal sign in Equation 12 represents the two faces of the pill-shaped volume. The quantity inside the first parenthesis of the curly brackets represents the irradiance passing through area A_o , from solid angle $d\Omega$ centered on unit vector $\hat{k}$, where θ is the angle between $\hat{k}$ and the normal to surface A_o (Figure 2). The quantity in the second parenthesis is the time it takes for all radiant energy traveling in direction $\hat{k}$ to leave the pill-shaped volume. The final “2” in Equation 12 refers to the two possible polarizations. The “blackbody” spectral brightness in direction $\hat{k}$ is $B_{fp}^b(\hat{k})$, where superscript b indicates that this is a Planck, or “blackbody,” radiance, and the subscripts designate spectral brightness at frequency f and polarization p . The units of $B_{fp}^b(\hat{k})$ are $\text{W m}^{-2} \text{ sr}^{-1} \text{ Hz}^{-1}$.

The dielectric in the pill-shaped volume is isotropic so that neither the refractive index, n , nor the spectral brightness, $B_{fp}^b(\hat{k})$, can depend upon $\hat{k}$. This allows the curly brackets of Equation 12 to be moved outside the integral. The integral becomes 2π , and

$$\delta W(f) = 8\pi B_{fp}^b A_o \delta \ell \left(\frac{n}{c} \right) \quad \text{J}^{-1} \text{ Hz}^{-1}.\quad (13)$$

Equating the right-hand sides of Equations 12 and 13 and solving for brightness yield

$$B_{fp}^b = h f \left(\frac{f n}{c} \right)^2 \left(\frac{1}{e^{k_B T} - 1} \right) \quad \text{W}^{-1} \text{ m}^{-2} \text{ sr}^{-1} \text{ Hz}^{-1}.\quad (14)$$

Equation 14 is Planck’s equation for single polarization thermal brightness in an isotropic medium, which was our objective. We next examine the assertion and assumptions used to obtain Planck’s equation.

The assertion of local thermal equilibrium. Local thermal equilibrium means that all mechanical and

electromagnetic modes of a dielectric in a local region of a size on the order of the electromagnetic wavelength are in thermal equilibrium. Because energy will leak from a local region to regions having different temperatures more rapidly by some modes than by others, local thermal equilibrium requires local mechanisms for relatively rapid exchanges of energy between local modes if they are to remain in thermal equilibrium. Primary mechanisms for this exchange include nonlinearity in the mechanical constitutive relations and dielectric loss expressed in the dielectric constitutive relation. Nonlinearity redistributes energy among electromagnetic modes, and loss converts energy between electromagnetic and mechanical modes. This author is not aware of any situation where a natural dielectric in the Earth’s thermal environment fails to exhibit local thermal equilibrium. There might be situations in deep space where temperatures approach those of the cosmic background, 2.7 K, where the assumption of local thermal equilibrium fails.

The assumption that $\lambda \ll a$. This is a requirement that local regions of a dielectric be homogeneous and large with respect to electromagnetic wavelengths of interest. The assumption is often violated at microwave frequencies in the exchange of radiant energy among small heterogeneities, for example, water droplets in a cloud. In such situations, Rayleigh or Mie scattering theory must be combined with the concepts of radiative transfer and thermal equilibrium (e.g., Chandrasekhar, 1960; Van de Hulst, 1981; Bohren and Huffman, 1983).

The assumption that refractive index n is isotropic. This assumption has no effect upon the spectral brightness sensed by a radiometer outside a beamfilling “black” emitter. We will see later in this section that spectral brightness normalized by the square of the refractive index is invariant upon transition from one medium to another if the interface is conditioned to avoid reflections. Consequently, Equation 14 requires that spectral brightness within an anisotropic dielectric also be anisotropic.

The assumption that $hf \ll k_B T$. Known as the Rayleigh–Jeans approximation, this assumption was neither needed nor used in our development of the Planck spectral brightness. It is included here because its use is common in the characterization of thermal microwave brightness within the Earth’s environment. With this approximation, Planck spectral brightness, Equation 14, becomes

$$\begin{aligned}B_{fp}^b &= \left(\frac{f n}{c} \right)^2 k_B T \\ &= \frac{k_B T}{\lambda^2} \quad \text{W}^{-1} \text{ m}^{-2} \text{ sr}^{-1} \text{ Hz}^{-1}.\end{aligned}\quad (15)$$

The Rayleigh–Jeans approximation offers the simple relationships that brightness varies linearly with temperature and inversely with wavelength squared.

Limitations of the Rayleigh–Jeans approximation are illustrated in log–log plots of brightness versus

Radiation (Natural) Within the Earth's Environment, Figure 3 Planck radiation for 300 and 2.7 K "black" emitters. In log-log plots of radiance such as these, the -2 slope of longer wavelength radiation corresponds to the region of validity of the Rayleigh-Jeans approximation. Note that the approximation becomes increasingly and non-negligibly poor at wavelengths shorter than 0.1 mm in the Earth's environment and at wavelengths shorter than 1 cm for cosmic emission.

wavelength for temperatures of 300 and 2.7 K, characteristic temperatures of the Earth's environment and of dust in deep space, respectively (Figure 3). The Rayleigh-Jeans approximation is valid in wavelength regions where brightness in Figure 3 exhibits a -2 spectral slope. For a 300 K environment, the approximation begins to fail for wavelengths shorter than ~ 0.1 mm. At the 2.7 K temperature of the cosmic background, the approximation begins to fail for wavelengths shorter than ~ 1 cm. While all natural thermal sources in the Earth's environment exhibit a -2 slope over the microwave spectrum, the low temperature of the cosmic background means that cosmic background-based calibrations of satellite microwave radiometers for wavelengths shorter than ~ 1 cm should be based upon Equation 14 rather than Equation 15 if radiometer calibration is to take maximum advantage of available radiometer linearity.

- (ii) Brightness temperature is invariant along a ray traversing a nonabsorbing, scatterer-free medium.

Thermal radiant sources are always extended sources and should not be modeled as point sources. An extended source model enables use of convenient aspects of the theory of rays and brightness. Think of a ray as radiant energy traveling in a tubular path, for example, between the two surfaces, δA and $\delta A'$, shown in Figure 4. Rays occupy an incremental volume, and radiant brightness along rays in media having constant refractive indices is invariant in the absence of absorption and scattering. This invariance is readily demonstrated by comparing the flow

Radiation (Natural) Within the Earth's Environment, Figure 4 A demonstration of the invariance of brightness along a ray in the absence of emission, absorption, and scattering. The radiance of a ray passing through surface δA as observed at surface $\delta A'$ in (a) is identical to the radiance of the ray passing through surface $\delta A'$ in (b).

of radiant energy between the two incremental areas from the perspective of δA (Figure 4a) and from the perspective of $\delta A'$ (Figure 4b). The areas are parallel and their respective centers, designated by points P and P' , are joined by a vector, $\vec{r} = \hat{r}r$, normal to the planes of the incremental areas, where $\hat{r}$ is the unit vector in the direction of $\vec{r}$ and r is the length of the vector.

The spectral radiation pattern, or spectral brightness, of a unit area centered on point P in area δA is $B_{fp}(\hat{k})$ $\text{W m}^{-2} \text{sr}^{-1} \text{Hz}^{-1}$, where f is frequency, p is choice of polarization, and $\hat{k}$ is the unit vector indicating radiation direction. If the transmitting medium is lossless, free of scatterers, and has a constant index of refraction, the spectral power leaving area δA and impinging upon area $\delta A'$ is (Figure 4a)

$$\delta W_{fp}(\hat{r}) = B_{fp}(\hat{r}) \delta A \delta \Omega' \quad \text{W Hz}^{-1}, \quad (16)$$

where $\delta \Omega'$ is the solid angle of $\delta A'$ as seen from P and $\hat{k} = \hat{r}$. Similarly, if the radiant brightness crossing surface $\delta A'$ is $B'_{fp}(\hat{r})$, the spectral power arriving on surface $\delta A'$ from δA is (Figure 4b)

Radiation (Natural) Within the Earth's Environment,

Figure 5 A ray passing through a dielectric interface at $z = 0$. If there are no reflections at the interface, the brightness of the ray in media of index n is related to the brightness of the ray in media n' by Equation 24.

$$\delta W'_{fp}(\hat{r}) = B'_{fp}(\hat{r}) \delta A' \delta \Omega \quad \text{W Hz}^{-1}, \quad (17)$$

where $\delta \Omega$ is the solid angle of δA as seen from $\mathbf{P}'$. Conservation of energy requires that $\delta W_{fp}(\hat{r}) = \delta W'_{fp}(\hat{r})$. Because $\delta \Omega = \frac{\delta A}{r^2}$ and $\delta \Omega' = \frac{\delta A'}{r'^2}$,

$$B_{fp}(\hat{r}) = B'_{fp}(\hat{r}). \quad (18)$$

This invariance allows radiant brightness to be viewed as a characteristic of an emitting medium without consideration of the distance between observer and medium. For example, the near-vacuum of space is effectively a lossless and scatterer-free medium with a constant index of refraction. From the perspective of a spacecraft anywhere within the solar system, the Sun is equally bright and only its apparent size varies with the inverse square of distance.

Consider lossless and scatterer-free medium, but, unlike the previous case, the refractive index of this medium varies with position. If the variation is slow over distances that are long relative to radiant wavelengths of interest, or if abrupt transitions are accompanied by interface impedance matching that avoids reflections, how does radiant brightness vary across such a transition? The question can be answered by considering the specific case of a ray traveling across a planar, nonreflecting interface. The more general case of a gradual transition can be modeled as a large set of small, discrete transitions.

An upwelling ray traversing from the lower medium to the upper medium in Figure 5 impinges at an incidence angle θ on a lossless, isotropic interface whose thickness and refractive index allow it to serve as a matching transformer between the media so that there are no reflections of the ray at the interface. $B_{fp}(\hat{k})$ is the upwelling

spectral brightness of the ray in the lower medium, and $B'_{fp}(\hat{k}')$ is the corresponding upwelling spectral brightness after it passes through the interface. The incident plane of the ray is defined as the normal to the interface and the unit vector, $\hat{k}$. For isotropic media, symmetry requires that $\hat{k}'$ also lies in the incident plane. Incident angles, θ and θ' , are related by Snell's Law,

$$n \sin \theta = n' \sin \theta', \quad (19)$$

a consequence of the requirement that phases match across the interface at every point on the interface. If δA_o is an incremental area defined as the intersection of the interface and the ray passing through it, then the spectral power, $\delta W_{fp}(\hat{k})$, in the solid angle, $\delta \Omega$, along direction $\hat{k}$ in the lower medium, impinging upon δA_o is

$$\delta W_{fp}(\hat{k}) = B_{fp}(\hat{k}) \delta A_o \cos \theta \delta \Omega \quad \text{W Hz}^{-1}. \quad (20)$$

Similarly the spectral power leaving δA_o in the solid angle $\delta \Omega'$ along $\hat{k}'$ in the upper medium is

$$\delta W'_{fp}(\hat{k}') = B'_{fp}(\hat{k}') \delta A_o \cos \theta' \delta \Omega' \quad \text{W Hz}^{-1}. \quad (21)$$

Conservation of energy requires that $\delta W_{fp}(\hat{k}) = \delta W'_{fp}(\hat{k}')$ and, canceling δA_o , yields

$$B_{fp}(\hat{k}) \cos \theta \delta \Omega = B'_{fp}(\hat{k}') \cos \theta' \delta \Omega' \quad \text{W m}^{-2} \text{Hz}^{-1}. \quad (22)$$

Expressed in polar coordinates, the incremental solid angles are $\delta \Omega = \sin \theta \delta \theta \delta \phi$ and $\delta \Omega' = \sin \theta' \delta \theta' \delta \phi'$, where $\delta \phi$ and $\delta \phi'$ are azimuth ray widths below and above the interface, respectively. Similar to the symmetry argument that $\hat{k}$ and $\hat{k}'$ lie in a common incident plane, $\delta \phi = \delta \phi'$ so that Equation 22 becomes

$$B_{fp}(\hat{k}) \cos \theta \sin \theta \delta \theta = B'_{fp}(\hat{k}') \cos \theta' \sin \theta' \delta \theta'. \quad (23)$$

Substituting Snell's Law (Equation 19) and the differential form of Snell's Law, $n \cos \theta \delta \theta = n' \cos \theta' \delta \theta'$, into Equation 23 yields

$$\frac{B_{fp}(\hat{k})}{n^2} = \frac{B'_{fp}(\hat{k}')}{n'^2} \quad \text{W m}^{-2} \text{sr}^{-1} \text{Hz}^{-1}. \quad (24)$$

That is, spectral brightness normalized by the refractive index squared is invariant along a ray in the absence of absorption and scattering. This equivalence suggests a convention long advocated by this author of using normalized spectral brightness, $B_{fp}^n(\hat{k})$, defined

$$B_{fp}^n(\hat{k}) = \frac{B_{fp}(\hat{k})}{n^2} \quad \text{W m}^{-2} \text{sr}^{-1} \text{Hz}^{-1}, \quad (25)$$

as the relevant parameter in a radiative transfer equation (RTE), a heuristic description of the change in brightness along a ray resulting from absorption and self-emission (e.g., Chandrasekhar, 1960). A convenient form for the RTE of a ray in local thermal equilibrium in a medium whose index varied sufficiently slowly would be

$$\frac{dB_{fp}^n(\hat{k})}{ds} + \kappa_{fa} B_{fp}^n(\hat{k}) = \alpha_f J_{fp}^n(\hat{k}) \quad (26)$$

where κ_{fa} is the spectral absorption coefficient in m^{-1} at frequency f , α_f is the volume emissivity in m^{-1} at frequency f , ds is incremental distance in direction $\hat{s}$ having dimension m^{-1} , and $J_{fp}^n(\hat{k})$ is a normalized source function in direction $\hat{k}$ having units $\text{W m}^{-2} \text{sr}^{-1} \text{Hz}^{-1}$. Normalization of the brightness of a ray traversing an ice–air interface would be significant, but normalization of the brightness of a ray traversing variations in the density of the Earth's atmosphere would be slight. For example, a ray traversing the atmosphere from sea level, where the index is 1.0003, to an Earth satellite would experience a divergence of only 0.06 %, an amount less than the likely calibration accuracy of a satellite radiometer. Normalization of the brightness of a ray traversing some part of the atmosphere of a gaseous planet, like Jupiter, could be significant.

The Rayleigh–Jeans approximation enables a more intuitive microwave parameter than normalized spectral brightness for thermal emitters in the Earth's environment. The linear relationship between brightness and temperature invites the definition of microwave brightness temperature:

$$Tb_{fp}(\hat{k}) = \frac{B_{fp}(\hat{k})}{\left(\frac{f n}{c}\right)^2 k_B} \quad \text{K sr}^{-1}. \quad (27)$$

While the supplementary SI unit, steradian, could be dropped, and most authors choose to do so, this author prefers to retain the unit as a reminder that brightness temperature has associated with it an incremental solid angle in direction $\hat{k}$. Brightness temperature is intuitive in that it is closely related to physical temperature. For example, the microwave brightness temperature of a “black” emitter having a thermal temperature of 270 K is 270 K sr^{-1} , and the brightness temperature of the night sky at 30 GHz might be 60 K sr^{-1} rather than the lessintuitive $8.3 \times 10^{-20} \text{ W m}^{-2} \text{sr}^{-1} \text{Hz}^{-1}$. Because brightness temperature is effectively normalized by the square of the refractive index, $Tb_{fp}(\hat{k})$ is automatically invariant in the absence of absorption and scattering.

(iii) Emissive power equals absorption as a condition of local thermal equilibrium.

Radiation (Natural) Within the Earth's Environment,

Figure 6 Schematic of a ray in a one-dimensional medium. An electromagnetic ray in a medium whose properties vary only with height, z , can be described as a tube of cross section δA containing an electromagnetic wave traveling in direction $\hat{k}$ specified by its direction cosine, $\mu = \cos \theta$, with respect to $\hat{z}$. An incremental volume of the tube would be $\delta A \delta s$.

Radiative transfer in the Earth's environment is often conveniently cast as a one-dimensional problem because the physical properties of many relevant natural media are horizontally stratified. Furthermore, because electromagnetic properties are often locally isotropic, the combination of horizontal stratification and local isotropy permits a reduction of the space and direction variables from five to two, i.e., z , the distance from the surface of the Earth along zenith direction, and μ , the direction cosine with respect to the zenith direction, $\hat{z}$. For purposes of this section, media are non-scattering, i.e., all relevant constitutive properties vary slowly with z relative to the wavelength of radiant energy. The RTE for a ray of brightness temperature traveling along the path, δs , ($= \frac{\delta z}{\mu}$) in Figure 6 is

$$\mu \frac{dTb_{fp}(z, \mu)}{dz} = \kappa_{fa}(z) Tb_{fp}(z, \mu) = \kappa_{fa}(z) J_{fp}(z) \quad (28)$$

where $\kappa_{fa}(z)$ is the absorption coefficient in units of m^{-1} at frequency f and $J_{fp}(z)$ is a source function at height z , frequency f , and polarization p . The emissive power of the incremental volume, $\delta s \delta A$, i.e., the right-hand side of Equation 28, is intrinsic to the medium. The source function, $J_{fp}(z)$, is independent of direction, μ , for an isotropic medium. A further assumption of this formulation is that the refractive index of the medium does not vary sufficiently with height, z , to require a z dependence

of the direction cosine, μ , i.e., the ray does not bend appreciably.

If the medium is infinite in all directions and has a uniform thermal temperature, T , local thermal equilibrium requires that

$$\frac{d T b_{fp}(z, \mu)}{dz} = 0. \quad (29)$$

In this case of an extended region in thermal equilibrium, the brightness temperature would not have location or directional dependence even though the medium need not be uniform in z . This argument is a consequence of assertion (ii) and an extension of the principle of detailed balance. Effectively, there cannot be a flow of energy if the potential difference is zero. The Planck brightness temperature would be the same for all z and all μ . Because the source function is an intrinsic function of the medium, the combination of Equations 28 and 29 illustrates the assertion that emissive power must equal absorption.

Removing the constraint of uniform temperature so that temperature varies with height, z , the source brightness temperature must have amplitude T and be isotropic, i.e.,

$$J_{fp}(z, \mu) = T(z)u(\mu) \text{ K sr}^{-1} \quad (30)$$

where thermal temperature at height z is $T(z)$ in Kelvin, and ray direction is indicated by $u(\mu)$, which has an amplitude of unity and units of sr^{-1} . The revised RTE becomes

$$\mu \frac{d T b_{fp}(z, \mu)}{dz} + \kappa_{fa}(z) T b_{fp}(z, \mu) = \kappa_{fa}(z) T(z) u(\mu). \quad (31)$$

The terms on the right of the equal sign are collectively referred to as the emissive power of the medium in direction $u(\mu)$. Equation 31 is a first-order, linear differential equation with emissive power as a source. The integral form is

$$T b_{fp}(z, \mu) = \left(\int_{-\infty}^z \left[\frac{1}{\mu} e^{\frac{-\kappa_{fa}(z')(z-z')}{\mu}} \right] \kappa_{fa}(z') T(z') dz' \right) u(\mu) \text{ K sr}^{-1}, \quad (32)$$

where the quantity in the square brackets is the relevant Green's function. In both the differential and integral forms of the RTE, the absorption coefficient, $\kappa_{fa}(z')$, plays a key role in governing the emissive power of sources in the Earth's environment. The remainder of the section is devoted to generating plausible physical models for electromagnetic absorption at microwave and thermal infrared frequencies and linking this absorption coefficient to the electromagnetic constitutive properties of natural media.

(iv) EM constitutive properties are most intuitive when expressed in the frequency domain.

Assertion (iv) can be understood by considering the alternative, a constitutive relationship in the time domain. Consider a charge-neutral, nonionized gas, but the approach could apply equally well to charge-neutral liquids or solids. The electric displacement, $\bar{D}(t)$, is the charge distortion of a dielectric medium caused by an imposed electric field, $\bar{E}(t)$. The relationship can be expressed as

$$\begin{aligned} \bar{D}(t) &= \varepsilon(t) \otimes \bar{E}(t) \\ &= \varepsilon_o \varepsilon_r(t) \otimes \bar{E}(t), \end{aligned} \quad (33)$$

where $\varepsilon(t)$ is electric permittivity in the time domain, ε_o is vacuum electric permittivity, $\varepsilon_r(t)$ is time-dependent increase in electric permittivity relative to a vacuum, or relative permittivity, and the explicit location dependence of each of the parameters is suppressed for clarity. The relative permittivity is time dependent because the electric displacement is a consequence of reorientation or distortion of gas molecules in response to the applied electric field, and inertia requires that this reorientation or distortion not be instantaneous. Specifically, electric displacement in the time domain is a convolution of all past electric fields experienced by the gas. The symbol $\otimes$ designates the convolution.

The several contributions of gas molecules to electric displacement can be isolated by introducing the definitions of a time-dependent electric polarization, $\bar{P}(t)$, where

$$\begin{aligned} \bar{P}(t) &= \bar{D}(t) - \varepsilon_o \bar{E}(t) \\ &= \varepsilon_o (\varepsilon_r(t) - 1) \otimes \bar{E}(t) \\ &= \varepsilon_o X_e(t) \otimes \bar{E}(t). \end{aligned} \quad (34)$$

The quantity $X_e(t) = \varepsilon_r(t) - 1$ is the electric susceptibility in the time domain. The effect upon a gas of neutral atoms caused by a step in the applied electric field at time t_o is depicted schematically in Figure 7. The distortion of the electron field about the nucleus of an atom occurs with characteristic times on the order of 10^{-15} s, a period that is short relative to the periods of thermal radiance in the Earth's environment. From this perspective, the adjustment of the electron field about an atom can be considered as effectively instantaneous as depicted in Figure 7b.

A gas comprised of molecules of more than one atom behaves in a more interesting manner. If an imposed electric field causes an induced polarization that is not aligned with the electric field, or if a molecule has a permanent electric moment, for example, the water molecule, an imposed electric field can cause the molecule to rotate, absorbing and reradiating energy. Similarly, an imposed electric field can cause molecular bonds between atoms to stretch or bend absorbing and reradiating energy. These processes involve acceleration of one or more atoms. Unlike the adjustment of an electron field about an atom, accelerations of atoms in more complex

Radiation (Natural) Within the Earth's Environment,

Figure 7 The dielectric response of an isolated atom to an imposed electric field. The electric displacement of electrons about an atomic nucleus of an isolated atom occurs rapidly ($\sim 10^{-15}$ s). From the perspective of the periods of thermal radiation in the Earth's environment, this adjustment is instantaneous.

molecules are not instantaneous relative to the periods of thermal radiance. Through processes of rotating or distorting complex molecules, absorption or emission of thermal radiant energy often results in spectral signatures that are diagnostic of the composition of the gas, its temperature, and its pressure. The Debye and Lorentz models illustrate these processes. More comprehensive discussions of spectral signatures can be found in texts on molecular spectroscopy.

The Debye process

The water molecule is arguably the most interesting environmental constituent from the perspective of remote sensing because it is central to weather and climate and because the water molecule exhibits an inherent electric dipole moment that is unique among abundant natural materials (Debye, 1929). The water molecule can be pictured as a large oxygen atom bonded to two small hydrogen atoms. The angle between lines joining the center of the oxygen atom to the centers of the hydrogen atoms is 105° as depicted in Figure 8a. The bond between the hydrogen and oxygen atoms is primarily covalent, which ordinarily results in an absence of electric moments typically found in ionic bonds. The hydrogen–oxygen bond in the water molecule is an exception. The bonding electrons are heuristically described as spending more time around the oxygen atom than around the hydrogen

Radiation (Natural) Within the Earth's Environment,

Figure 8 Schematic of the electric displacement response of water vapor molecules to a step electromagnetic field. Water vapor molecules have permanent electric moments (a) that can be modeled as an array of electric dipoles (b). Imposition of an electric field at time t_0 will cause free dipoles to spin about electric field lines (c), but the adjustment to a step electric field will take time relative to the periods of thermal radiation in the Earth's environment. Following the instantaneous adjustment of the electrons about each nucleus, represented by an immediate rise in electric susceptibility, the adjustment of the electric dipoles to the steady-state field is represented in (d) as an asymptotic approach to a steady-state dielectric susceptibility.

atom causing a time-average permanent electric moment that is modeled as the electric dipole shown in Figure 8b. An oscillating electric field of the right frequency will couple with the permanent electric moment causing the molecule to rotate, or spin, at discrete frequencies dictated by quantum mechanics. The process can be understood without appealing to quantum mechanics through use of the Debye model (1929).

If the experiment of a uniform step electric field, $\bar{E}_o$, is imposed upon a water vapor, the result will be an instantaneous adjustment of the electron fields around each atom as described for a monatomic gas and a much slower rotation of water molecules so that their electric moments align counter to the imposed electric field as shown in Figure 8c. The amplitude of the consequent electric susceptibility is depicted in Figure 8d where the average of the time needed for the rotational adjustment of molecules is described by the characteristic time, τ . For any time $t > t_o$, the electric polarization is modeled:

$$\bar{P}(t - t_o) = \epsilon_o(\epsilon_i - 1)\bar{E}_o + \epsilon_o(\epsilon_f - \epsilon_i)\left(1 - e^{-\frac{(t-t_o)}{\tau}}\right)\bar{E}_o, \quad (35)$$

Radiation (Natural) Within the Earth's Environment,

Figure 9 The electric displacement response of water vapor molecules to an impulse electromagnetic field. An electric field impulse in a linear system is represented as a positive step at time t_0 (a), followed by a negative step of equal amplitude at time $t_0 + \delta t$ (b). The consequent electric susceptibility of water vapor is then the superposition of positive and negative response like that in Figure 8. The susceptibility at any time t (c) is the sum of the step functions in Figures 9a and 9b. This impulse becomes for forcing function applied to the dielectric (d) is dependent upon the electric fields at all earlier times so that electric polarization, $\bar{P}(t)$, becomes a convolution of electric susceptibility and the imposed electric field.

where $\varepsilon_o(\varepsilon_i - 1)\bar{E}_o$ is the initial electric polarization resulting from the adjustment of the electron fields around atoms and $\varepsilon_o(\varepsilon_i - 1)\bar{E}_o$ is additional electric polarization from the rotation of the water molecules. The electric polarization as $t \rightarrow \infty$ is $\varepsilon_o(\varepsilon_f - 1)\bar{E}_o$.

An impulse, the forcing element of a convolution, is created by adding a negative step, $-\bar{E}_o$, at time $t + \delta t$ as

shown in Figure 9. The consequent amplitude of the electric susceptibility is shown in Figure 9d. For time $t > t_0 + \delta t$, the electric polarization resulting from an impulse at time t_0 is

$$\begin{aligned} \delta \bar{P}(t - t_0) &= \varepsilon_o(\varepsilon_f - \varepsilon_i) \left(e^{-\frac{-(t-t_0+\delta t)}{\tau}} - e^{-\frac{-(t-t_0)}{\tau}} \right) \bar{E}_o \\ &= \varepsilon_o(\varepsilon_f - \varepsilon_i) \left(\frac{\partial}{\partial t_0} \left\{ e^{-\frac{-(t-t_0)}{\tau}} \right\} \delta t_0 \right) \bar{E}_o \\ &= \varepsilon_o(\varepsilon_f - \varepsilon_i) \left(\frac{e^{-\frac{-(t-t_0)}{\tau}}}{\tau} \right) \bar{E}_o \delta t_0. \end{aligned} \quad (36)$$

Given this impulse response of the water vapor system, the electric polarization at time, t , resulting from a history of imposed electric fields, $\bar{E}(t_0)$, where $t_0 < t$, is

$$\bar{P}(t) = \varepsilon_o(\varepsilon_i - 1) \bar{E}(t) + \int_{-\infty}^t \varepsilon_o(\varepsilon_f - \varepsilon_i) \frac{e^{-\frac{-(t-t_0)}{\tau}}}{\tau} \bar{E}(t_0) dt_0. \quad (37)$$

Equation 37 in the frequency domain becomes

$$\begin{aligned} \bar{P}(\omega) &= F[\bar{P}(t)] \\ &= \varepsilon_o(\varepsilon_i - 1) \bar{E}(\omega) + \varepsilon_o(\varepsilon_f - \varepsilon_i) \\ &\quad F \left[\int_{-\infty}^t \varepsilon_o(\varepsilon_f - \varepsilon_i) \frac{e^{-\frac{-(t-t_0)}{\tau}}}{\tau} \bar{E}(t_0) dt_0 \right] \end{aligned} \quad (38)$$

where $F[f(t)]$ is the complex Fourier transform of $f(t)$ and $\bar{E}(\omega)$ is the imposed electric field in the frequency domain. The complex Fourier transform in Equation 38 is

$$\begin{aligned} F[\dots] &= \frac{1}{\sqrt{2\pi}} \int_{t=-\infty}^{t=\infty} \left\{ \int_{t_0=-\infty}^{t_0=t} \varepsilon_o(\varepsilon_f - \varepsilon_i) \frac{e^{-\frac{-(t-t_0)}{\tau}}}{\tau} \bar{E}(t_0) dt_0 \right\} e^{-j\omega t} dt \\ &= \frac{\varepsilon_o(\varepsilon_f - \varepsilon_i)}{\sqrt{2\pi}} \int_{t_0=-\infty}^{\infty} e^{\frac{t_0}{\tau}} \left\{ \int_{t=t_0}^{\infty} \frac{e^{-\frac{-(t-t_0)}{\tau}}}{\tau} dt \right\} \bar{E}(t_0) dt_0 \\ &= \frac{\varepsilon_o(\varepsilon_f - \varepsilon_i)}{\sqrt{2\pi}} \int_{t_0=-\infty}^{\infty} e^{\frac{t_0}{\tau}} \left\{ \frac{e^{-\frac{t_0}{\tau}}}{1+j\omega\tau} \right\} \bar{E}(t_0) dt_0 \\ &= \frac{\varepsilon_o(\varepsilon_f - \varepsilon_i)}{1+j\omega\tau} \left\{ \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{-j\omega t_0} \bar{E}(t_0) dt_0 \right\} \\ &= \frac{\varepsilon_o(\varepsilon_f - \varepsilon_i)}{1+j\omega\tau} \bar{E}(\omega). \end{aligned} \quad (39)$$

Equations 38 and 39 yield the electric polarization in the frequency domain:

$$\bar{P}(\omega) = \varepsilon_o \left\{ (\varepsilon_i - 1) + \frac{(\varepsilon_f - \varepsilon_i)}{(1 + j\omega\tau)} \right\} \bar{E}(\omega). \quad (40)$$

Unlike electric polarization in the time domain, which involves a convolution, electric polarization in the frequency domain is a simple product of a complex function of frequency and the electric field in the frequency domain. While a transformation from the time

domain to the frequency domain always converts a convolution to a simple product, demonstrating this characteristic for electric permittivity emphasizes the intuitive power in this case of working in the frequency domain.

The electric polarization in the frequency domain is defined

$$\begin{aligned}\bar{P}(\omega) &= \bar{D}(\omega) - \epsilon_0 \bar{E}(\omega) \\ &= \epsilon_0 (\tilde{\epsilon}_r(\omega) - 1) \bar{E}(\omega),\end{aligned}\quad (41)$$

where $\bar{D}(\omega)$ is the electric displacement in the frequency domain and the complex function, $\tilde{\epsilon}_r(\omega)$, is the relative electric permittivity in the frequency domain. Equations 40 and 41 yield the relative permittivity:

$$\tilde{\epsilon}_r(\omega) = \epsilon_i + \frac{\epsilon_f - \epsilon_i}{1 + j\omega\tau}, \quad (42)$$

which is the frequency domain expression for relative permittivity of a Debye relaxation process, i.e., a process of reorientation.

The mathematical description of the Debye relaxation process is most easily understood by introducing the relaxation frequency, $f_o = (2\pi\tau)^{-1}$, and comparing the frequency dependences of the real and imaginary parts of the relative permittivity. For $\tilde{\epsilon}_r = \epsilon'_r - j\epsilon''_r$,

$$\begin{aligned}\epsilon'_r &= \frac{\epsilon_f + \epsilon_i \left(\frac{f}{f_o}\right)^2}{1 + \left(\frac{f}{f_o}\right)^2} \\ \epsilon''_r &= \frac{(\epsilon_f - \epsilon_i) \left(\frac{f}{f_o}\right)}{1 + \left(\frac{f}{f_o}\right)^2}.\end{aligned}\quad (43)$$

The dielectric loss will be shown to be a direct result of the imaginary component of the complex relative permittivity, and the real and imaginary parts of relative permittivity will be shown to be interdependent – that is, one can be obtained from extensive knowledge of the other. The imaginary component of relative permittivity in the Debye relaxation process (Equation 43) is zero both at zero frequency and at infinite frequency, and maximum loss will occur at frequency $f = f_o$. The f_o of water vapor is 22.235 GHz (Liebe, 1969; Waters, 1976; Ulaby et al., 1981). The f_o of liquid water varies between 9 GHz at 0 °C and 17 GHz at 20 °C (Grant et al., 1957; Stogryn, 1971). The ϵ_i and ϵ_f for water vapor are proportional to vapor density, but are approximately $\epsilon_i = 4.9$ and $\epsilon_f = 88$ for liquid water at relevant temperatures in the Earth's environment (Klein and Swift, 1977; Ulaby et al., 1986). The real and imaginary components of the electric susceptibility, $X_e(\omega) = \tilde{\epsilon}_r(\omega) - 1$, of liquid water are shown as a function of frequency in Figure 10. Note that ϵ_i represents the infinite frequency limit of the real part of the relative permittivity,

Radiation (Natural) Within the Earth's Environment,

Figure 10 Debye relaxation model of the dielectric susceptibility of liquid water at 0 °C. The dielectric susceptibility at frequencies below ~1 GHz is consistent with all the water molecules following the orientation of the imposed electric field without significant loss. At frequencies above ~100 GHz, none of the water molecules can follow the imposed field, again, without significant loss. Maximum loss occurs at the maximum in the imaginary component of dielectric susceptibility. This maximum moves from 9 GHz at 0 °C to 17 GHz at 20 °C.

ϵ_f represents the zero frequency limit, and f_o is the frequency where $\epsilon'_r = \frac{\epsilon_f + \epsilon_i}{2}$.

The Lorentz process

Bending or stretching a bond between atoms also stores energy and, therefore, offers the possibility of a resonant process (Bohren and Huffman, 1983). For example, imagine the water molecule subjected to an oscillating electric field at a sufficiently high frequency that little rotation occurs. $\bar{E}(t)$ will cause water molecules to store elastic energy through bending and stretching of O–H bonds as shown schematically in Figure 11. Like rotation processes, specific vibrational resonances depend upon transitions specified by quantum mechanics, but the process can be understood without appealing to quantum mechanics through use of the model proposed by Lorentz in the early 1900s (e.g., Bohren and Huffman, 1983). The Lorentz model employs multiple spring–damper–mass systems, like those shown in Figure 11b. The systems are forced by an electric field, $\bar{E}(t)$, accelerating the charged masses. The dynamical equation for one system would be

$$m\ddot{z}(t) + b\dot{z}(t) + kz(t) = eE(t), \quad (44)$$

Radiation (Natural) Within the Earth's Environment,
Figure 11 Schematic of the Lorentz vibrational model of dielectric susceptibility. At frequencies well above those that permit a polyatomic molecule to align with an imposed electric field (a), the response of the molecule can be a vibrational mode modeled as a mass–spring–damper system forced by the imposed electric field (b). The system exchanges potential energy stored in the spring with kinetic energy stored in the motion of the mass. Unlike the Debye system, this system, if not overdamped, exhibits a resonance at angular frequency $\omega_o = \sqrt{\frac{k}{m}}$. Without damping, the system will attempt to store infinite energy at its resonant frequency.

where m is the atomic mass, b is a damping constant, k is a spring constant, and e is the electric charge. The number of dots over the coordinate, z , indicates the order of the time derivative. Polarization, $p(\omega)$, in the frequency domain, takes the form

$$\begin{aligned} p(\omega) &= e z(\omega) \\ &= \epsilon_o X_e(\omega) E(\omega) \end{aligned} \quad (45)$$

where $z(\omega)$ is the Fourier transform of $z(t)$ and $X_e(\omega)$ is the electric susceptibility in the frequency domain.

The dynamical equation in the frequency domain is

$$m(j\omega)^2 z(\omega) + b(j\omega) z(\omega) + k z(\omega) = e E(\omega), \quad (46)$$

and the frequency domain response to forcing becomes

$$p(\omega) = \frac{\left(\frac{e^2}{m}\right) E(\omega)}{(\omega_o^2 - \omega^2) + j\gamma\omega} \quad (47)$$

where damping coefficient, γ , replaces $\frac{b}{m}$ and resonant frequency, ω_o , replaces $\sqrt{\frac{k}{m}}$.

By recasting Equation 47 in the form of Equation 45 and writing $X_e(\omega)$ in polar form

$$X_e(\omega) = |X_e(\omega)| e^{-j\theta(\omega)}, \quad (48)$$

frequency-dependent amplitude, $X_e(\omega)$, and phase, $\theta(\omega)$, are

$$\begin{aligned} |X_e(\omega)| &= \frac{\left(\frac{e^2}{\epsilon_o m}\right)}{\sqrt{(\omega_o^2 - \omega^2)^2 + \gamma^2 \omega^2}} \\ \theta(\omega) &= \tan^{-1}\left(\frac{\gamma\omega}{\omega_o^2 - \omega^2}\right). \end{aligned} \quad (49)$$

The dielectric susceptibility exhibited by this mass–spring–damper model, reflected in Equation 49, is illustrated in Figure 12 for a resonant frequency of 100 THz ($\omega_o = 2\pi \cdot 10^{14}$) and a damping coefficient, $\gamma = 0.5 \omega_o$. For $\omega \ll \omega_o$, the system responds purely as a spring with no energy dissipated and no phase lag. For $\omega = \omega_o$, the system exhibits maximum susceptibility, i.e., a resonance, most energy dissipated, and a phase lag of $\pi/2$. For $\omega \gg \omega_o$, the damping element dominates the system, the system cannot follow the forcing, there is no energy dissipated, and the phase lag approaches π .

The water vapor molecule exhibits reorientation processes, or Debye behavior, at 22.235 and 183.3 GHz (e.g., Waters, 1976). The O_2 molecule exhibits reorientation processes, or Debye behavior, as a series of features referred to as the 60 GHz complex and at 118.75 GHz (e.g., Rosenkranz, 1975). These Debye processes in water vapor and oxygen are the basis of most satellite remote sensing of atmospheric water vapor and temperature profiles. The CO_2 molecule exhibits a vibrational process, or Lorentz behavior, at 1.61 μm (186 THz) (e.g., Tolton and Plouffe, 2001). This Lorentz process in CO_2 was to be the basis of the first Orbiting Carbon Observatory (OCO), which experienced a launch failure in February 2009. The 1.62 μm band is well above the thermal infrared band, but the feature is included here because of the importance of atmospheric carbon sensing.

(v) Real and imaginary components of frequency domain EM constitutive properties are related through Kramers–Kronig relationships.

The Kramers–Kronig relationships represent constraints on the frequency domain behavior of a system that is real in the time domain and causal, i.e., system response cannot lead the causative impulse (e.g., Bohren and Huffman, 1983). Mathematical literature refers to such relationships as Poisson's formulas (e.g., Morse and Feshbach, 1953), and systems theory literature refers to them as Hilbert transform relations (e.g., Guillemin, 1949).

Development of the Kramers–Kronig relations for dielectric constitutive properties is eased if the problem can be cast in a form where the constitutive relation represents a difference between the response of a dielectric material and that of a vacuum. A useful consequence of this approach is that the difference property

Radiation (Natural) Within the Earth's Environment, Figure 12 Lorentz model of dielectric susceptibility. This example is based upon a resonant frequency of $f_o = 10^{14}$ Hz and a damping coefficient $\gamma = 0.5 \times 2\pi f_o$.

Radiation (Natural) Within the Earth's Environment, Figure 13 Cauchy integral paths. (a) shows a path for an infinite frequency time domain dielectric susceptibility of zero – essentially a self-consistent statement that the system cannot respond to an infinite frequency. (b) shows a path for dielectric susceptibility at frequency ω_o yielding the Kramers–Kronig relations.

goes to zero at infinite frequency because real materials cannot mechanically respond to an infinite frequency. Electric susceptibility in the frequency domain, $X_e(\omega) = \tilde{\epsilon}_r(\omega) - 1$, exhibits this behavior as illustrated in Figures 10 and 12 for both the Debye and Lorentz processes.

Electric susceptibility, the physical change in a system that results in electric polarization when an electric field is applied, is causal in that it is zero prior to an electric field impulse, i.e., in the time domain, $X_e(t - t_o) = X_e(\tau) = 0$ for an impulse at time $t \leq t_o$ or, equivalently, $\tau \leq 0$. It is mathematically convenient to define a complex frequency, $\tilde{\omega} = \omega - j\eta$, so that

$$e^{-j\tilde{\omega}\tau} = e^{-j\omega\tau} e^{-\eta\tau}, \quad (50)$$

where the first term to the right of the equal sign is a wave and the second term is an attenuation for $\eta > 0$.

The Fourier transform from time domain to complex frequency domain

$$X_e(\tilde{\omega}) = \int_0^\infty X_e(\tau) e^{-j\tilde{\omega}\tau} d\tau, \quad (51)$$

converges because $X_e(\omega)$ exists and $X_e(\tilde{\omega}) < X_e(\omega)$ for $\eta > 0$. That is, $X_e(\tilde{\omega}) = \tilde{\epsilon}_r(\tilde{\omega}) - 1$ is everywhere analytic (always finite) in the upper half of the ω and η plane shown in Figure 13a. The inverse transform of $X_e(\tilde{\omega})$ for $\tau = 0$ is

$$X_e(\tau = 0) = \int_C X_e(\tilde{\omega}) d\tilde{\omega} = 0 \quad (52)$$

by Cauchy's Theorem because contour, C , does not enclose a pole. Physically, this is equivalent to saying that the medium cannot respond instantaneously to an impulse

or, equivalently, that the medium cannot respond to an infinite frequency.

We introduce a pole in the susceptibility relation to explore the system response at frequency ω_o , i.e., $X'_e(\tilde{\omega}) = \frac{X_e(\tilde{\omega})}{\tilde{\omega} - \omega_o}$, which has a pole at $\tilde{\omega} = \omega_o$. The integral of $X'_e(\tilde{\omega})$ around the contour $C = C_1 + C_2$ in Figure 13b is the sum of the integrals along contours C_1 and C_2 . There are no poles within the contour, which means the integral around C is zero and the integral around C_2 is also zero because $X_e(\tilde{\omega}) \rightarrow 0$ as $\omega \rightarrow \infty$ and $\eta \rightarrow \infty$. That is, the integral along C_1 ($\eta = 0$) becomes

$$P \int_{\omega=-\infty}^{\omega=+\infty} X'_e(\omega) d\omega + j\pi X_e(\omega_o) = 0, \quad (53)$$

where P designates the Cauchy principal value and the second term represents the outcome of a Cauchy integral halfway around a pole at $\tilde{\omega} = \omega_o$. The conjugate symmetry of $X_e(\omega)$ (a result of its time domain version being real and causal) permits

$$\begin{aligned} P \int_{\omega=-\infty}^{\infty} X_e(\omega) \omega - \omega_o d\omega &= P \int_{-\infty}^{\infty} X_e(\omega) \omega - \omega_o d\omega \\ &+ P \int_0^{\infty} X_e(\omega) \omega - \omega_o d\omega \\ &= P \int_{-\infty}^0 X_e(-\omega') - (\omega' + \omega_o) d(-\omega') \\ &+ P \int_0^{\infty} X_e(\omega) \omega - \omega_o d\omega \\ &= \int_0^{\infty} -X_e^*(\omega') (\omega' + \omega_o) d(\omega') \\ &+ P \int_0^{\infty} X_e(\omega) \omega - \omega_o d\omega \end{aligned} \quad (54)$$

where $\omega' = -\omega$. The independent variables ω' and ω in the integrals on the right side of Equation 54 are dummy variables for the purposes of the integrals and can be combined to yield

$$P \int_{\omega=-\infty}^{\infty} \frac{X_e(\omega)}{\omega - \omega_o} d\omega = P \int_0^{\infty} \left\{ \frac{-X_e^*(\omega) (\omega - \omega_o) + X_e(\omega) (\omega + \omega_o)}{\omega^2 - \omega_o^2} \right\} d\omega. \quad (55)$$

Expanding the second term in Equation 53,

$$j\pi X_e(\omega_o) = j\pi(\varepsilon'_r(\omega_o) - 1) + j\pi(-j\varepsilon''_r(\omega_o)), \quad (56)$$

substituting the result of Equation 55 for the first term in Equation 53, and separating the real and imaginary parts of Equation 53 yield

$$\begin{aligned} \varepsilon'_r(\omega_o) &= 1 + \frac{2}{\pi} P \int_0^{\infty} \frac{\omega \varepsilon''_r(\omega)}{\omega^2 - \omega_o^2} d\omega \\ \varepsilon''_r(\omega_o) &= -\frac{2\omega_o}{\pi} P \int_0^{\infty} \frac{\varepsilon'_r(\omega) - 1}{\omega^2 - \omega_o^2} d\omega. \end{aligned} \quad (57)$$

Equations 57 are the Kramers–Kronig relations for relative permittivity. Equivalently, knowledge of either the real or the imaginary component of relative permittivity at all frequencies is equivalent to knowing the other component at any frequency, ω_o . In practice, it is usually adequate to know the first component over a frequency range of several decades centered upon ω_o to infer the other component. These relationships are often used to derive an unmeasured component from experimental knowledge of the other component. The reader is invited to verify that the Debye and Lorentz models satisfy the Kramers–Kronig relations.

(vi) Emissive power is a consequence of the imaginary component of relative permittivity.

The frequency-dependent absorption coefficient is a product of relationships among frequency domain electromagnetic fields. These relationships define the extinction of an electromagnetic wave and, consequently, the frequency-dependent absorption of power. The frequency domain expressions of Maxwell's Equations for charge-neutral media are

$$\begin{aligned} \nabla \times \bar{E}(\bar{r}, \omega) &= -j\omega \bar{B}(\bar{r}, \omega) \\ \nabla \times \bar{H}(\bar{r}, \omega) &= \bar{J}(\bar{r}, \omega) + j\omega \bar{D}(\bar{r}, \omega) \\ \nabla \cdot \bar{D}(\bar{r}, \omega) &= 0 \\ \nabla \cdot \bar{B}(\bar{r}, \omega) &= 0. \end{aligned} \quad (58)$$

where $\bar{E}(\bar{r}, \omega)$ and $\bar{H}(\bar{r}, \omega)$ are the electric and magnetic vector fields, $\bar{D}(\bar{r}, \omega)$ is the electric displacement vector field, $\bar{B}(\bar{r}, \omega)$ is the magnetic induction vector field, and $\bar{J}(\bar{r}, \omega)$ is the electric current density vector field. Unlike imaginary numbers in the time domain where their use often appears as a mathematical shortcut with limited physical meaning, imaginary numbers in the frequency domain have a precise physical meaning. For example, $-j$ in the Faraday Law (the first equation of Equation 58) denotes a 90° phase lead of the magnetic induction relative to the curl of the electric field, and $+j$ in the Ampere/Maxwell's Law (the second equation of Equation 58) denotes a 90° phase lag of the electric displacement relative to the curl of the magnetic field and the current density.

Materials found in significant abundances in the natural environment predominantly exhibit linear constitutive relationships at microwave frequencies, i.e.,

$$\begin{aligned} \bar{D}(\bar{r}, \omega) &= \varepsilon_o \bar{\varepsilon}_r(\bar{r}, \omega) \bar{E}(\bar{r}, \omega) \\ \bar{B}(\bar{r}, \omega) &= \mu_o \bar{H}(\bar{r}, \omega) \\ \bar{J}(\bar{r}, \omega) &= \sigma(\bar{r}) \bar{E}(\bar{r}, \omega). \end{aligned} \quad (59)$$

Magnetic permeability is vacuum permeability, μ_o , because natural media are predominantly nonmagnetic. The dominant electrical conduction process for natural media at temperatures found in the Earth's environment is either electron/hole migration at frequencies above 1 GHz or ion migration at frequencies well below 1 GHz. Interest in this section lies above 1 GHz where electron/hole migration dominates. At a given

temperature, these processes are approximately linear with the imposed electric field and independent of frequency over relevant frequencies so that conductivity, $\sigma(\bar{r})$, can be modeled as a real constant dependent only upon position vector, $\bar{r}$. The universality of this physical model for electric conductivity is unimportant in the context of this section because, for computational convenience, $\sigma(\bar{r})$ will be subsumed within a combined dielectric loss term where the contribution from electric conductivity is small relative to actual dielectric loss for the overwhelming majority of media of interest.

A combination of the frequency domain Maxwell's Equations and the vector identity, $\nabla \times \nabla \times \bar{E}(\bar{r}, \omega) = \nabla \nabla \cdot \bar{E}(\bar{r}, \omega) - \nabla^2 \bar{E}(\bar{r}, \omega)$, yields the Helmholtz wave equation in terms of the electric field:

$$(\nabla^2 + \omega^2 \mu_o \epsilon_o \tilde{\epsilon}_r(\omega)) \bar{E}(\bar{r}, \omega) = 0. \quad (60)$$

where electric conductivity has been subsumed into the definition of relative permittivity, i.e.,

$$\tilde{\epsilon}(\omega)_r = \epsilon'_r(\omega) - j \left(\epsilon''_r + \frac{\sigma}{\epsilon_o \omega} \right). \quad (61)$$

The conduction component, $\frac{\sigma}{\epsilon_o \omega}$, is typically much smaller than the dielectric component, ϵ''_r , at all thermally radiant frequencies. For simplicity, the conduction component is often ignored in further development of the loss term, a practice followed here, but users of these concepts should be aware that the imaginary component of relative permittivity potentially includes an electric conduction term that exhibits an inverse frequency dependence.

A plane wave traveling in the $\hat{k}$ direction can be written

$$\bar{E} = \hat{e} E_o e^{-j \hat{k} \cdot \bar{r}}. \quad (62)$$

The electric field direction is designated by unit vector $\hat{e}$ normal to $\hat{k}$, and the wave vector is $\bar{k} = \hat{k} k$, where k is the wave number (or angular spatial frequency), and the explicit dependences upon position, $\bar{r}$, and frequency, ω , have been suppressed. In a Cartesian frame, $\hat{x}$, $\hat{y}$, and $\hat{z}$, the phase term of the electric field becomes

$$\begin{aligned} \bar{k} \cdot \bar{r} &= (\hat{x} k_x + \hat{y} k_y + \hat{z} k_z) \cdot (\hat{x} x + \hat{y} y + \hat{z} z) \\ &= k_x x + k_y y + k_z z \end{aligned} \quad (63)$$

where k_x , k_y , and k_z are the orthogonal components of $\mathbf{k}$. The Laplacian of the electric field is

$$\begin{aligned} \nabla^2 \bar{E} &= \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \right) \bar{E} \\ &= - \left(k_x^2 + k_y^2 + k_z^2 \right) \bar{E} \\ &= -k^2 \bar{E}. \end{aligned} \quad (64)$$

Substituting Equation 64 into the Helmholtz wave equation (Equation 60) yields

$$(-k^2 + \omega^2 \mu_o \epsilon_o \tilde{\epsilon}_r) \bar{E} = 0. \quad (65)$$

The characteristic equation of Equation 65, the dispersion relation, becomes

$$\begin{aligned} k &= \omega \sqrt{\mu_o \epsilon_o} \sqrt{\tilde{\epsilon}_r} \\ &= \frac{\omega}{c} \sqrt{\tilde{\epsilon}_r} \\ &= k_o \tilde{n} \end{aligned} \quad (66)$$

where $\sqrt{\mu_o \epsilon_o}$ is the inverse of the vacuum speed of light, c ; $\frac{\omega}{c}$ is the vacuum wave number, k_o ; and $\tilde{n}$, the complex index of refraction, is the square root of the relative permittivity. The complex index of refraction, $\tilde{n}$, is defined $\tilde{n} = n - j\kappa$ where n is the familiar index of refraction and κ is the wave extinction coefficient. The role of the complex index of refraction, $\tilde{n}$, in wave propagation is illustrated as follows:

$$\begin{aligned} \bar{E} &= \hat{e} E_o e^{-j \hat{k} \cdot \bar{r}} \\ &= \hat{e} E_o e^{-j (\hat{k} \cdot \bar{r}) k r} \\ &= \hat{e} E_o e^{-j (\hat{k} \cdot \bar{r}) k_o \tilde{n} r} \\ &= \hat{e} E_o e^{-j (\hat{k} \cdot \bar{r}) k_o n r} e^{-(\hat{k} \cdot \bar{r}) k_o \kappa r}. \end{aligned} \quad (67)$$

The first exponential term in the last line of Equation 67 is phase, and the second exponential term is attenuation. If the relative permittivity, $\tilde{\epsilon}_r$, is real, its square root, $\tilde{n}$, is real. That is, $\kappa = 0$, i.e., there would be no extinction of the wave.

Converting from propagation of an electric field to radiant power requires knowledge of the magnetic field. Combining the Faraday and the Ampere/Maxwell laws yields

$$\begin{aligned} \bar{H} &= \hat{h} \sqrt{\frac{\epsilon_o}{\mu_o}} \tilde{n} E_o e^{-j k_o \tilde{n} r} \\ &= \hat{h} \frac{\tilde{n} E_o}{\eta_o} e^{-j k_o \tilde{n} r} \end{aligned} \quad (68)$$

where $\hat{h}$ is a unit vector indicating the direction of the magnetic field and $\eta_o = \sqrt{\frac{\mu_o}{\epsilon_o}}$ is the vacuum impedance to an electromagnetic wave. It is easily shown that $\hat{h}$ is mutually perpendicular to $\hat{k}$ and $\hat{e}$. Average radiant power, expressed as a Poynting vector, is half the real part of the product of the electric field crossed with the complex conjugate of the magnetic field, i.e.,

$$\begin{aligned} \bar{S} &= \frac{1}{2} \text{Re} \{ \bar{E} \times \bar{H}^* \} \\ &= \frac{1}{2} \hat{k} \text{Re} \{ E H^* \} \\ &= \frac{1}{2} \hat{k} \text{Re} \left\{ E \left(\frac{\tilde{n}}{\eta_o} E \right)^* \right\} \\ &= \frac{1}{2} \hat{k} \text{Re} \left\{ E E^* \frac{\tilde{n}^*}{\eta_o} \right\} \\ &= \hat{k} \frac{E_o^2}{2 \eta_o} n e^{-2 k_o \kappa r}. \end{aligned} \quad (69)$$

The exponential term in the last line of Equation 69 represents absorption of the radiant power. Defining the absorption coefficient, $\kappa_{fa} = 2 k_o \kappa$, yields the familiar expression

$$\bar{S} = \hat{k} S_o e^{-\kappa_{fa} r}, \quad (70)$$

where S_o is the power density at $r = 0$. Aspects of Equation 70 to remember are that the absorption coefficient, κ_{fa} , is a frequency domain concept and that it is nonzero only if either the dielectric contribution or the conduction contribution to the imaginary component of the relative permittivity is nonzero.

Scattering loss, often referred to as scatter darkening, introduces an additional multiplier to Equation 70 of the form $e^{-\kappa_{fs} r}$, where κ_{fs} is a frequency-dependent scattering coefficient. The sum of absorption and scattering coefficients is the frequency-dependent power extinction coefficient, $\kappa_{fe} = \kappa_{fa} + \kappa_{fs}$. Scattering is beyond the scope of this section, but it is appropriate to note that scattering influences emissive power only to the extent that scattering warms the emitting medium. Scattering effectively increases the length of ray paths within the scattering medium. Longer ray paths are subject to increased absorption so that the radiant brightness escaping from the scattering medium will be diminished. This scatter darkening contributes to the thermal temperature of the medium only for scattered energy that is a significant fraction of the total thermal energy of the scattering medium. In practice, this means radiant energy from the Sun or thermal infrared energy from sources within the Earth's environment. Scattering at millimeter and microwave wavelengths does not appreciably increase the thermal temperature of the medium and, therefore, does not influence the emissive power of the medium.

Summary

Natural radiation originating within the Earth's environment at frequencies between 1 GHz and 40 THz ($\sim 8 \mu\text{m}$, the upper end of the TIR band) is a consequence of Planck thermal emission. This radiation can be used to infer thermal and compositional states of the natural emitter and the media traversed by the ray after it leaves the natural emitter. A condition for Planck emission is local thermal equilibrium. Emissive power equaling absorption at every frequency, i.e., the principle of detailed balance (e.g., McQuarrie, 2000), is a condition of thermal equilibrium. A corollary of that principle is that, in the absence of absorption and scattering, radiant brightness temperature is invariant along a ray. Emissive power, an intrinsic property of a medium, is determined by the medium's dielectric loss, conduction loss, and thermal temperature. Dielectric and electric conduction constitutive properties are most intuitive when expressed in the frequency domain. The real and imaginary components of frequency domain constitutive

properties carry physical meaning and are related through Kramers–Kronig relationships. The contribution of the constitutive properties to emissive power originates in the imaginary component of relative permittivity.

Definition

Natural radiation is an electromagnetic product of physical processes in the Earth or space environment and, as such, is often a remotely sensed indicator of aspects of those processes.

Natural radiation sources, characteristics

Remote sensing techniques that sense electromagnetic radiation are referred to as “active” if they employ artificial sources or “passive” if they employ natural sources. **RADAR** and **LiDAR** are examples of active techniques. Sources for “passive” techniques, that is, those employing natural radiation, are classified as thermal and nonthermal. Thermal sources include Planck emission from any dielectric medium whose temperature is above absolute zero (Planck, 1909) and ionized hydrogen emission from hot plasmas like those found at the surfaces of the Sun and stars (e.g., Hjellming, 1974). Nonthermal sources are of little importance in remote sensing of the Earth except for studies using radio emission from lightning (sferics) or from the ionosphere (synchrotron radiation). Nonthermal sources are significant in radio astronomy where synchrotron radiation, a result of interactions between plasmas and magnetic fields, can be strong and diagnostic of stellar or galactic processes (Salter and Brown, 1974; Harwit, 1988).

Planck emission is leakage of radiant energy from a dielectric whose size is large with respect to a wavelength, whose temperature is uniform over distances that are large with respect to a wavelength, and whose internal radiant energy is in thermal equilibrium. The Planck brightness for polarization, p , within a homogeneous dielectric medium, readily derived using statistical mechanics (e.g., McQuarrie, 2000), is given by

$$B_p(f, T, n) = \left(\frac{n}{c}\right)^2 \frac{h f^3}{(e^{\frac{hf}{kT}} - 1)} \text{Wm}^{-2}\text{Hz}^{-1}\text{sr}^{-1}, \quad (1)$$

where f is frequency (Hz), T is temperature (K), n is index of refraction, c is vacuum speed of light (2.9979×10^8 m/s), h is Planck's constant (6.6256×10^{-34} J · s), and k is Boltzmann's constant (1.3805×10^{-23} J/K).

If a ray can leak out of the dielectric medium without reflection at the dielectric-vacuum interface, then the medium is classified as a blackbody and its brightness is given by

$$B_p^b(f, T) = B_p(f, T, n = 1) \text{Wm}^{-2}\text{Hz}^{-1}\text{sr}^{-1}, \quad (2)$$

where superscript b identifies blackbody radiance. Even though blackbody brightness is independent of polarization, subscript p reminds us that B_p^b refers to single-polarization brightness and that the microwave brightness of a non-black (or “gray”) surface is typically polarization dependent. Total blackbody spectral brightness would be $2B_p^b$.

Figure 1 shows blackbody brightness spectra, $B_p^b(f, T)$, plotted against wavelength using the relationship, $\lambda = c/f$, for dielectrics whose temperatures are 300 K (approximately the physical temperature of the Earth or Moon) and 6,000 K (approximately the physical temperature of the visible disk, or photosphere, of the Sun). The ionized hydrogen brightness of the solar photosphere looks nearly like a 6,000 K Planck emitter for UV through millimeter wavelengths. The exceptions are several hundred dark lines, or Fraunhofer lines, caused by absorption in the cooler gaseous shell, or chromosphere, surrounding the Sun. These lines are too narrow to be factors in UV, visible, or reflectance infrared (near-IR) sensing of the Earth and are too narrow to be depicted at the scale of the 6,000 K spectrum in Figure 1.

The solar brightness at wavelengths longer than a millimeter increases and varies spectacularly with the 11 year solar cycle (limits depicted in Figure 1). At solar minimum, spectral regions of the microwave brightness reach the equivalent of a 10^6 K Planck emitter. At solar maximum, the peak brightness in a limited band can exceed the equivalent of a 10^{10} K emitter, a four orders of magnitude difference (Kraus, 1966).

There are three salient characteristics of Planck, or “blackbody,” emission that are fundamental to remote sensing (e.g., Ulaby et al., 1981). The first salient characteristic, called Wien's displacement law, is the maximum brightness of a Planck spectrum that occurs at a wavelength that is inversely proportional to the emitter's thermal temperature, that is,

$$\lambda_{\max} = \frac{C_w}{T} \text{ m}, \quad (3)$$

where Wien's displacement constant, C_w , in vacuum is 2.899×10^{-3} m K. Given that most temperatures in the Earth's environment are near 300 K, convention has defined thermal infrared (TIR) remote sensing of the Earth as centered about $\lambda_{\max} = 10 \mu$.

The second salient characteristic of Planck emission, called the Stefan-Boltzmann law, is the total spectral brightness integrated over all frequencies, and both polarizations are proportional to the fourth power of the thermal temperature, that is,

$$B_{\text{tot}} = \frac{\sigma T^4}{\pi} \text{ W} \cdot \text{m}^{-2} \cdot \text{sr}^{-1}, \quad (4)$$

where the Stefan-Boltzmann constant, σ , in vacuum is $5.673 \times 10^{-8} \text{ W} \cdot \text{m}^{-2} \cdot \text{K}^{-4} \cdot \text{sr}^{-1}$. Because the brightness of a “black” emitter is uniform in all directions, B_{tot} is

Radiation Sources (Natural) and Characteristics, Figure 1 Examples of natural source, single-polarization brightness spectra. The Earth and Moon exhibit a 300 K Planck radiance, which is typical of the Earth and Moon. Because of nonthermal processes in the solar corona, the solar spectrum deviates from a 6,000 K Planck curve at wavelengths longer than a centimeter. The brightness spectra of Planck emitters exhibit -2 slopes at longer wavelengths on a log-log plot. Nonthermal emitters, like the solar corona and galactic sources, typically exhibit other than -2 slopes.

a constant in the integral defining total radiant power lost through a square meter of a “black” surface.

$$\begin{aligned} \text{Radiant Power Lost} &= \int_{\phi=0}^{\phi=2\pi} \int_{\theta=0}^{\theta=\pi/2} (\sin \theta \, d\phi) \\ &\quad \times (B_{\text{tot}} \cos \theta) \, d\theta = \sigma T^4 \quad \text{W/m}^{-2}. \end{aligned} \quad (5)$$

This version of the Stefan-Boltzmann law is a staple of thermal design of engineered systems (e.g., Modest, 2003).

The third salient characteristic of Planck emission, called the Raleigh-Jeans approximation for any wavelength that is long with respect to λ_{max} , defines that single-polarization brightness is proportional to temperature. The relationship in vacuum is given by

$$B_p(f, T) = \frac{kT}{\lambda^2} \text{ W} \cdot \text{m}^{-2} \cdot \text{Hz}^{-1} \cdot \text{sr}^{-1}. \quad (6)$$

Equation 6 suggests that a -2 slope appearing in a log-log plot of spectral brightness versus wavelength could be diagnostic of a Planck emitter. The distinction is exhibited in the differences between the observed spectral brightness of the Moon and Mars and those of the examples of galactic sources in Figure 1. The Moon and Mars, thermal emitters, exhibit slopes of -2 , while the galactic sources,

nonthermal emitters, exhibit positive spectral slopes. A -2 slope is also characteristic of the microwave brightness spectra of media in the Earth’s environment. Exceptions to the rule occur when volume scattering, surface scattering, or interference within relatively transparent layers modifies the Planck spectrum of dielectric media. These situations will be discussed more fully in later sections.

The natural radiation itself can be a diagnostic feature of an emitter. For example, the Planck-like spectrum defines the temperature at the surface of the solar optical disk as 6,000 K, and the Fraunhofer absorption lines in that spectrum are used to infer the composition of gases in the solar chromosphere (e.g., Ross and Aller, 1976). The microwave spectral brightness of the Earth’s atmosphere is used to infer temperature and moisture profiles in the atmosphere, and the brightness of soil at wavelengths longer than 10 cm is used to infer an integrated liquid moisture content of soils to depths of something like half a wavelength in the soil (e.g., Ulaby et al., 1986).

Natural radiation is also used to illuminate remotely sensed objects of interest. For example, solar brightness is the source of visible and near-infrared (reflectance IR) sensing in the Earth’s environment (e.g., Deering, 1989). There is also background illumination, like that depicted in the cartoon of retrieval of soil moisture (Figure 2). The microwave signature of soil moisture is primarily

Radiation, Electromagnetic, Figure 2 Cartoon of scheme for sensing soil moisture. The radio sky includes the ubiquitous 2.7 K cosmic background radiation plus a nonthermal contribution from galactic sources. The galactic contribution is only significant at frequencies near and below 1 GHz. The galactic contribution is greatest from the center of the Milky Way and least from its poles. At 1.4 GHz, the maximum contribution is about 10 K and the minimum is below the cosmic background (Tiuri, 1966). Absorption and emission by the atmosphere is frequency dependent but relatively insignificant at the preferred soil moisture sensing frequency of 1.4 GHz (Ulaby et al., 1986). Emission from wet soil has a wetness-dependent dynamic range of tens of Kelvins at 1.4 GHz even through significant agricultural canopies (e.g., Hornbuckle and England, 2004).

due to Planck emission from wet soil, but satellite radiometers will sense Planck emission from the soil, sky brightness reflected by the soil, and modification of both by absorption and emission in the atmosphere between the soil and the radiometer. An accurate retrieval of soil moisture requires that all of these processes be considered. Such retrievals will be explored in later sections.

Conclusion

Natural radiation is the source for “passive” remote sensing techniques based upon electromagnetic radiation. These passive techniques are typically labeled gamma ray, X-ray, reflectance ultraviolet, reflectance visible, reflectance infrared, millimeter radiometry, and microwave radiometry. Techniques in the UV through microwave bands are significant for Earth remote sensing.

Natural radiation sources are either thermal or nonthermal. Thermal means that the radiant energy is derived from thermal processes in the emitting medium. Nonthermal usually means that the radiant energy is derived from an interaction between a plasma and a magnetic field, that is, synchrotron radiation. Thermal sources are

overwhelmingly the dominant source for remote sensing in the Earth’s environment.

The spectral brightness of a thermal source can be diagnostic of the source, for example, the temperature and salinity of standing water, or of the medium the rays pass through in route to the radiometer, for example, the temperature and water vapor profiles of the atmosphere.

Definition

Electromagnetic radiation is the means by which *information* is transmitted from an object to the sensor

through an emitted, transmitted, or reflected electric and/or magnetic field. The *interaction* of the electromagnetic waves with the environment is strongly dependent on the wavelength and the geometrical, electrical, magnetic, and conductive properties of the interacting medium. Electromagnetic waves in different frequency bands tend to excite different interaction mechanisms such as electronic, molecular, or conductive. Electromagnetic radiation is the most commonly used means to retrieve information about an object by means of remote sensing techniques.

Introduction

Remote sensing is the methodology to remotely retrieve information about an object (Ulaby et al., 1981). This information is acquired by measuring changes that the object under investigation imposes on the interacting field. The latter can be an electromagnetic, acoustic, or gravitational field. The electromagnetic methods, which are the most commonly used, cover the whole electromagnetic spectrum from radio frequency waves to gamma rays through microwaves, submillimeter waves, and far-infrared, near-infrared, visible, ultraviolet, and X-ray waves (Elachi, 1987).

Electromagnetic radiation spectrum

From the classic electromagnetic theory point of view, the *electromagnetic radiation* at a given frequency is a wave phenomenon due to the contemporary propagation of periodic perturbations of an electric and a magnetic field, in free space oscillating in planes perpendicular to each other (Ishimaru, 1991). For a wave periodic phenomenon, it is usual to introduce the wavelength λ and the frequency ν so that the wave velocity c in free space is expressed by

$$c = \frac{\lambda}{T} = \lambda\nu = \lambda \frac{\omega}{2\pi} = \frac{\omega}{\beta} \quad (1)$$

where T is the time period, ω is angular pulsation, and β the propagation constant (or wave number). From Eq. 1, an electromagnetic wave with a higher frequency will exhibit a shorter wavelength. The *electromagnetic spectrum* is divided into a number of spectral regions, each of them conventionally labeled as in Table 1 (Ulaby et al., 1981). The latter emphasizes the spectral bands of interest for remote sensing purposes.

The *radio wave region* covers wavelengths shorter than 10 cm and is used by active radio sensors such as imaging radars, altimeters, and sounders. The main mechanism of interaction is due to scattering, reflection, conduction, and ionospheric effects.

The *microwave region* is governed by molecular rotation, particularly at shorter wavelength, and the main interaction mechanisms include thermal emission, scattering, and conduction. The major applications refer to microwave radars, radiometers, and spectrometers. It is customary to subdivide the microwave region in

Radiation, Electromagnetic, Table 1 Electromagnetic spectrum and its nomenclature

Band	Frequency range (ν)	Wavelength range (λ)
Radio wave	<3 GHz	>10 cm
Microwave	3–300 GHz	1 mm–10 cm
Submillimeter	300 GHz–3 THz	10 cm–0.1 mm
Infrared	3–428 THz	0.1 mm–700 nm
Visible	428–749 THz	700–400 nm
Ultraviolet	749 THz–30 PHz	400–10 nm
X-rays	30 PHz–300 EHHz	10 nm–1 pm
Gamma rays	>300 EHHz	<1 pm

frequency bands, labeled by a letter: P (0.5–1 GHz), S (2–4 GHz), C (4–8 GHz), X (8.124 GHz), Ku (12.4–18 GHz), K (18–26.5 GHz), Ka (26.5–40 GHz), V (40–75 GHz), and W (75–90 GHz).

The *submillimeter and infrared region* covers a wavelength interval between 1 mm and 0.7 μ m. The infrared region is usually subdivided into far-infrared (15–1,000 μ m), thermal infrared (8–15 μ m), mid-infrared (3–8 μ m), and near-infrared (0.75–3 μ m). In this region, molecular rotation and vibration play an important role together with thermal emission. Imagers, spectrometers, radiometers, polarimeters, interferometers, and lasers are typical sensors exploiting this frequency region for remote sensing.

The *visible region* covers the electromagnetic spectrum portion visible by human eyes between 380 and 750 nm. This interval is usually subdivided into colors: violet (380–450 nm), blue (450–495 nm), green (495–570 nm), yellow (570–590 nm), orange (590–620 nm), and red (620–759 nm). In this region, electronic energy levels start to play a key role together with vibrational processes in the wave–matter interactions. Imagers, spectrometers, radiometers, polarimeters, and lasers are among the sensors operating in this region.

The *ultraviolet region* is characterized by interactions dominated by electronic processes. Major applications are related to planetary atmosphere sounding because of the string gas opacity at these wavelengths.

The *X-ray and gamma-ray regions* are related to wave–matter interaction involving atomic processes. Where the X photons are produced by energetic electrons, the gamma ones are generated by transitions within an atomic nucleus. The strong atmospheric opacity limits their use to planetary surfaces without atmosphere.

Electromagnetic radiation theory

Following classical physics, the macroscopic behavior of electromagnetic waves is governed by Maxwell's differential equations, which relate the electric field vector $\mathbf{E}(\mathbf{r},t)$ [V/m] to the magnetic field vector $\mathbf{H}(\mathbf{r},t)$ [A/m] in a given instant t and point, indicated by a position vector $\mathbf{r}$ (Tsang et al., 1985). In a linear, isotropic, homogeneous,

non-ferromagnetic, and dissipative medium, the Maxwell equations can be written as

$$\begin{cases} \nabla \times \mathbf{E} = -\mu \frac{\partial \mathbf{H}}{\partial t} \\ \nabla \times \mathbf{H} = -\varepsilon \frac{\partial \mathbf{E}}{\partial t} + \sigma \mathbf{E} + \mathbf{J}_i \\ \nabla \cdot \mathbf{E} = \frac{\rho_i}{\varepsilon} \end{cases} \quad (2)$$

where ∇ is the *nabla* spatial differential operator, μ [H/m] is the medium magnetic permeability, ε [F/m] is the medium electric permittivity, and σ is the medium electronic conductivity. The density current $\mathbf{J}_i$ and electric charge concentration ρ_i [C/m³] represent the impressed quantities, either generated by an electromagnetic source or known from proper boundary conditions. The last equation in Eq. 2 is the Gauss law. Previous equations state that a wave motion exists in the electric and magnetic force fields. In any region where there is a temporal change of the electric field, a magnetic field appears in that region as a conjugal partner and vice versa.

Free-space radiation

In absence of impressed quantities (electromagnetic sources) and in a non-dissipative medium (i.e., $\sigma = 0$), the previous Maxwell equations can be combined to derive the following *wave equation* for the electric field:

$$\nabla^2 \mathbf{E} - \mu \varepsilon \frac{\partial^2 \mathbf{E}}{\partial t^2} = 0 \quad (3)$$

where ∇^2 is the *Laplacian* spatial second-order differential operator. A dual wave equation for the magnetic field can be derived from Eq. 3, substituting $\mathbf{E}$ with $\mathbf{H}$. In case of cosinusoidal time-periodic waves and in an unbounded medium, a relevant solution of the previous wave equation is represented by the uniform plane wave expressed by

$$\mathbf{E}(\mathbf{r}, t) = \text{Re}[\mathbf{E}_0 e^{j\omega t - j\beta \cdot \mathbf{r}}] = \eta[\hat{\mathbf{r}} \times \mathbf{H}(\mathbf{r}, t)] \quad (4)$$

where $\mathbf{E}_0$ is the complex polarization state vector, $j = \sqrt{-1}$ is the imaginary unit, $\eta = \sqrt{\mu/\varepsilon}$ [Ω] is the *characteristic impedance* of the medium, and $\hat{\mathbf{r}}$ is the unit vector of the position vector $\mathbf{r}$. In Eq. 4, Re is the *real-part* operator, and the quantity $\Psi(\mathbf{r}, \omega) = \omega t - \beta \cdot \mathbf{r}$ is also called the plane-wave *phase function* with $\omega = 2\pi\nu$ the angular pulsation, proportional to the frequency ν , and $\beta = \beta \hat{\mathbf{r}}$ the propagation vector. The uniform plane wave expresses the typical characteristic of a transverse electromagnetic (TEM) wave where $\mathbf{E}$ and $\mathbf{H}$ are proportional, mutually orthogonal, and oscillate in a plane perpendicular to direction of propagation indicated by the propagation vector β . It is worth noting that the plane wave is a nonphysical solution due to its infinite energy; it is, however, important to express wave propagation properties (Ulaby et al., 1981).

In presence of electromagnetic sources and in a non-dissipative medium, the Maxwell equations in an

unbounded free space can be formally solved, and the monochromatic electric field $\mathbf{E}$ in spherical coordinates $\mathbf{r} = [r, \theta, \varphi]$ has the following expression:

$$\begin{aligned} \mathbf{E}(\mathbf{r}, t) &= \text{Re} \left\{ e^{j\omega t} \mathbf{F}_E(\theta, \varphi) \frac{e^{-j\beta r}}{r} \right\} \\ &= \eta[\hat{\mathbf{r}} \times \mathbf{H}(\mathbf{r}, t)] \end{aligned} \quad (5)$$

where $\mathbf{F}_E$ is the electric radiation vector function, indicating the polarization property and relating the radiated field to the electromagnetic sources in terms of a transform. The latter, for example, in case the sources are expressed in Cartesian coordinates, is explicitly a Fourier three-dimensional transform. The quantity $\Psi(\mathbf{r}, \omega) = \omega t - \beta r$ is the spherical-wave phase function in Eq. 5. The fact that electric radiation vector function $\mathbf{F}_E(\theta, \varphi)$ is not depending on the distance r is true only in the so-called far-field radiation zone (or Fraunhofer's zone) which is a region where r is larger than D_s^2/λ , with D_s the maximum size of the electromagnetic source. Equation 5 highlights the major properties of the radiated field in a free space: (1) it is a spherical wave; (2) its amplitude is inversely proportional to the distance r ; (3) it can be locally modeled as a TEM plane wave (Fung, 1994).

When the electromagnetic problem is solved either in a bounded medium or in presence of other sources and obstacles, the free-space solution is no more valid (Ishimaru, 1991). Proper initial and boundary conditions, describing the tangential components of the electromagnetic field on the boundaries and their initial time state, need to be imposed to the Maxwell equations. These conditions ensure the uniqueness of the electromagnetic solution within the considered volume.

Quantum radiation

Maxwell's theory fails to account for certain significant phenomena when the wave interacts with matter, especially at very short wavelengths where electronic, atomic, and molecular forces play a dominant role. In these cases, *quantum electrodynamics* is a theory more appropriate than classical electromagnetics to describe electromagnetic radiation (Elachi, 1988).

The electromagnetic energy can be presented in a quantized form as bursts of radiation with a quantized radiant energy, called photon Q , which is proportional to the frequency ν :

$$Q(\mathbf{r}, t) = h\nu \quad (6)$$

where h is the Planck constant ($h = 6.626 \cdot 10^{-34}$ J s). The quantum-matter interaction is mainly dependent on the frequency of the wave (i.e., its photon energy) and the energy level structure of the matter. As a wave interacts with a material in gas, liquid, or solid state, electrons, molecules, and/or nuclei are put into motion (i.e., rotation, vibration, or displacement) which leads to exchange of energy between the wave and the material.

The radiant energy, carried by the wave, is not delivered in a continuous deterministic way, but on a probabilistic quantum basis. The probability that a wave train will deliver its radiant energy at some place along the wave direction is proportional to the flux density of the wave at that place. If a very large number of wave trains are coexistent, then the overall average effect can be described by Maxwell's equations.

Radiation quantities

The *power flux density* of the electromagnetic radiation can be expressed by the Poynting vector $\mathbf{S}(\mathbf{r}, t)$ [W/m²], defined by

$$\begin{aligned}\mathbf{S}(\mathbf{r}, t) &= \mathbf{E}(\mathbf{r}, t) \times \mathbf{H}(\mathbf{r}, t) \\ &= \frac{|\mathbf{E}(\mathbf{r}, t)|^2}{\eta} \hat{\mathbf{r}} = S(\mathbf{r}, t) \hat{\mathbf{r}}\end{aligned}\quad (7)$$

where the last equality is true only if a TEM structure holds for the radiated field. The power flux density of a monochromatic field is directed along the wave propagation direction $\hat{\mathbf{r}}$.

In case of natural sources, the power flux density can be very low and angularly spread. It is convenient to express the radiation flow through the specific intensity or radiance (Chandrasekhar, 1960; Ishimaru, 1978). At a given point $\mathbf{r}$, the scalar specific intensity $I(\mathbf{r}, t)$ [W m⁻² sr⁻¹] (where sr stands for steradian or solid unit angle) represents the amount of elementary power dP [W] flowing within a solid angle $d\Omega$ through an elementary area dA [m²] oriented along the direction of the unit vector $\hat{\mathbf{n}}$ and is given by

$$I(\mathbf{r}, t) = \frac{dP(\mathbf{r}, t)}{dA \cos \theta d\Omega} = \frac{dS(\mathbf{r}, t)}{\cos \theta d\Omega} \quad (8)$$

where θ is the angle between $\hat{\mathbf{n}}$ and $\hat{\mathbf{r}}$. The specific intensity expresses the electromagnetic power leaving or intercepting an extended area in a given direction per unit project area in that direction. From Eq. 7, the *radiant intensity* is defined as $R(\mathbf{r}, t) = I(\mathbf{r}, t) dA \cos \theta$ [W sr⁻¹]. It is worth noting that both I and R are spatially invariant. Moreover, each radiation quantity can be considered as being composed by a number of sinusoidal waves or spectral components of frequency between ν and $\nu + d\nu$, each carrying a part of the power flux density. The spectral band over which these different components extend is called *spectral width* or *bandwidth* of the electromagnetic radiation. All radiation quantities have equivalent spectral quantities that correspond to their density per unit frequency (or wavelength) interval $d\nu$.

In random media, the specific intensity $I(\mathbf{r}, t)$ can be statistically related to the Poynting vector $\mathbf{S}$. If the latter at a given point $\mathbf{r}$ is a random function of time and each component of $\mathbf{S}$ varies in time, the tip vector of $\mathbf{S}$ moves randomly in time (Ishimaru, 1978). If this random variability is expressed by a probability density function, we can then define the specific intensity as the *ensemble*

average value of the random vector $\mathbf{S}$. This means that the $I(\mathbf{r}, t)$ is basically the sum of all random Poynting vectors $\mathbf{S}$ whose tips are located within a solid unit angle in the direction.

Electromagnetic radiation information

Electromagnetic radiation is employed in remote sensing as a means to sound and retrieve the features of an object and/or a medium (e.g., Elachi, 1988; Marzano and Visconti, 2002). In this respect, referring from simplicity to Eq. 4 or 5, peculiar features of the electromagnetic wave, perturbed in its interaction with matter, can be exploited:

1. *Amplitude*, described by the modulus of the wave field $|\mathbf{E}(\mathbf{r}, t)|$ or by its power flux density $S(\mathbf{r}, t)$ defined in Eq. 6. The transmitted wave amplitude can be, for example, modulated in order to perform a scatterer detection as in radars and lidars.
2. *Phase*, described by the phase function $\Psi(\mathbf{r}, \omega)$ in Eq. 4. The wave phase can be exploited, for example, by adopting frequency diversity (or multispectral techniques) for medium sounding as in radiometers and spectrometers, by measuring the time delay of the received signal to perform spatial ranging as in radars and lidars, by extracting the frequency shift of the received signal to estimate a scatterer radial velocity as in radars and lidars, by frequency modulating the transmitted signal to perform range profiling as in radars, and by coherently processing the received signal as in synthetic aperture radars.
3. *Polarization*, described by the polarization state vector $\mathbf{E}_0$ in Eq. 5. The wave polarization can be used, for example, by transmitting orthogonal states to detect scatterer shape and orientation as in radars and lidars and by receiving orthogonal states to detect emitter motion as in radiometers.

Some of the previous features of the electromagnetic radiation are analyzed in the following text.

Polarization diversity

An electromagnetic radiation consists of a coupled electric and magnetic force field. An electromagnetic wave that produces an electric field in a fixed plane along the direction of propagation is said to be linearly polarized (Ishimaru, 1991). In general, referring to plane waves for simplicity in Eq. 4, an *elliptically polarized* electrical field $\mathbf{E}(\mathbf{r}, t)$ can be represented, for example, by

$$\mathbf{E}(\mathbf{r}, t) = \text{Re}[e^{j\omega t} (E_{0h} \hat{\mathbf{h}} + E_{0v} \hat{\mathbf{v}}) e^{-j\beta \cdot \mathbf{r}}] \quad (9)$$

where $\hat{\mathbf{h}}$ and $\hat{\mathbf{v}}$ are the unit horizontal and vertical polarization vectors with E_{0h} and E_{0v} their complex amplitudes characterized by a modulus $|E_{0h}|$ and $|E_{0v}|$ and initial phase Ψ_{0h} and Ψ_{0v} , respectively. If $|E_{0h}| = |E_{0v}|$ and $\Delta\Psi_0 = \Psi_{0h} - \Psi_{0v} = \pm 90^\circ$, then the electromagnetic wave is *circularly polarized*; if $|E_{0h}| = 0$ or $|E_{0v}| = 0$ or $\Delta\Psi_0 = 0^\circ$, then the electromagnetic wave is

linearly polarized. The same definitions can be expressed through the related specific intensity by introducing the Stokes intensity vector $\mathbf{I}(\mathbf{r}, t)$ (Ishimaru, 1978).

If the polarization phase difference $\Delta\Psi_0$ is a random function, then the electromagnetic wave radiation does not have any clearly defined polarization and is called *unpolarized*; a typical example is the radiation from natural sources as the sun. In between, when the polarization phase difference $\Delta\Psi_0$ has a deterministic component (average) and random variability (fluctuation), the radiation is said to be *partially polarized*.

Radiation coherency

The wave phase function can be expressed through the *phase velocity*, the velocity at which a constant phase front progresses. From Eq. 4 or 5, putting $d\Psi(\mathbf{r}, \omega) = 0$, the phase velocity v_p is equal to

$$v_p = \frac{\omega}{\beta} \quad (10)$$

The wave phase velocity v_p is equal to the group velocity v_g , equal to $\partial\omega/\partial\beta$, only in case of a nondispersive medium such that ω is proportional to β .

If the medium is dispersive or has a narrow band $\Delta\nu$ around the central frequency ν_0 , then the instantaneous field will be a superposition of spectral components with a frequency between ν_0 and $\nu_0 \pm \Delta\nu/2$, whose random addition will lead to irregular fluctuations of the resultant field. The *coherency time* Δt is defined as the period over which there is a strong correlation of the field amplitude or the time after which two waves at ν and $\nu + \Delta\nu$ are out of phase by one cycle. From the phase function expression in a given point $\mathbf{r}$ and the equality $\omega\Delta t - (\omega + \Delta\omega)\Delta t = 1$, it results as follows:

$$\Delta t = \frac{2\pi}{\Delta\omega} = \frac{1}{\Delta\nu} = \frac{\Delta l}{v_p} \quad (11)$$

where $\Delta\nu$ is the *coherence bandwidth* and Δl is the *correlation length* at a given instant t .

The *wave interference* is a field amplitude effect. If two waves or two sources are coherent with each other, there is a systematic relationship between their instantaneous amplitudes. The amplitude of the resultant field varies between the sum (constructive interference) and the difference (destructive interference) of the two amplitudes. If the two waves are incoherent (i.e., infinite coherence bandwidth), then the correlation between the two waves is zero, and the power of the resultant wave is equal to the sum of the power of the two constituent waves. In general, an electromagnetic radiation will be *partially coherent*, and, if polarized, this will reflect in a partial polarization state.

Doppler effect

If the relative distance between a source radiating at a fixed frequency ν (or a wavelength λ) and an observer

varies, the electromagnetic wave, received by the observer, will have a frequency ν' (or a wavelength λ') different from ν . The difference $\nu_d = \nu - \nu'$ is called *Doppler frequency shift*. If the source–observer distance is decreasing, then $\nu_d > 0$; otherwise it holds $\nu_d < 0$.

The expression of the Doppler shift ν_d can be derived by differentiating the phase function $\Psi(\mathbf{r}, \omega)$ with respect to r so that from Eq. 5 we have as follows:

$$\begin{aligned} \nu_d &\equiv \frac{1}{2\pi} \frac{d\Psi(r, \omega)}{dr} = \pm u_r \frac{\beta}{2\pi} \\ &= \pm \frac{u \cos \theta_d}{\lambda} \\ &= \pm \nu \frac{\mathbf{u} \cdot \hat{\mathbf{r}}}{v_p} \end{aligned} \quad (12)$$

where $\mathbf{u}$ is the observer velocity vector and $\hat{\mathbf{r}}$ is the unit vector of the observer direction with θ_d the angle between $\mathbf{u}$ and $\hat{\mathbf{r}}$ and u_r the projection of $\mathbf{u}$ along $\hat{\mathbf{r}}$. In case of a *monostatic observation*, as in radars, where the observer and the source are collocated and a scattering object is moving, the expression of the Doppler shift ν_d in Eq. 11 must be multiplied by a factor 2 due to the two-way distance traveled by the electromagnetic radiation. It is clear that the Doppler effect can be used to retrieve target motion as in radars, but it is also useful to coherently process synthetic aperture radar signals to achieve very high-resolution imaging.

Radiation generation and detection

Electromagnetic radiation is generated by transformation of energy from other sources such as kinetic, chemical, thermal, electrical, magnetic, or nuclear. Several transformation mechanisms lead to electromagnetic waves over different regions of the electromagnetic spectrum. Generally speaking, the more organized (as opposed to random) the transformation mechanism is, the more coherent (i.e., narrower coherence bandwidth) is the generated radiation.

Electromagnetic fields, depending on the wavelength, can be generated in active remote sensing systems from periodic currents of electron charges in wires, electron beams, antenna surfaces, electron tubes, or molecular excitations followed by decay. The Rayleigh diffraction limit governs the beamwidth of the transmitted radiation such that it increases as the radiator size increases and the wavelength decreases. On the other hand, electromagnetic passive remote sensing systems measure the random emission of electromagnetic waves due to heat energy. The latter is the kinetic energy whose particle random motion results in excitation (electronic, vibrational, or rotational) due to random collisions followed by decay and emission. The transformation of heat energy into radiant energy is governed by the Planck's law.

In order to measure electromagnetic radiation, a collector is generally used followed by a detector. Radiation collectors may be either dipoles or reflectors at radio frequency and microwave frequency, whereas either

focusing lenses or reflectors in case of optical radiation. Detection is usually a transformation of electromagnetic radiation into another form of energy such as heat, electric current, or state change.

RADIATION, GALACTIC, AND COSMIC BACKGROUND

David M. Le Vine

 Space Flight Center, Greenbelt, MD, USA

Definition

Galactic radiation. Electromagnetic radiation whose sources lie primarily within our galaxy.
Cosmic background. Radiation associated with the origin of the universe (“big bang”).

Introduction

Stars and other celestial objects outside our solar system contribute radiation that can be important for Earth remote sensing. In many directions, this radiation is small. In fact, for many applications the “heavens” are used as a cold reference source (“cold sky”). However, this radiation can also be strong enough to require compensation as an unwanted background signal. For example, this is the case

in remote sensing of ocean salinity which is done at 1.4 GHz in the window set aside for radio astronomy applications. This background radiation can impact remote sensing of the Earth either as radiation directly to the sensor or as downwelling radiation that is reflected from the Earth surface to the sensor, and taking it into account can be complex because there are many sources of this celestial radiation both localized (discrete) and distributed in space.

Sources of radiation

There are three important categories of radiation that originate outside our solar system. These are the cosmic microwave background (CMB), line emission, and continuum emission such as is emitted by thermal sources.

Cosmic microwave background

The cosmic microwave background radiation is a remnant of the origin of the universe in a “big bang.” It appears as a uniform (same in all directions) thermal source with an effective brightness temperature of 2.73 K. Although recent cosmological research has focused on the details of its spatial distribution, these variations (milli-Kelvin) are not important for most applications to remote sensing of the Earth. For microwave remote sensing applications, the cosmic background radiation is essentially constant in both space and time. This radiation can contribute to a measurement of an Earth-viewing sensor such as a radiometer observing the surface in a direct manner, for example, by entering through antenna side lobes in directions above the horizon. It also can contribute indirectly via reflection of downwelling radiation that is reflected off the surface (Blume and Kendall, 1982). The latter is especially important in remote sensing of targets such as the ocean surface where the reflection coefficient is relatively large and where applications such as monitoring sea surface salinity require high accuracy.

Line emission

Line emission is the radiation from matter associated with transitions in its atomic structure from one energy state to another with lower energy. The radiation tends to be relatively narrow in bandwidth (e.g., associated with a specific transition energy).

An example is the emission from a hyperfine transition in neutral hydrogen that occurs at 1.413 GHz. A window of the spectrum around this line (1.40–1.427 GHz) has been protected for passive measurements so that radio astronomers could use this radiation to monitor the distribution of hydrogen in the galaxy. This radiation provides information on the temperature, density, and motion of hydrogen. The radiation is concentrated around the plane of the galaxy, but clouds of hydrogen are widespread and no direction is observed without some such radiation.

Figure 1 shows the distribution of this radiation in celestial coordinates (an inertial coordinate system in which declination corresponds to latitude and right

Radiation, Galactic, and Cosmic Background, Figure 1 The equivalent brightness temperature of line emission from hydrogen at 1.413 GHz.

ascension corresponds to longitude referenced to a fixed time, defined by the “epoch”). The distribution of hydrogen lies largely in the plane of the galaxy. The distribution appears to have a U shape in celestial coordinates because the plane of the galaxy and the equatorial plane of the Earth, which is a reference plane in celestial coordinates, are tilted with respect to each other.

The data shown in [Figure 1](#) is a composite of two relatively recent radio astronomy surveys: (a) the Leiden/Dwingeloo survey by Hartmann and Burton (1997) which used the 25 m Dwingeloo radio telescope and covered the northern sky down to a declination of -30° , and (b) the IAR survey with the 30 m antenna at the Instituto Argentino de Radioastronomía (IAR) and reported by Arnal et al. (2000) which covered declinations south of -25° filling in the portions of the southern sky missing in the earlier survey. The result of the two surveys is data over the entire celestial sphere with spatial resolution of $0.5^\circ \times 0.5^\circ$ and good radiometric resolution ($\Delta T < 0.1$ K).

The data from these two surveys are plotted in [Figure 1](#) in the form of an equivalent brightness temperature. This is the temperature that a blackbody would have if it radiated the same power but distributed over a bandwidth of 20 MHz (Le Vine and Abraham, 2004). Any bandwidth could have been chosen, but 20 MHz is representative of the bandwidth of radiometers operating in the radio astronomy window at L-band.

Line emission provides a valuable tool in radio astronomy, and many spectral “windows” have been set aside for radio astronomy applications. For example, see the spectrum allocation chart at the National Telecommunications and Information Administration (NTIA, 2009).

Continuum radiation

In addition to radiation with discrete spectra associated with atomic transitions, objects in the celestial sky emit

radiation with a continuous spectrum. The two dominant sources of this radiation are synchrotron radiation (radiation from accelerated relativistic electrons) and thermal radiation (radiation from a random collection of charged particles in motion). The latter has a spectrum given by Planck’s radiation law. The strongest sources of continuum radiation tend to lie in the plane of the galaxy and may be diffuse or discrete. Examples of discrete sources of synchrotron radiation, and among the strongest radio sources in the sky, are Cassiopeia A and the extragalactic source Cygnus A. The Orion Nebula is an example of a source of thermal radiation (Kraus, 1986). [Figure 2](#) shows the location of the strongest discrete sources together with their flux at 1.4 GHz in Jansky ($\text{W m}^{-2} \text{Hz}^{-1}$). (See Sect. 2.01.01.02 for a definition of flux.) The plot is in celestial coordinates and the solid line represents the plane of the galaxy. It is clear that most of the strong sources lie close to the plane of the galaxy.

[Figure 3](#) shows a map of the continuum radiation at L-band. As in [Figure 1](#), the data is presented as the equivalent temperature of a blackbody with a bandwidth of 20 MHz centered at 1.413 GHz (Le Vine and Abraham, 2004). This map is a composite of two recent “all-sky” surveys of the continuum radiation at this frequency. The first was a survey with the Stockert telescope at Bonn University (Reich, 1982; Reich and Reich, 1986). The Stockert survey covered all of the northern sky and the southern sky to -19° declination. The data includes all sources except for a region around Cassiopeia A which was too strong for receivers used in this survey. The survey of the southern sky was completed using the 30 m radio telescope of the Instituto Argentino de Radioastronomía (Reich et al., 2001; Testori et al., 2001). The IAR continuum survey covers the southern sky for declination below -10° with spatial resolution and sensitivity similar to that of the Stockert survey. The composite map has a resolution of about $0.5^\circ \times 0.5^\circ$, an absolute accuracy of about 0.5 K, and a sensitivity of 0.05 K (rms error).

Notice the different scales on [Figures 1](#) and [3](#). The continuum radiation is significantly stronger than the line emission when spread over a 20 MHz bandwidth. Also, notice that again the radiation generally follows the plane of the galaxy.

[Figure 3](#) represents the radiation from all sources (e.g., distributed and discrete). Comparing with [Figure 2](#) many of the strongest discrete sources can be identified in [Figure 3](#). They would be easily identified if the data were plotted with higher resolution. [Figure 4](#) is an example. At the top is shown a section of [Figure 3](#) in the vicinity of Cygnus A plotted with higher resolution. Cygnus A is identified by the circle. The insert at the bottom of [Figure 4](#) is a plot of the same data but in three dimensions (vertical dimension is brightness temperature), to give an idea of the relative magnitude and size of Cygnus A. Cygnus A is a distant extragalactic object. The peak in radiation to the right of Cygnus A originates in the galaxy and corresponds to a line of sight along one of the spiral arms of the galaxy (Kraus, 1986).

Radiation, Galactic, and Cosmic Background, Figure 2 Celestial position of strong radio sources. The solid line indicates the galactic plane.

Radiation, Galactic, and Cosmic Background, Figure 3 The continuum radiation at L-band (1.413 GHz). This is a composite of the Stockert and IAR surveys.

Radiation at other frequencies

The data presented in Figures 1 and 3 at L-band is available with a resolution of 0.5° at the Aquarius project website (Aquarius). The website includes explanations and references to the original surveys. Additional background can be found in Le Vine and Abraham (2004).

It would be convenient if the maps at L-band could be extrapolated to other frequencies. There are obvious problems. Clearly the line emission will be different for each frequency. The continuum data (Figure 3) could be extrapolated if the spectral shape were known. For example, if the source were thermal, with a fixed temperature, the radiated power would be described by the Rayleigh-Jeans approximation (i.e., vary as f^2). Unfortunately, there are many processes responsible for the observed radiation, and for most sources the radiated power decreases with frequency (Kraus, 1986). Reich and Reich (1988) used the survey described above (1.4 GHz) and an all-sky survey at 480 MHz (Haslam et al., 1982) to compute an index, β , for brightness temperature ($T_B \sim f^{-\beta}$). They obtained values of $2.3 < \beta < 3.0$ with most values around $\beta = 2.7$. Whether or not this can be used to reliably scale the L-band data needs to be verified by comparison with measurements.

Summary

Radiation from outside of our solar system can impact an Earth-viewing sensor either as direct radiation or radiation reflected from the Earth surface to the sensor. In the microwave part of the spectrum, there are three important categories of this radiation: the cosmic microwave background (a uniform thermal source at 2.73 K), line emission, and continuum emission. The hydrogen line at 1.413 GHz (L-band) is an example of line emission, and

Radiation, Galactic, and Cosmic Background, Figure 4 Top: expanded section of Figure 2 in the vicinity of Cygnus A. Bottom: the data at the top plotted in three dimensions.

synchrotron emission is an example of continuum emission. Strong radio sources tend to be concentrated near the plane of the galaxy.

Definition

Multiple scattering is an effect due to propagation of waves through a medium characterized by a random distribution of discrete scatterers, usually embedded in a continuum medium. The random distribution may be due to the size probability distribution of the scatterer polydispersion, their orientation, and their relative motion, whereas scatterers may be particles, objects, or medium spatial irregularities.

Introduction

The propagation of waves through a medium characterized by a random distribution of discrete scatterers, usually embedded in a continuum medium, is usually characterized by multiple scattering. This effect is strongly dependent on the ratio between the scatterer average size and the wavelength. Examples of such media, where multiple scattering may happen, are hydrometeors and aerosols in atmosphere; leaves, branches, and trunks in forests; ice-air irregularities in snow packs; air bubbles and fishes in oceans; and cellular structures and blood cells in biology. The multiple scattering effect can be macroscopically referred to either electromagnetic waves or acoustic waves.

Multiple scattering and radiative transfer

In order to identify multiple scattering effects, it is customary to distinguish between two extreme cases: *sparse* and *dense random distribution* of particles. This distinction can be first evaluated by quantifying the fractional volume occupied by the ensemble of particles: in case it is less than few tenths percent, then we deal with *sparse distribution* of particles, whereas a fraction volume larger than few percent represents *dense distribution* of particles.

Intermediate cases may be generally labeled as *rarefied distribution* of particles.

Indeed, more rigorously, the distinction of the random distribution regime should be made on the basis of the optical distance and the albedo of particle distribution which express, respectively, the properties of medium extinction and geometrical extension and scattering efficiency with respect to total extinction (equal to the sum of absorption and scattering). Both medium optical distance and albedo depend on the wavelength, scatterer size, composition, and orientation, as well as on the transmitter and receiver characteristics. When the medium optical thickness is low, the medium is said to be *tenuous*, otherwise *non-tenuous*.

In this respect, it is convenient to adopt the *radiative transfer theory* as a general framework to describe both absorption and scattering of wave propagation through a random medium with discrete scatterers and then distinguish among its various approximations. A fairly general expression of the radiative transfer equation (RTE), for the unpolarized diffuse specific intensity $I_d(\mathbf{r}, \hat{\mathbf{s}})$ ($\text{W m}^{-2} \text{sr}^{-1} \text{Hz}^{-1}$) and under the basic assumption of *independent wave scattering* from each scatterer, is given by Tsang et al. (1985) and Ishimaru (1997):

$$\frac{dI_d(\mathbf{r}, \hat{\mathbf{s}})}{d\tau} = -I_d(\mathbf{r}, \hat{\mathbf{s}}) + \frac{w(\mathbf{r})}{4\pi} \times \int_{4\pi} p(\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}') I_d(\mathbf{r}, \hat{\mathbf{s}}) d\Omega' + J(\mathbf{r}, \hat{\mathbf{s}}) \quad (1)$$

where τ is the medium optical thickness or distance (product of the distance ds and extinction coefficient k_e), $\mathbf{r}$ is the position vector and $\hat{\mathbf{s}}$ is the direction unit vector, w is the albedo (ratio between medium scattering coefficient k_s and extinction coefficient k_e), p is the scattering phase function, Ω is the solid angle, and J is the source function due to *source intensity* in the form of either medium thermal emission or attenuated incident wave (or reduced specific intensity). The total intensity $I(\mathbf{r}, \hat{\mathbf{s}})$ is given by the sum of the diffuse specific intensity $I_d(\mathbf{r}, \hat{\mathbf{s}})$ and the coherent one $I_c(\mathbf{r}, \hat{\mathbf{s}})$.

The RTE describes the spatial differential variation of the specific intensity which is decreased by extinction (first term on the right side), increased by the multiple scattering mechanism (first term on the right side, often called *pseudo-source function*), and increased by the emitted and incident radiation (third term on the right side). Thus, the analysis of the RTE indicates that multiple scattering is an effect which tends to recover radiation due to double, triple, etc., order of scattering of the radiation itself (Marzano and Roberti, 2003).

Wave scattering from random distribution of particles

The radiative transfer framework can provide a useful way to distinguish among the various random distribution

Radiation, Multiple Scattering, Figure 1 Schematic view of multiple scattering regimes: (1) single scattering, (2) first-order multiple scattering, (3) multiple scattering, and (4) diffusive scattering. TX stands for radiation transmitter (or source) and RX for receiver. Particles are drawn as circles, and dashed lines stand for scattered waves (and when bold, it means that they are also attenuated), whereas continuous lines denote direct wave (and when bold, it means that they are also attenuated).

scenarios. A schematic view of the basic multiple scattering mechanisms is shown in Figure 1.

In case of a *sparse tenuous random distribution*, we can use the so-called single scattering approximation where the incident wave, irradiated by the transmitter, reaches the receiver after encountering very few particles. In this case, the scattered wave is assumed to be due to a single scattering by a particle and all higher-order scattering are considered to be negligible. This means that the optical thickness is much than one, and the specific intensity in the multiple scattering term of Equation 1 is approximated by the source-specific intensity. The “single scattering” approximation can be adopted in many environmental applications such as weather radars in case of electromagnetic waves and ocean acoustics in case of acoustic waves (e.g., Tsang et al., 1985; Stephens, 1970).

If the particle density is increased but can be still considered a sparse distribution, it is needed to take into account both absorption and scattering along the path. This implies to deal with a *sparse non-tenuous random distribution* of scatterers. In this case, the scattered wave is scattered once by a particle, but both the incident and scattered waves have likewise been attenuated. This means that the optical thickness is not negligible and the specific intensity in the multiple scattering term of Equation 1 is still approximated by the source-specific intensity. This approximation is very often called *first-order multiple scattering* in order to point out that some of the multiple scattering is taken into consideration. Microwave extinction due to rain and optical extinction due to aerosols, for example, have been extensively studied using this approximation (e.g., Klett, 1981; Marzano and Ferrauto, 2003).

When the particle density is such that a *dense tenuous distribution* is considered, we cannot disregard any more severe multiple scattering effects even though independent scattering from each particle is still assumed. This problem can be described by the so-called diffusive

scattering (or diffusion approximation), where the scattered wave is almost uniformly diffracted in all directions. When the scattering is angularly uniform, diffusive scattering is called *isotropic scattering*. The latter corresponds to a constant scattering phase function p in Equation 1. This approximation has been successfully applied, for example, in the analysis of optical fiber oximeter of blood (e.g., Johnson and Guy, 1972).

When neither *first-order multiple scattering* nor *diffusive scattering* can be applied, we need to deal with a general random distribution of particles whose fractional volume is around 1 % typically. Such distributions may be classified as *rarefied non-tenuous media*. This means that the independent wave scattering is still valid and the problem needs to be solved resorting to the complete integrodifferential expression of the RTE, given in Equation 1. In this case, not only all order of multiple scattering and absorption effects must be considered but also the scattered wave is angularly not uniform. These applications range, for example, from microwave radiometry of clouds and precipitation to radar meteorology and microwave scattering from vegetated canopies (e.g., Ishimaru and Cheung, 1980; Ferrazzoli and Guerriero, 1996; Marzano et al., 2003; Marzano, 2007).

Problems dealing with *dense non-tenuous distribution media*, where the spatial correlation of particle wave scattering is not negligible, cannot be approached by means of the RTE model (Tsang and Ishimaru, 1987). The lack of the independent scattering assumption prompts to face the *analytical theory of multiple scattering*.

Analytical theory of multiple scattering

As already mentioned, the radiative transfer theory describes the power intensity balance of the transmission, absorption, and scattering processes and is heuristically derived from considerations on energy conservation, as apparent in Equation 2.

The same problem can be cast in terms of field quantities and their statistical characterization. When this approach is followed, we can refer to the *analytical theory of multiple scattering* (or multiple scattering theory), whose general formulation is well summarized by the integral equation set of Twersky-Foldy (Twersky, 1964; Ishimaru, 1997).

The *analytical theory of multiple scattering* generally starts from the Maxwell wave equation of a scalar field $\Psi(\mathbf{r})$, which can represent either a component of the electric or magnetic field or a pressure wave and describes the various processes of multiple scattering in a detailed way, usually resorting to the concise formalism of the diagram method. The general result of it is that the total field $\Psi(\mathbf{r})$ is composed by the following: (1) the incident wave, (2) multiply scattered waves involving chains of successive scattering through different scatterers, and (3) multiply scattered waves containing all the paths which go through a scatterer more than once. This general picture is consistent with that schematically shown in Figure 1. The *Twersky theory* adopts the so-called expanded representation which retains only the previous groups (1) and (2) but disregards the effects due to group (3). When the number of scattering events becomes large, the errors associated with the Twersky approximation become very small.

Starting from the Twersky expanded representation, it is then possible to provide a statistical description of the random field $\Psi(\mathbf{r})$, distinguishing between the coherent (or average) field $\Psi_c(\mathbf{r})$ and the diffuse (also incoherent or fluctuating) field $\Psi_d(\mathbf{r})$:

$$\Psi(\mathbf{r}) = \Psi_c(\mathbf{r}) + \Psi_d(\mathbf{r}) \quad (2)$$

where $\Psi_c(\mathbf{r}) = \langle \Psi(\mathbf{r}) \rangle$ and $\langle \Psi_d(\mathbf{r}) \rangle = 0$ with the angle brackets indicating ensemble average. It can be shown that the total field intensity $\langle |\Psi(\mathbf{r})|^2 \rangle$, which can be decomposed into the sum of coherent intensity $|\langle \Psi(\mathbf{r}) \rangle|^2$ and diffusive intensity $\langle |\Psi_d(\mathbf{r})|^2 \rangle$ from Equation 2, satisfies the so-called Twersky-Foldy integral equations. The latter are, in their turn, consistent with the first-order smoothing approximation of the more rigorous Dyson and Bethe-Salpeter equations (e.g., Furutsu, 1975).

Considering that the RTE in Equation 1 and the Twersky-Foldy integral equations describe the same multiple scattering phenomenon, even though from two different points of view, a link between the two theories is expected (Ishimaru, 1975). Indeed, if $\Gamma_\Psi(\mathbf{r}, \Delta\mathbf{r})$ is the correlation function (or mutual coherence function) of the random field $\Psi(\mathbf{r})$ in a given position $\mathbf{r}$ and at a distance $\Delta\mathbf{r}$, it can be shown that it holds the following approximate equality (Furutsu, 1975):

$$\Gamma_\Psi(\mathbf{r}, 0) = \langle |\Psi(\mathbf{r})|^2 \rangle \cong \int_{4\pi} I(\mathbf{r}, \hat{\mathbf{s}}) d\Omega \quad (3)$$

The previous relation indicates that the angular integral of the total specific intensity I (i.e., the radiation intensity)

is intensity $\langle |\Psi(\mathbf{r})|^2 \rangle$. Equation 3 can be generalized showing that the field correlation function Γ_Ψ is related to the Fourier transform of the specific intensity I . It shows that the description of multiple scattering effects, based on the radiative transfer theory, does include information concerning the field quantities in the form of mutual coherence function (Ishimaru, 1997).

In a dense non-tenuous medium, the assumption of independent scattering, which is often used in conventional radiative transfer theory, is not valid (Tsang and Ishimaru, 1987). In the ladder approximation of correlated scatterers, wave interactions between different particles (whether of far, near, or intermediate range) are weighted by the pair distribution function of particle positions; therefore, the wave interactions of all ranges of distance separation are included. The extinction rate, albedo, and phase matrix of the dense medium radiative transfer equation are expressed in terms of the physical parameters of the medium. The dense medium radiative transfer equation takes the following into account: (a) the scattering by correlated scatterers, (b) the pair distribution function of scatterer positions, and (c) the effective propagation constant of a dense medium. In particular, for volume fractions higher than 10 %, the quasicrystalline approximation has shown to be effective solutions when coupled either with the Percus-Yevick pair correlation function or with the coherent potential approximation (Tsang et al., 1985).

RADIATION, POLARIZATION, AND COHERENCE

Yang Du
Zhejiang University, Hangzhou, People's Republic of China

Definition

Radiation. The process of electromagnetic energy propagation from the source.

Polarization. A property of electromagnetic waves to describe the orientation of their oscillations.

Coherence. A property of electromagnetic waves that enables stationary interference.

Radiation

Radiation of energy characterizes a source in an unbounded space. To illustrate the radiation mechanisms and the dependence of the radiation on the source, first consider the case of a single wire, where there is no radiation if a charge is not moving or charge is moving with uniform velocity along a straight and infinite wire, whereas there is radiation if the wire is deformed in certain ways (curved, bent, truncated, discontinuous) or charge is oscillating (Balanis, 1997). Next consider another simple case of current I forming an electric dipole of moment Il by extending over an incremental length l , the results of which can be readily extended to general source distributions. For simplicity, current element is placed at origin and directed in the z direction. The magnetic

Radiation, Polarization, and Coherence, Figure 1 The magnitude of the radiated field $|E_\theta|$ as a function of θ .

vector potential, having its rectangular components corresponding to those of sources, is z directed. The vector Helmholtz equation governing the magnetic vector potential is reduced to a scalar one governing the z component of the magnetic vector potential. The solution is simply $A_z = \frac{Il}{4\pi r} e^{ikr}$. The electric and magnetic fields can be readily obtained from the magnetic vector potential (Harrington, 1961). The electromagnetic fields behave very differently as the observation point moves away from the source. For the case that the source dimension l is very small compared to the wavelength λ , three spatial regions can be classified:

- The near zone (static), if $l \ll r \ll \lambda$
- The intermediate zone (induction), if $l \ll r \sim \lambda$
- The far zone (radiation), if $r \gg \lambda$

In the radiation zone, the fields fall off as r^{-1} and are transverse to the radial direction (Jackson, 1998). The radiation field is depicted in Figure 1, where the magnitude of $|E_\theta|$ as a function of θ is shown.

For general current source $\mathbf{J}(\mathbf{r}, \omega)$, the magnetic vector potential is obtained through the Green's function. In characterizing radiated fields in the far zone, if the source dimensions are small compared to the wavelength, Taylor series expansion of the exponential factor of the integrand can be performed, with each term in the series attaining certain physical interpretation, such as electric dipole, magnetic dipole, and electric quadrupole, for the first few terms. A more systematic treatment can be carried out by means of multipole expansion (Jackson, 1998). According to the wavelength, a diagram of the electromagnetic spectrum is shown in Figure 2.

Polarization

Polarization is a property of electromagnetic waves to describe the orientation of their oscillations. Polarization may be helpful in understanding the physics of some elusive phenomena. For example, the sources of the gamma-ray bursts (GRBs) remain a mystery albeit they are known to locate in distant galaxies. The detection of polarization may provide clues on the sources' identities and on the gamma-ray-generating mechanism (Waxman, 2003).

Radiation, Polarization, and Coherence, Figure 2 Electromagnetic wave spectrum (Source: J.A. Kong, *Electromagnetic Wave Theory*, EMW Publishing, Cambridge, MA, 2005. Reprinted with permission of J.A. Kong).

For a plane wave, the polarization at a fixed point of space is associated with the time variation of the tip of the electric field vector in a plane perpendicular to the direction of propagation. If the two mutually orthogonal components of the electric vector in the plane have the same or opposite phases, then the tip moves along a straight line and the wave is linearly polarized. If the two components have different phases, the locus of the tip is, in general, an ellipse and the wave is elliptically

polarized, except the special case when the magnitudes of the two components are the same and the phase difference is $\pm 90^\circ$, the locus of the tip is a circle, and the wave is circularly polarized. Furthermore, for an elliptically or circularly polarized wave, if the right-hand thumb points to the propagation direction and the fingers are along the tip sweeping direction, the wave is right-hand polarized; otherwise, it is left-hand polarized (Jackson, 1998; Kong, 2005). These polarizations are sketched in Figure 3.

Radiation, Polarization, and Coherence, Figure 3 Sketch of polarizations (Source: J.A. Kong, *Electromagnetic Wave Theory*, EMW Publishing, Cambridge, MA, 2005. Reprinted with permission of J.A. Kong).

To determine the state of polarization of a plane wave from observations, the four Stokes parameters are useful. These parameters, being quadratic in fields, allow for mere intensity measurements. If the electric field is written as $\mathbf{E}(t) = \hat{h}E_h + \hat{v}E_v$, where $\hat{h}$ and $\hat{v}$ are mutually orthogonal unit vectors perpendicular to the direction of propagation, the four Stokes parameters are defined as

$$\begin{bmatrix} I \\ Q \\ U \\ V \end{bmatrix} = \frac{1}{\eta} \begin{bmatrix} |E_v|^2 + |E_h|^2 \\ |E_v|^2 - |E_h|^2 \\ 2 \operatorname{Re}(E_v E_h^*) \\ 2 \operatorname{Im}(E_v E_h^*) \end{bmatrix},$$

where η is the wave impedance of the medium, superscript asterisk refers to conjugate operation, and

$\operatorname{Re}()$ and $\operatorname{Im}()$ refer to real and imaginary parts (Tsang et al., 1985; Kong, 2005).

In the above the concept of full polarization is applied to monochromatic field. Actually, monochromaticity is not a necessary condition for the field to be fully polarized. The requirement is that the ratio of two mutually orthogonal components of the electric field perpendicular to the propagation direction is constant (Mandel and Wolf, 1995).

In the case of random electromagnetic fields, the concept of polarization is closely related to the concept of correlation between components of the electromagnetic fields, just as is the concept of coherence. For this reason, we defer the description of polarization to the coherence subsection so as to bring forth an integrated treatment.

Coherence

Coherence is a property of electromagnetic waves that enables stationary interference (e.g., as those patterns observed in the famous Young's slit interference experiment). More generally, coherence describes all correlation properties between physical quantities of a wave.

Temporal coherence between two electromagnetic fields refers to the capability of producing interference fringes in an interferometer (e.g., Michelson interferometer for lights) even if a time delay is introduced between them. A measure of the temporal coherence is the coherent time, which is approximately the reciprocity of the effective bandwidth of the field (Mandel and Wolf, 1965).

The electromagnetic fields may be generated by random sources and become random fields. At times, the resultant randomness is beneficial to the specific application. For instance, light beams generated by sources that are partially coherent are useful in the reduction of speckle in optical systems. If the fields are generated by a Gaussian random process such as thermal sources, for example, incandescent matter, then the second-order tensors, such as the concept of correlation between the fields at two space-time points and the governing dynamic laws, are adequate for the description of fields. The concepts of coherence and polarization can attain their respective meaning in terms of the concept of correlation.

The 2×2 electric cross-spectral tensor of the field is defined as the correlation between the components perpendicular to the propagation direction of electric fields at two positions. The coherence matrix at some point is determined by making the two positions identical in the electric cross-spectral tensor. The degree of polarization and degree of coherence can be subsequently defined. The former is defined as the square root of one minus four times the determinant of the coherence matrix divided by squared value of the trace of the coherence matrix, while the latter is defined as the ratio of the trace of the electric cross-spectral tensor over the square root of the product of the traces of the electric cross-spectral tensor specified at each point (James, 1994; Wolf, 2003; Ellis et al., 2004).

The dynamics of polarization and coherence of random electromagnetic fields can be quite different from their

deterministic counterparts. For the simple case of a partially coherent, partially polarized light beam that propagates along the same axis, analytical results show that the degree of polarization of the light beam changes as the beam propagates in free space (James, 1994). This observation is contrary to the assumption about the invariance of the state of polarization of a light beam propagating in free space. In fact, the quantities that change are not limited to the state of polarization; the state of coherence changes as well. Moreover, these coherence and polarization properties can be characterized for an electromagnetic beam propagating in free space as well as in linear media. In the latter case, the media can be deterministic or random (Wolf, 2003).

However, the issue of inclusion of the vectorial character of electromagnetic waves in defining coherence is complex and delicate. There are alternative definitions of the degree of coherence (Tervo et al., 2003; Setälä et al., 2004). Searching for the right form of the degree of coherence is an ongoing endeavor (Luis, 2007).

Meanwhile, there are voices that advocate a more comprehensive treatment by arguing that magnetic field and magnetic coherence are important for tightly focused electromagnetic waves and magnetic interactions in semiconductor quantum dots. Extension of electric coherence to magnetic coherence, and connection between these two coherences in free electromagnetic fields, is proposed (Jouttenus et al., 2005).

There are also other issues to deal with. The above descriptions are based on the assumption that the random electromagnetic fields are generated by Gaussian random process. However, there are fields that are generated by non-Gaussian random process, as evident in some important experiments of Hanbury Brown and Twiss, and in optics with the development of some new types of light source, for example, the Smith-Purcell radiator and the optical maser. In these cases, correlation phenomena need to be readdressed (Mandel and Wolf, 1965).

Summary

Radiation of energy characterizes a source in an unbounded space. In the radiation zone, the fields fall off as the reciprocity of distance from the source and are transverse to the radial direction. Polarization is a property of electromagnetic waves to describe the orientation of their oscillations. Coherence is a property of electromagnetic waves that enables stationary interference. In the case of random electromagnetic fields, the concepts of polarization and coherence are closely related to the concept of correlation between components of the electromagnetic fields.

RADIATION, SOLAR AND LUNAR

David M. Le Vine

Code 615, Cryospheric Sciences Branch, NASA/Goddard Space Flight Center, Greenbelt, MD, USA

Definition

Solar Radiation: electromagnetic radiation emanating from the Sun with emphasis on microwaves.

Lunar Radiation: electromagnetic radiation from the Moon with emphasis on thermal emission in the microwave portion of the spectrum.

Solar radiation

Introduction

The Sun is a relatively typical star located about two thirds of the galactic radius from the center of the spiral (Aarons, 1965; Chap. 1). To a first approximation, the Sun has an effective temperature of about 5,800 K. This is the temperature of a thermal source with the same total flux (3.9×10^{26} W). At this temperature, the radiation peak is in the visible portion of the spectrum ($\lambda = 470$ nm).

However, the Sun is a dynamic structure that does not meet the conditions for thermal equilibrium, and there are considerable departures from this behavior, for example, in the UV (Aarons, 1965; Chap. 1) and in the microwave portion of the spectrum at wavelengths greater than about 1 cm (Kraus, 1966; Chap. 8.7). The level of radiation in the microwave portion of the spectrum follows the 11 year solar cycle associated with the number of sunspots and can reach extreme levels for brief periods associated with solar flares. For example, at 1.4 GHz, the effective temperature can range from 5×10^5 at solar minimum to more than 10^6 K near solar maximum, and the radiation can reach even higher levels during brief periods associated with solar flares (short-lived events associated with sudden brightening of a limited region on the solar disk). The discussion below focuses on the behavior in the microwave portion of the spectrum.

Terminology

Radiation from the Sun is commonly described in terms of “solar flux,” F_λ . The solar flux is the power density (W/m^2) incident at a given frequency (Hertz) integrated over the solar disk. Since the solar disk is small and assuming a mean value for the brightness ($\text{Wm}^{-2} \text{Hz}^{-1} \text{sr}^{-1}$), the solar flux is approximately

$$F_\lambda = B_{\text{sun}} \Omega_{\text{sun}} \quad (1)$$

where B_{sun} is the mean brightness and Ω_{sun} is the solid angle (steradians) of the Sun as seen from the Earth: $\Omega_{\text{sun}} = 2\pi[1 - \cos(\theta_{\text{sun}})] = 8.22 \times 10^{-5}$ sr. In this expression, θ_{sun} is the angular radius of the Sun as viewed from the Earth. The angular radius depends on wavelength and the physics generating the radiation. At 21 cm (1.4 GHz), $\theta_{\text{sun}} \approx 0.293^\circ$ which is about 10 % greater than the optical angular radius (Aarons, 1965; Chap. 3). The integral over space and frequency (called “luminosity”) is about 3.9×10^{16} W but this is dominated by radiation in the optical and nearby portions of the spectrum.

Values of F_λ expressed in solar flux units, sfu ($1 \text{ sfu} = 10^{-22} \text{ Wm}^{-2} \text{Hz}^{-1}$), are available at various radio wavelengths from ground stations around the world that monitor the Sun daily. Among these are the observatories in the Radio Solar Telescope Network (RSTN) operated by the US Air Weather Service (Sagamore Hill, 42 °N, 71 °W; Learmonth, Australia 22 °S, 114 E; Palehua, Hawaii 21 °N, 158 °W; and San Vito, Italy 41 °N, 18 E). Data from the RSTN can be obtained through the National Geophysical Data Center at Boulder, Colorado (NGDC website).

The radiation in solar flux units can be converted into an equivalent blackbody temperature by assuming that the Sun is a uniform thermal source (blackbody) and using the Rayleigh-Jeans approximation to the Planck radiation law for radio frequencies (Kraus, 1966 Chap. 3.9; Ulaby et al., 1981 Chap. 4.3). In this case, the relationship between the equivalent temperature, T_{sun} , and the solar flux, F_λ , is

$$T_{\text{sun}} = [\lambda^2/2k]B_{\text{sun}} \approx .00044\lambda^2F_\lambda \quad (2)$$

where k is the Boltzmann constant, λ is in meters, F_λ is in solar flux units, and T_{sun} is in Kelvin.

Characteristics

Radiation from the Sun follows the 11 year sunspot cycle, being relatively low during solar minimum (quiet Sun) and large and variable during solar maximum. It is convenient to separate radio emission from the Sun into two categories on the basis of their characteristic scale of temporal variation (Kraus, 1966, Chap. 8.7)

$$T_{\text{sun}}(t) = T_S(t) + T_R(t) \quad (3)$$

T_S is a slowly varying component (timescale of hours to days) which consists of two parts: (a) a relatively stable background level associated with the quiet Sun (solar minimum) that is largely due to thermal radiation from the hot plasma in the atmosphere of the Sun and (b) superimposed on this is a varying component that correlates with number of sunspots. The latter component changes irregularly with an amplitude that varies with the 11 year solar cycle (small at solar minima and large at solar maxima). Figure 1 shows the T_S component of the solar flux at 1.4 GHz measured at the Sagamore Hill solar observatory (these data are available from the NGDC website). The daily value of flux measured at local noon is plotted in sfu for the period 1980–2004 which includes the peak of three solar cycles. Figure 2 displays data for a period of 1 year with higher temporal resolution. The blue curve is for a minimum in the solar cycle (1986) and the red curve (1989) is near the maximum of the same solar cycle.

T_R is a rapidly varying component (seconds to minutes in duration) and is associated with flares and other transient activity on the Sun. Solar flares occur due to a sudden release of magnetic energy in the solar

Radiation, Solar and Lunar, Figure 1 Solar flux at 1.4 GHz at noon from Sagamore Hill (Le Vine et al., 2005).

Radiation, Solar and Lunar, Figure 2 Solar flux at 1.4 GHz at noon. High solar activity (1989, red) and low solar activity (1986, blue) (Data are from Sagamore Hill; Le Vine et al., 2005).

atmosphere and their frequency varies with the 11 year solar cycle. During periods of low solar activity, few solar flares are detected but there can be thousands during periods of high solar activity. Not all flares are associated with an enhancement of radiation at microwave frequencies. When such enhancements occur, they are called solar microwave bursts (SMB). Over the range 1–18 GHz, the spectrum of this radiation has a characteristic shape with a double peak at the low frequency end (1–2 GHz) and then a gradual decrease with frequency. A worldwide network of observing stations reports the SMB. Stations in the Radio Solar Telescope Network (RSTN) observe at 1 s intervals at eight frequencies in the microwave range 1–15 GHz. Bursts are reported at these stations only when flux exceeds 50 sfu. The Owens Valley Solar Array (OVSA) records solar flares with lower thresholds (OVSA website). An example of the distribution of peak amplitude and duration at 1.4 GHz is shown in Figure 3 (Le Vine et al., 2005).

Lunar radiation

The Moon is a source of both thermal emission and reflected solar radiation. At radio frequencies (e.g., microwave portion of the spectrum and longer wavelengths), the reflected solar radio emission is negligibly small compared to the thermal emission (Mayer, 1964). This is in contrast to optical frequencies, where reflected solar radiation is the dominant contribution (Evans, 1961).

Thermal emission from the Moon at radio frequencies was first reported by Dicke and Beringer (1946) and by Piddington and Minnett (1949). The source is believed to be the heating of lunar regolith due to solar radiation. Piddington and Minnett (1949) demonstrated a

dependence on lunar phase at 1.25 cm, but the dependence on phase decreases with increasing wavelength and the radiation is nearly independent of lunar phase at 21 cm (Hagfors, 1970).

The effective temperature of the Moon for thermal radiation depends on frequency. In the infrared, the temperature depends on the solar illumination and varies from about 400 K when the Moon is illuminated by the Sun (day time) to about 100 K at night (Hagfors, 1970). In the microwave portion of the spectrum, the dependence on lunar phase decreases from a change on the order of ± 115 K at 0.1 cm to negligible variation at 21 cm (Hagfors, 1970). The effective temperature for thermal emission in this portion of the spectrum is somewhat uncertain, ranging from about 200 to 275 K depending on the investigator, but the value is relatively independent of frequency (Hagfors, 1970). A median value for all investigations in the microwave portion of the spectrum is about 220 K (Hagfors, 1970, Table 3).

Impact of the sun and moon on remote sensing

Radiation from the Sun and Moon can impact passive remote sensing when looking down toward the surface of the Earth in several ways: (a) Radiation can enter the antenna via the “direct ray” along the line of sight from source to sensor and (b) Radiation can be reflected or scattered from the surface to the sensor. In the case of radiation from the Sun, the signal scattered from the ocean is often called “glitter.”

Direct ray

The contribution to the antenna temperature, T_A , can be obtained by integrating the incident radiation weighted by the antenna pattern over the extent of the source. Using the Rayleigh-Jeans approximation to express the radiation in terms of equivalent temperature, one obtains (Kraus, 1966, Chap. 3.18; Ulaby et al., 1981, Chaps. 4.4–6)

$$T_A = (1/4\pi) \int T_{\text{source}}(\Omega) G(\Omega) d\Omega \quad (4)$$

where Ω is solid angle and G is the antenna gain (Ulaby et al., 1981, Chap. 3.2). If T_{source} is constant and the source is small compared to the main beam of the antenna, then to a good first approximation,

$$T_A = (G/4\pi) T_{\text{source}} \Omega_{\text{source}} \quad (5)$$

As viewed from the Earth, the solid angles of the Sun and Moon (Ω_{source}) are very similar. However, T_{sun} is orders of magnitude larger than T_{moon} (e.g., $T_{\text{sun}} \approx 500,000$ K even for the quiet conditions, whereas $T_{\text{moon}} \approx 220$ K). The contribution of the direct rays from the Sun can be significant even for good antennas with low sidelobes in the direction of the Sun, but the direct ray from the Moon is almost always negligible.

Radiation, Solar and Lunar, Figure 3 Histograms showing the distribution of peak amplitude (*left*) and duration (*right*) for solar microwave bursts at 1.4 GHz during a period (1989) of high solar activity (Le Vine, et al., 2005).

Reflected ray

The effect of the reflected ray can be computed in the same manner except that the radiation is modified by reflection at the surface and the reflected ray encounters the antenna from a different direction. Using Eq. 5, one obtains

$$T_A = (G/4\pi)T_{\text{source}}\Omega_{\text{source}}R \quad (6)$$

R is a coefficient, called “reflectivity” to account for the reflection at the surface. In the case of a smooth surface, R is the magnitude squared of the Fresnel reflection coefficient. But, depending on the location of the observer, it may have to be modified to include effects of curvature of the Earth’s surface. Curvature will cause the reflected waves to diverge. For distant sources like the Sun and Moon, this can be taken into account by multiplying the reflectivity of a flat surface by a “divergence coefficient,” D (Beckmann and Spizzichino, 1963). In the case of a sphere, one finds that (Dinnat et al., 2009)

$$1/D \approx [1 + (2h/R_e \cos \gamma)][1 + (2h/R_e)] \quad (7)$$

where h is the distance from the reflection point to the spacecraft (i.e., slant range), R_e is the mean radius of the Earth (6,371 km), and γ is the angle between the ray from the source and the normal to the surface at the point of reflection. R is on the order of 0.7 for the ocean surface (no roughness) and 0.3 for land. For a satellite in low Earth orbit (about 800 km), D is on the order of 0.6, except for small values of $\cos(\gamma)$.

As in the case of the direct ray, reflected radiation from the Sun is much stronger than radiation from the Moon. The contribution due to the Moon is almost always negligible. However, in the case of a sensor looking down at the surface of the Earth, it is possible for radiation from the Moon to be reflected into the main beam of the antenna.

In this case, changes in T_A on the order of 1 K are possible (Dinnat et al., 2009).

The discussion above does not include the impact of roughness (e.g., waves on the ocean). See section 02.01.03 for information on scattering from rough surfaces.

Summary

To a first approximation, the Sun is a thermal source with an effective temperature of about 5,800 K. However, the radiation varies with the 11 year solar cycle and radio frequencies can greatly exceed this level during periods of high solar activity. The Moon is a source of both thermal emission and reflected solar radiation. In the microwave portion of the spectrum and longer wavelengths, the reflected solar radio emission is negligibly small compared to the thermal emission. At optical wavelengths, the reflected solar radiation is the dominant contribution.

RADIATION, VOLUME SCATTERING

Leung Tsang¹ and Kung-Hau Ding²

¹Paul Allen Center, Department of Electrical Engineering, University of Washington, Seattle, WA, USA

²Air Force Research Laboratory, Wright-Patterson AFB, Dayton, OH, USA

Definition

Volume scattering. Multiple scattering events taking place when electromagnetic wave inside a medium containing scatterers with discrete dielectric properties.

Radiative transfer. The transport of electromagnetic radiation power, scattered or absorbed, while propagating through a medium containing inhomogeneities.

Specific intensity. The instantaneous radiation power per unit area, per unit frequency interval at a specific frequency, at a position inside the medium, and in a specific direction per unit solid angle.

Independent scattering. Assumption of particles being far apart from each other, separation much greater than the incident wavelength, such that no correlation of scattered fields from different scatterers.

Introduction

The volumetric scattering effects play an important role in radar remote sensing of geophysical media (Tsang et al., 1985; Tsang and Kong, 2001). The volume scattering contributes to the bistatic scattering in the active radar remote sensing. In the passive remote sensing, the volume scattering redistributes the thermal emission. Electromagnetic waves have amplitudes and phases. The phase depends on the distance of propagation. However, in geophysical media, the scatterers are randomly positioned, so that the observed wave in bistatic directions

usually has random phase as the wave propagates many wavelengths of distances. Such a wave is called the “incoherent wave.” Although the final observed wave is incoherent, the wave interactions among the scatterers can have coherent effects. For example, in microwave scattering by ice grains in snow, there are many ice grains within the distance of a wavelength. Thus, the wave interactions among particles in the neighborhood of each other are coherent. Another example is the scattering by vegetation. Because of the partial ordering of the trunks, branches, and leaves, partial coherence effects are also exhibited in the phase difference between the horizontal and vertical polarizations.

Radiative transfer theory

Consider a medium consisting of scatterers that are randomly distributed, as shown in Figure 1. Inside the medium, the differential change of the specific intensity $\bar{I}(\bar{r}, \hat{s})$ at the position $\bar{r}$ and in the direction $\hat{s}$ obeys the radiative transfer equation:

$$\frac{d\bar{I}(\bar{r}, \hat{s})}{ds} = -\kappa_e \bar{I}(\bar{r}, \hat{s}) + \kappa_a T \begin{bmatrix} 1 \\ 1 \\ 0 \\ 0 \end{bmatrix} + \int d\hat{s}' \bar{P}(\hat{s}, \hat{s}') \cdot \bar{I}(\bar{r}, \hat{s}') \quad (1)$$

in which κ_e is the extinction coefficient that is a summation of absorption and scattering and κ_a is the absorption coefficient. The term $\kappa_e \bar{I}(\bar{r}, \hat{s})$ in the radiative transfer equation represents the decrease of the specific intensity $\bar{I}$ due to extinction, while the term $\kappa_a T$ represents an increase of specific intensity due to microwave emission that is proportional to the temperature of

Radiation, Volume Scattering, Figure 1 A random medium consists of a large number of scatterers. Due to scattering, the distribution of the specific intensity $\bar{I}$ is over all directions $\hat{s}$ and all positions $\bar{r}$. The differential change in the specific intensity as it passes through a small volume is along the direction of $\hat{s}$.

medium T . The term $\int d\hat{s}' \bar{\bar{P}}(\hat{s}, \hat{s}') \cdot \bar{I}(\hat{r}, \hat{s}')$ inside the integral of the radiative transfer equation represents an increase of the specific intensity due to the scattering of $\bar{I}$ from the direction $\hat{s}'$ into the direction $\hat{s}$. This increase is proportional to the specific intensity $\bar{I}(\hat{r}, \hat{s}')$ in the direction of $\hat{s}'$. The quantity $\bar{\bar{P}}(\hat{s}, \hat{s}')$ is the phase matrix that is related to the scattering properties of the particles and describes the coupling of specific intensities from the direction $\hat{s}'$ to the direction $\hat{s}$. The vector notation of the specific intensity $\bar{I}$ is because it has four components. The first two components are the vertically polarized intensity and the horizontally polarized intensity. The third and fourth components are respectively the real part and the imaginary part of the correlation between the vertical polarization and the horizontal polarization.

Solution of radiative transfer equation and relations to remote sensing signatures

Remote sensing consists of active remote sensing using radars and passive remote sensing using radiometers. In the active remote sensing, as illustrated in Figure 2 for a snow layer, we can neglect the emission term in the radiative transfer Eq. 1. An incident wave with a specific intensity $\bar{I}_0$ is impinging in the $\hat{s}_0$ direction. We then solve the radiative transfer equation subject to the boundary conditions at the boundary $z = 0$ and at the boundary $z = -d$. The bistatic scattering coefficient will be proportional to the resultant-specific intensity $\bar{I}(z = 0, \hat{s})$ at the boundary $z = 0$. The backscattering coefficient is for the specific intensity $\bar{I}(z = 0, \hat{s} = -\hat{s}_0)$ at the direction $\hat{s} = -\hat{s}_0$.

In the passive remote sensing, as depicted in Figure 3 for a snow medium, the boundary condition of the radiative transfer equation for a smooth surface at $z = 0$ is given by

$$\bar{I}(\hat{s}_d) = \bar{\bar{R}}_{10} \cdot \bar{I}(\hat{s}_u) \quad (2)$$

where $\bar{\bar{R}}_{10}$ is the Fresnel reflectivity for a smooth surface between medium 1 and medium 0, $\hat{s}_u$ denotes the upward direction, and $\hat{s}_d$ is for the downward direction corresponding to the specular reflection of $\hat{s}_u$. This boundary condition is saying that the downward intensity at the interface of media 0 and 1 is equal to the upward intensity in the medium 1 reflected by the boundary between the media 1 and 0. At the boundary $z = -d$, the interface between medium 1 and medium 2, the boundary condition is

$$\bar{I}(\hat{s}_u) = \bar{\bar{R}}_{12} \cdot \bar{I}(\hat{s}_d) + \bar{\bar{T}}_{12} \cdot \bar{T}_2 \quad (3)$$

in which $\bar{\bar{R}}_{12}$ and $\bar{\bar{T}}_{12}$ are respectively the Fresnel reflectivity and transmissivity for a smooth surface between medium 1 and medium 2 and $\bar{T}_2$ is the temperature of medium 2. This boundary condition says that the upward intensity in the medium 1 is equal to the sum of the downward intensity in the medium 1 reflected by the boundary between media 1 and 2 and the emissions from the medium 2.

Radiation, Volume Scattering, Figure 2 Active microwave remote sensing: microwave from radar to snow is scattered and attenuated by snow grains. Backscattered microwaves received by radar give the backscattering coefficient.

Radiation, Volume Scattering, Figure 3 Passive microwave remote sensing: ground emission and snow emission are scattered and attenuated by snow grains before received by radiometer as brightness temperature.

The radiative transfer equations are to be solved subject to the boundary conditions. The brightness temperature $\bar{T}_B$ as measured by a radiometer can be expressed as

$$\bar{T}_B(\hat{s}_{0u}) = \bar{\bar{T}}_{10} \cdot \bar{I}(z = 0, \hat{s}_u) \quad (4)$$

where the directions $\hat{s}_{0u}$ and $\hat{s}_u$ are related by the Snell's law and $\bar{\bar{T}}_{10}$ is the transmissivity for a smooth surface between medium 1 and medium 0.

Solution techniques of radiative transfer equations

There are several techniques of solving the radiative transfer equations (Tsang et al., 1985). One technique consists of an iterative approach by assuming that the phase matrix is small. Then one can solve the radiative transfer equation by first neglecting the phase matrix term. The solution is then obtained by solving a first-order ordinary differential equation. The solution is the zeroth-order solution. Then one adds the phase matrix term back and uses the zeroth-order solution to obtain the first-order solution. One can proceed further to obtain the higher-order solutions.

A second method is the eigen-quadrature approach. It consists of discretizing the propagation direction of the specific intensity, for example, into 16 directions. Then the integral term $\int d\hat{s}' \bar{P}(\hat{s}, \hat{s}') \cdot \bar{I}(\hat{r}, \hat{s}')$ becomes a product of a matrix and a column vector. The radiative transfer equation becomes a system of ordinary differential equations which are solved by the summation of the particular solution and the eigensystem for the homogeneous solution. The coefficients are obtained by matching boundary conditions. The solution by this eigen-quadrature method includes the full multiple scattering effects within the radiative transfer theory.

A third approach is by using the method of invariant embedding or by the doubling of layers. The essence of this approach is based on recognizing that the bistatic scattering properties of a layer of thickness much less than the optical thickness can be expressed in terms of the bistatic scattering properties of a layer of half of its thickness. By using this property, the solution of a layer of finite thickness can be obtained by starting with a thin layer and then continuing the doubling of layer thickness until the desired thickness is obtained.

Independent scattering: calculation of scattering and absorption coefficients and phase matrix

To relate to the physical properties of the medium, it is required to express the scattering coefficient, absorption coefficient, and phase matrix in terms of the physical properties of the constituent particles, such as fractional volume, particle sizes, shapes, orientations, and permittivities (Tsang et al., 1985, 2001). The classical method is based on the independent scattering. The independent scattering means that the scattering of a conglomeration of particles is equal to the addition of individual particle scattering properties. Under the independent scattering assumption, the scattering coefficient κ_s of a medium with identical particles is equal to

$$\kappa_s = n_0 \sigma_s \quad (5)$$

where n_0 is the number of particles per unit volume and σ_s is the scattering cross section of a single particle. Similarly, the absorption coefficient κ_a is given by

$$\kappa_a = n_0 \sigma_a \quad (6)$$

where σ_a is the absorption cross section of a single particle. The phase matrix of a medium with identical particles is given by

$$\bar{P}(\hat{s}, \hat{s}') = n_0 \bar{\sigma}_{bs}(\hat{s}, \hat{s}') \quad (7)$$

in which $\bar{\sigma}_{bs}(\hat{s}, \hat{s}')$ is the bistatic scattering cross section of a single particle.

Maxwell equations and coherent effects

Electromagnetic wave propagation and scattering in natural or man-made media are governed exactly by Maxwell equations. Thus, one can solve Maxwell equations for a collection of particles to calculate various electromagnetic properties, such as the scattering, absorption, and extinction coefficients. However, in Maxwell equations, electromagnetic fields have amplitudes and phases. Such a solution will exhibit interference effects of scattering by different particles. Therefore, the solutions of Maxwell equations have to be averaged over realizations or samples of collections of particles. If the medium is statistically homogeneous and the concentration of particles is sparse, the solutions of Maxwell equations, when averaged over realizations, will agree with those of independent scattering. The independent scattering approach is usually employed to study the scattering of atmospheric particles, for example, rain, fog, and cloud.

Scattering by dense media

In dense media, the constituent scatterers are closely packed. In densely packed media, the particles do not scatter independently. The correlation between particles has to be taken into account. A dense medium theory takes into account the collective and dependent scattering of particles. For example, snow is a dense medium because the ice grains in snow are densely packed with the volume fraction of ice ranging from 10 % to 50 %. In the dense medium theory, the analytic method consists of using the quasicrystalline approximation (QCA) to calculate the scattering properties of the particles (Tsang et al., 1985; Tsang and Kong, 2001). The scattering signatures of dense media depend on the pair distribution functions of particles which describe the relative positions of the particles. The phase matrices of dense media depend on the Fourier transform of the pair distribution functions. The dense medium approach gives scattering results distinctly different from those of independent scattering. For example, for a collection of particles that are much smaller in size than a wavelength, independent Rayleigh scattering gives the scattering coefficient that depends on frequency to the fourth power. However, from the theory of quasicrystalline approximation (QCA), the aggregated property of densely packed particles gives weaker frequency dependence than the fourth power. For example, consider a dense medium with spherical particles of diameter 1.2 mm, dielectric

Radiation, Volume Scattering, Figure 4 Scattering rate: quasicrystalline approximation (QCA) compared with classical scattering theory. The particle size is 1.2 mm and the volume fraction is 20 %.

constant 3.2, and volume fraction 20 %. In Figure 4, we compare the scattering coefficients between QCA and the classical scattering theory as a function of frequency for this medium. It shows that the scattering coefficient of QCA has weaker frequency dependence than that of the classical theory (Chen et al., 2003; Tse et al., 2007).

Foldy-Lax multiple scattering equations

In addition to the analytic approach, one can also use the Numerical Maxwell Model of 3-Dimensional (NMM3D) simulations to study the scattering by dense media (Tse et al., 2007). In the NMM3D method, the positions of particles in a medium are randomly computer generated. The particles are also allowed to bond together to form aggregates. Maxwell equations are then solved numerically. A common approach of solving Maxwell equations in multiple scattering by many scatterers is through the use of Foldy-Lax multiple scattering equations (Tsang et al., 1985, 2001).

Consider a collection of N particles; the Foldy-Lax multiple scattering equations are of the following form:

$$\bar{E}_j^{ex} = \bar{E}^{inc} + \sum_{\ell=1, \ell \neq j}^N \bar{G}_0 \cdot \bar{T}_\ell \cdot \bar{E}_\ell^{ex} \quad (8)$$

It says that the field exciting the particle j , $\bar{E}_j^{ex}$, is equal to the sum of the electric field of the incident wave, $\bar{E}^{inc}$,

and the scattered wave from all other particles excluding itself, as shown in Figure 5. In the Foldy-Lax scattering equation, $\bar{G}_0 \cdot \bar{T}_\ell \cdot \bar{E}_\ell^{ex}$ gives the scattered wave from the particle ℓ to the particle j , and the summation symbol $\sum_{\ell=1, \ell \neq j}^N$ represents the sum of such scattered waves. The transition matrix or T-matrix, $\bar{T}_\ell$, of particle ℓ acting on the exciting field, $\bar{E}_\ell^{ex}$, of the ℓ particle gives the scattered wave of the ℓ particle which travels to the j^{th} particle through the Green's function or the propagator, $\bar{G}_0$. Note that we have exciting fields on both the sides of the Foldy-Lax equations.

To solve the Foldy-Lax equations, vector wave expansions are applied and the Foldy-Lax scattering equations are cast into a matrix equation. The dimension of the matrix equation is equal to the number of particles, N , multiplied by the number of multipole terms used in the vector wave expansions. As a large number of particles are usually required to simulate the coherent and incoherent waves in dense media, the dimension of the resultant matrix equation is quite large. The Foldy-Lax equations can be solved using the iterative technique.

Results of QCA and NMM3D

For the case of dense media, the solutions of the Maxwell equation approach are consistent with QCA. However, the solution of Maxwell equations gives appreciable cross-polarization in the phase matrix even for a collection of spheres, a feature that is different from the independent scattering and from the quasicrystalline approximation.

Radiation, Volume Scattering, Figure 5 A schematic diagram shows the incident electromagnetic fields and the exciting electromagnetic fields in a medium of randomly positioned scatterers.

Radiation, Volume Scattering, Figure 6 An example of computer-simulated dense medium with randomly distributed spherical particles.

In Figure 6, we show a collection of spherical particles densely packed within a cubic box based on the computer simulation.

In Figures 7 and 8, we compare the extinction coefficients for snow as a function of frequency. We show the results of independent scattering, QCA, Monte Carlo

Radiation, Volume Scattering, Figure 7 Comparison of extinction coefficients (in $1/\text{cm}$) between the independent scattering, QCA, and Monte Carlo NMM3D results.

NMM3D, and those of experimental measurements. The results of NMM3D have the closest agreement with the experimental data that exhibit much weaker frequency dependence than that of independent scattering (Chen et al., 2003).

The phase matrices are best represented by the 1–2 frame (Tsang et al., 2000). The 1–2 frame is shown in Figure 9, in which $\hat{k}_i$ is the incident direction and $\hat{k}_s$ is the scattered direction. The polarization vectors $\hat{l}_i$ and $\hat{l}_s$, with $\hat{l}_i = \hat{l}_s$, are perpendicular to the plane formed by $\hat{k}_i$ and $\hat{k}_s$. The $\hat{2}_i$ direction is perpendicular to $\hat{k}_i$ and $\hat{l}_i$, while the $\hat{2}_s$ direction is perpendicular to $\hat{k}_s$ and $\hat{l}_s$.

In Figure 10, the phase matrix elements are plotted as a function of the angle Θ between the incident and scattered directions for two frequencies, 18 and 37 GHz. The medium considered is the same as in Figure 4. The results are shown and compared for the independent scattering and QCA approaches. The phase matrix component P_{11} is the scattering from the polarization $\hat{l}_i$ to the polarization $\hat{l}_s$, while P_{22} is the phase matrix component of scattering from the polarization $\hat{2}_i$ to the polarization $\hat{2}_s$. We note that for the same grain size, QCA predicts more forward scattering than the independent scattering (Tsang et al., 2007).

In Figure 11, we compare the brightness temperatures from QCA/DMRT predictions with experimental data of passive remote sensing of snow. Four channels of brightness temperatures are shown, with vertically and horizontally polarized brightness temperatures at 18.7 and 36.5 GHz. A multilayer snow model is used with varying snow density and grain size. We note that the brightness temperatures at 18.7 GHz are higher than those of the 36.5 GHz because the scattering at 36.5 GHz is stronger than that at 18 GHz. The brightness temperature for vertical polarization is higher than that of horizontal

Radiation, Volume Scattering, Figure 8 Comparison of extinction (in dB/m) between the independent scattering, Monte Carlo NMM3D results, and experimental data.

Radiation, Volume Scattering, Figure 9 Geometry for defining the 1-2 system based on the scattering plane. The scattering plane contains $\hat{k}_i$ and $\hat{k}_s$. The angle between $\hat{k}_i$ and $\hat{k}_s$ is Θ .

polarization because of stronger boundary reflection for horizontal polarization. The QCA/DMRT results are in good agreement with experimental observations (Liang et al., 2008).

Scattering by vegetation

Various scattering models of vegetation have been developed for scattering of foliage, vegetation, and forests. We can divide them into three kinds of models: (1) empirical/physical model, (2) vector radiative transfer model, and (3) coherent approach and full-wave multiple scattering model. The empirical model is based on a simplified radiative transfer model with empirical fitting parameters

for various vegetation types. The vector radiative transfer approach is based on incoherent interactions of branches, leaves, and trunks (Tsang et al., 1985; Ulaby et al., 1990). The Michigan Microwave Canopy Scattering model (MIMICS) (McDonald et al., 1990) was commonly used based on a first-order vector radiative transfer theory. The coherent superposition approach takes into account the relative phase shifts between scattering from different branches and leaves. It accounts for clustering structures. A computer growth model of Lindenmayer system can be used to grow and characterize the clustering properties. The full-wave multiple scattering model takes into account the coherent wave interaction among branches and leaves. The advantages of empirical model are that they use the fewest parameters that have been tuned to experimental measurements. However, the tuning parameters can be site specific and vegetation type specific. Both vector radiative transfer model and coherent wave model are physically based. Numerical full-wave simulations can be used to validate analytical radiative transfer models. Physical models can also be used to compare with empirical models. In actual implementation of physical models, the number of physical parameters can be reduced by having fixed relations of the physical parameters that are tuned to vegetation types.

Empirical/simplified physical model

The usefulness of an empirical model is that the parameters can be related to experimental data. Models with the

Radiation, Volume Scattering, Figure 10 Comparison between QCA and the Mie scattering phase matrices. The particle size is 1.2 mm and the volume fraction is 20 %. The frequencies are 18 GHz (left) and 37 GHz (right).

Radiation, Volume Scattering, Figure 11 Comparison of brightness temperatures (in K) between ground observation data at CLPX and model QCA/DMRT simulations. The observation frequencies are 18.7 and 36.5 GHz.

fewest parameters are desirable. For vegetation volume scattering, the radar backscattering coefficient can be expressed as

$$\sigma = \sigma_v + \sigma_{vg} + \sigma_{gv} \quad (9)$$

in which the three terms are respectively the (1) direct volume scattering (σ_v), (2) the scattering by the ground which is subsequently scattered by the vegetation (σ_{vg}), and (3) the scattering by the vegetation that is

subsequently scattered by the ground (σ_{gv}). Empirical formulas can be established for each of the three terms using simplified radiative transfer models in a manner similar to that of the passive microwave remote sensing soil moisture algorithms. The empirical parameters can be in terms of optical thickness, τ , and the scattering albedo $\bar{\omega}$. Both parameters can be polarization dependent. The optical thickness can be related to the vegetation moisture content. The scattering albedo can be decomposed into like-polarization albedo and cross-polarization albedo. If we assume that the optical thickness can be retrieved from the vegetation moisture content that can be auxiliary information from NDVI, then the empirical model requires only two parameters, the like-polarization albedo and the cross-polarization albedo.

Vector radiative transfer theory

The vegetation canopy consists of leaves, branches, and trunks. In the theoretical scattering models, the leaves are usually assumed to be circular disks, the branches are treated as finite length cylinders, and the trunks are treated as vertical cylinders. Thus, based on the independent scattering assumption, the vector radiative transfer theory can be constructed for the vegetation scattering (Tsang et al., 1985; Ulaby et al., 1990):

$$\frac{d\bar{I}(\bar{r}, \hat{s})}{ds} = -\bar{\kappa}_e \cdot \bar{I}(\bar{r}, \hat{s}) + \bar{\kappa}_a T + \int d\hat{s}' \bar{P}(\hat{s}, \hat{s}') \cdot \bar{I}(\bar{r}, \hat{s}') \quad (10)$$

Because the circular disks and the cylinders are nonspherical objects with some orientation distributions, the extinction in the radiative transfer theory becomes

Radiation, Volume Scattering, Figure 12 Four major backscattering mechanisms in the vegetation canopy scattering model: (a) direct scattering; (b) single scattering followed by reflection; (c) reflection followed by single scattering; and (d) reflection followed by single scattering and further reflection.

a 4 by 4 extinction matrix, $\bar{\kappa}_e$, and the absorption is a 4 by 1 absorption vector, $\bar{\kappa}_a$. For active radar scattering applications, the temperature emission term can be ignored. The vector radiative transfer model can be decomposed into multilayers. The first layer consists of branches and leaves and the second layer consists of trunks. The vector radiative transfer equations are to be solved subject to boundary conditions at the vegetation and ground interface. The boundary conditions can be of rough surface boundary conditions or that of specular reflection (Tsang et al., 1985).

Phase matrices of branch and leaf

The components of phase matrices for branches and leaves have been computed based on approximate and exact solutions of Maxwell's equations (Tsang et al., 1992, 2000, 2001). However, care must be exercised in calculating the phase matrices in a manner that is consistent with energy conservation.

Approximate scattering amplitudes. The scattering models are that of disks to represent leaves and finite length cylinders to represent branches and trunks. Approximate solutions of these objects were constructed based on infinite cylinder approximation, physical optics, and small disks assumptions.

Exact scattering amplitudes based on BOR. The body of revolution (BOR) codes are based on the method of moments (MoM) and have been used to replace the approximate solutions (Tsang et al., 1992). It converts a 3D problem through rotational symmetry into a 2D solution of Maxwell equations. The CPU is presently

acceptable because it is a 2D problem and because of the advance of modern computers. The advantage of BOR is that it gives accurate forward scattering amplitudes which can be used in the computation of extinction matrix elements in the vector radiative transfer theory.

First-order solution

The first-order solution is valid when the optical thickness of the vegetation canopy is thin, such as equal to or less than 0.2. The first-order solution consists of four terms, as shown in Figure 12. They are (1) direct volume scattering, (2) scattering by the ground which is subsequently scattered by the vegetation, (3) scattering by the vegetation that is subsequently scattered by the ground, and (4) scattering by the ground, then by the vegetation, and then by the ground again. These are four distinct contributions for bistatic scattering. The radar scattering coefficient can be expressed as

$$\sigma = \sigma_v + \sigma_{vg} + \sigma_{gv} + \sigma_{gvg} \quad (11)$$

Within the radiative transfer theory, these four contributions are added incoherently for the bistatic scattering. For radar monostatic backscattering, contributions (2) and (3) are identical because of reciprocity. Furthermore, contributions (2) and (3) interfere constructively so that the field adds coherently and the intensity becomes four times in the exact backscattering direction. Thus, in the backscattering direction, the incoherent approach gives $\sigma = \sigma_v + 2\sigma_{vg} + \sigma_{gvg}$, while the coherent approach gives $\sigma = \sigma_v + 4\sigma_{vg} + \sigma_{gvg}$. Whether the factor should be "2" or "4" or somewhere between 2 and 4 depends on the angular width of the backscattering enhancement and the radar beam width. These issues are yet to be studied

Radiation, Volume Scattering, Figure 13 Comparison of theoretical results with backscattering measurements from soybean at 1.1 GHz. The parameters used in the theoretical model are ground permittivity $\epsilon_2 = 4\epsilon_0$; depth $d = 1$ m; fractional volume 0.3 %; particles permittivity $\epsilon_s = (30.66 + i1.7)\epsilon_0$; major axis $a = 1.5$ cm; minor axis $c = 0.02$ cm; and the orientation angles $\beta_2 = \pi/2$, $\gamma_1 = 0$, and $\gamma_2 = 0$.

(Tsang et al., 1985; Tsang and Kong, 2001). To illustrate the usefulness, we make a comparison of theoretical results in Figure 13 with backscattering measurements from soybeans (Dobson et al., 1977). The simulation uses a layer of randomly positioned and oriented elliptical particles.

Second-order radiative transfer theory

This theory consists of a second iteration of the vector radiative transfer theory and is useful when the optical thickness is between 0.2 and 0.8. It includes the effects of double volume scattering in vector radiative transfer theory (Tsang et al., 1992).

Coherent approach and full-wave multiple scattering

The vector radiative transfer approach assumes that the scatterers scatter incoherently so that the intensities add. For wave propagation and scattering, the fields are coherent with amplitude and phase. Thus, much work has been done in using a coherent approach and a full-wave multiple scattering in the last decade. The coherent approach can have important differences from the incoherent approach in vegetation because the scatterers of vegetation are not uniformly randomly distributed. For example, leaves are usually in clusters and the positions of branches follow some architectural patterns. This means that scattering fields from different branches or

leaves can have definite relative phases. Thus, a coherent approach is sometimes necessary, particularly for long wavelengths such as L-band.

Coherent superposition

A first-order approximation is also known as the coherent superposition approximation, or coherent addition approximation (CAA), in which the electric fields from different scattering objects are summed together coherently (Zhang et al., 1996). For N scattering objects, the electric field of the scattered wave is expressed as

$$\bar{E} = \bar{E}_1 + \bar{E}_2 + \cdots + \bar{E}_N \quad (12)$$

where $\bar{E}_i$ is the electric field of the scattered wave from the i^{th} object. The scattered intensity is proportional to $|\bar{E}|^2$. Thus, the relative phases of the scattered waves from different objects are included in the intensity. In actual computational implementations, it is necessary to define the positions of the branches and leaves. In vegetation scattering simulations, a common approach is to use computer growth mechanisms such as the Lindenmayer systems (L-systems) of tree growth (Chen et al., 1995; Tsang et al., 2001). An example of treelike structure generated by using the L-systems is shown in Figure 14.

In Figure 15, we show the backscattering coefficients of σ_{vv} and σ_{hh} , respectively, for the active remote sensing case based on the coherent superposition approach. The frequency is at 1.5 GHz. The trees are generated using the L-systems and the maximum tree height is about 1.64 m. The fractional volume occupied by the branches in the forest of trees is 0.12 %. The dielectric constant of branches is $11 + i4$ and that of the ground is $16 + i4$. The differences of the co-polarizations between the coherent addition approximation and the independent scattering approximation can be larger than 3 dB, especially for the horizontal polarization. One can observe some clustering effects since the distance between neighboring branches can be smaller than one wavelength and the scatterers' positions are correlated.

Full-wave multiple scattering

Scattering of electromagnetic waves by a layer of vertical cylinders overlying a ground surface has useful applications in both active and passive remote sensing of vegetation canopies (Tsang et al., 1995). For example, in forests and cornfields, the dominant scattering structures of plants are the trunks and cornstalks. The Foldy-Lax multiple scattering equations have been applied with the use of half-space Green's function to take into account the ground reflection effects. The half-space Green's function is expressed in terms of vector cylindrical waves. The Foldy-Lax scattering equations are solved to the second order to account for the clustering effects of cylinders in close proximity with each other.

In Figure 16, we show the bistatic scattering results for vertical cylinders in the clustered distribution case, where

Radiation, Volume Scattering, Figure 14 Example of tree-like structure generated using the L-systems.

the second-order solution becomes important. The total fractional volume of cylinders is 0.1 %. We note that the second-order scattering is much larger than the first-order scattering. The second-order scattering of vertical polarization is more important than that of horizontal polarization. That is because vertical cylinders scatter vertically polarized waves more than horizontally polarized waves and create more coherent wave interaction among the cylinders in a cluster.

An important application of the vertical cylinder scattering model is in the remote sensing of paddy rice. The rice field is featured with a flooded ground surface during a large portion of its growing period and a nearly vertical rice plant structure. The rice crop scattering model consists of four major backscattering mechanisms: (a) direct scattering from the scatterer, (b) single scattering from the scatterer followed by reflection off the ground surface, (c) ground surface reflection followed by single scattering from the scatterer, and (d) reflection by ground surface followed by single scattering from the scatterer and further reflection off the ground surface, which are shown in Figure 12.

The rice canopy scattering model has been applied to simulate the backscattering signatures at different rice growth stages and compared with ERS-1 data. In Figure 15, the model backscattering results at different growth stages are compared with the ERS-1 vertical polarization data. The frequency is 5.3 GHz and the incidence angle is 23° . The comparison shows good agreement between model and measurements. The increasing trend of the temporal radar response is well captured by the model. Since the bottom of rice plants is immersed in water, the backscattering returns are dominated by the volume-surface interactions (Figure 17).

Summary

This entry describes the volume scattering which occurs inside a medium containing scatterers with discrete permittivity. The electromagnetic wave will be absorbed and scattered in various directions when it propagates through the medium. Because of the complicated nature of geophysical media and the need of experimental data interpretation and geophysical parameters retrieval for remote sensing, this entry presents a physically based vector radiative transfer model and the full-wave approach for volume scattering in dense media and

vegetation canopy. This entry also provides some validations between the forward scattering model simulations and microwave remote sensing measurements in snow and vegetation and illustrates the usefulness of these volume scattering models. Through the advent of computer technology and fast computational algorithm development, and better understanding of scattering physics in geophysical media, continuous progress has been made in improving electromagnetic wave propagation and scattering models to assist in data interpretation and geophysical inversion.

Introduction

From the pioneering books by Chandrasekhar (1960) and Sobolev (1975) to today, many different books on light propagation in the atmosphere have been written. All these works investigate different methods and algorithms to obtain solutions suitable for use as application models. We can divide the methods into three categories. The first

is based on analytical solutions and includes, in addition to Chandrasekhar and Sobolev, and Yanovitsky (1997), the work done by Van de Hulst (1980) on double adding and on its implemented code, done by DeHaan et al. (1987), which also contains polarization computation, and the method developed by Kondratiev et al. (1992).

The second category includes numerical solution methods, starting from the two books by Liou (1980, 1992) up to the most recent by Thomas and Stamnes (1999), Bohren and Clothiaux (2006), a revised version of the book by Petty (2006), Goody and Young (1989), and Lenoble (1993).

The third category consists of statistical modeling or Monte Carlo methods, for example, the books by Marchuk et al. (1980), Preisendorfer (1965), and the most recent for 3D in cloudy atmosphere by Marshak and Davis (2005). A valuable work was also done by the I3RC group (<http://code.google.com/p/i3rc-monte-carlo-model/>).

In 1975 and 1980, the International Association of Meteorology and Atmospheric Physics (IAMAP) Radiation Commission released two documents (1975; 1980) describing the different solutions of the radiative transfer equations in order to investigate the accuracy of the different methods proposed and to find the most economical procedures for various future applications. In 1985, Lenoble (1985) wrote a more complete book in which several solution methods were described in more detail and a numerical comparison of the methods was shown.

At present, it is not easy to define which method is more precise than another. New methods should not only overcome the present limitations, mainly linked to the geometry and dimensions of the system, but also should be able to capture the real interactions between the scattering and absorption by molecule and aerosol. Models of radiation are becoming increasingly sophisticated due to hyperspectral sensors mounted on board satellites which have high spatial resolution.

Radiative transfer: initial boundary value problem

Let us consider a photon beam traveling into a vertically nonuniform atmosphere containing aerosols and clouds. Bounded from a non-orthotropic reflecting bottom, it produces complex phenomena of multiple scattering and emissions requiring the simultaneous solution of two equations applied to an atmosphere-surface system. One of these is the radiative transfer, which analyzes the intensity change of radiation, while the other expresses the emission in terms of radiative equilibrium. The light theory of scattering in planetary atmosphere can be formulated with the aid of these equations. The solution of these equations is the topic of this entry.

Now let us consider a plane-parallel planetary atmosphere of a finite optical thickness τ_0 overlying an arbitrary reflecting surface. The primary scattering and absorption process somewhere in the atmosphere at any optical depth τ and each fixed wavelength λ is described by the albedo of single scattering $\Lambda(\tau)$ and by the

Radiative Transfer, Solution Techniques, Figure 1 Definition of geometrical variables and optical quantities employed to describe multiple light scattering.

phase function $\chi(\tau, \eta', \eta'', \phi' - \phi'')$. If we define, with respect to a downward normal, the cosine of the scattered beam with variable angles η' , and that of the light beams incident with η'' , and azimuthal angles with the variables ϕ' and ϕ'' measured clockwise looking from the bottom to the top of the atmosphere, then the proper scattering angles are denoted by γ , which is a function of the above-defined angular variables

$$\cos \gamma = \eta' \eta'' + \sqrt{(1 - \eta'^2)(1 - \eta''^2)} \cos(\phi' - \phi'')$$

Since it is well known that the real primary optical characteristics of planet's atmospheres and natural underlying surfaces are strongly variable in space-time scales, we shall consider vertical nonuniformities and bottom reflectance laws arbitrarily. Our approach to the problem, at first, is to neglect horizontal nonuniformities of optical atmospheric parameters, besides refraction and polarization effects.

Let us suppose now that the top of this planetary atmosphere is uniformly illuminated by parallel solar rays in the direction (ζ, ϕ_0) and that the incident monochromatic net flux of solar radiation per a unit area normal to the direction of solar ray propagation is equal to πS . The intensity of radiation in the current direction (η, ϕ) at any atmospheric optical depth τ will be denoted by $I(\tau; \eta, \phi - \phi_0, \tau_0)$, whereas all current angles $\arccos \zeta$ and $\arccos \eta$ are measured, respectively, for the inward normal of a slab, as shown in Figure 1. The wavelength index λ , depending on all abovementioned optical quantities, will be omitted for simplicity.

The law of bidirectional light reflectance from underlying surfaces is described by the arbitrary probabilistic function $y(\eta', \eta'', \phi' - \phi'')$, which transforms the intensity I'' of incident radiation from the direction η'', ϕ'' into the intensity I' of reflected radiation in the direction $-\eta', \phi'$ (Preisendorfer, 1965):

$$I' \eta' = \frac{1}{2\pi} y(\eta', \eta'', \phi' - \phi'') I'' \eta'' \quad (1)$$

The planet surface is illuminated by both unscattered but attenuated solar radiation and by diffuse radiation from atmosphere.

The probabilistic function introduced in the classical radiative transfer theory by V. Sobolev (1975) can be also used for the surface phase function $r_{sur}(\tau, \eta', \eta'', \phi' - \phi'')$ according to the following relation:

$$2\eta' r_{sur}(\eta', \eta'', \phi' - \phi'') = y(\eta', \eta'', \phi' - \phi'') \quad (2)$$

Due to the probabilistic character of function $y(\eta', \eta'', \phi' - \phi'')$, the normalized condition has to be taken into account:

$$\frac{1}{2\pi} \int_{\Omega} y(\eta', \eta'', \phi' - \phi'') = 1 \quad (3)$$

We need to emphasize that, unlike atmospheric and surface phase functions, respectively, defined as $\chi(\eta', \eta'', \phi' - \phi'')$ and $r_{sur}(\eta', \eta'', \phi' - \phi'')$, the probabilistic function $y(\eta', \eta'', \phi' - \phi'')$ does not possess the angular symmetry properties expressed by the principle of

optical reciprocity. Namely, we have the following disequality:

$$y(\eta', \eta'', \varphi' - \varphi'') \neq y(\eta'', \eta', \varphi' - \varphi'') \quad (4)$$

With these statements in mind, let us formulate the initial boundary value problem of the radiative transfer theory needed for the determination of unknown intensities $I(\tau, \eta, \zeta, \varphi - \varphi_0, \tau_0)$.

According to well-known classical considerations (see, e.g., Sobolev, 1975), the intensity is a solution of the following initial boundary value problem:

$$\begin{aligned} \eta \frac{dI(\tau, \eta, \zeta, \varphi - \varphi_0, \tau_0)}{d\tau} = & -I(\tau, \eta, \zeta, \varphi - \varphi_0, \tau_0) \\ & + B(\tau, \eta, \zeta, \varphi - \varphi_0, \tau_0) \\ & \tau \in [0, \tau_0], \eta \in [-1, 1], \\ & \zeta \in [0, 1] \end{aligned} \quad (5)$$

where the source function $B(\tau, \eta, \zeta, \varphi - \varphi_0, \tau_0)$ can be represented in integral form:

$$\begin{aligned} B(\tau, \eta, \zeta, \varphi - \varphi_0, \tau_0) = & \frac{\Lambda(\tau)}{4\pi} \int_0^{2\pi} d\varphi' \int_{-1}^1 \chi(\tau, \eta, \eta', \varphi - \varphi') \\ & I(\tau, \eta, \varphi' - \varphi_0, \tau_0) d\eta' \\ & + \frac{S}{4} \Lambda(\tau) \chi(\tau, \eta, \zeta, \varphi - \varphi_0) \exp\left(-\frac{\tau}{\zeta}\right) \\ & \tau \in [0, \tau_0], \eta \in [-1, 1], \zeta \in [0, 1] \end{aligned} \quad (6)$$

The boundary conditions for the given boundary value problem are:

$$\begin{aligned} I(0, \eta, \zeta, \varphi - \varphi_0, \tau_0) &= 0 \quad \eta \in [0, 1], \zeta \in [0, 1] \\ I(\tau_0, -\eta, \zeta, \varphi - \varphi_0, \tau_0) &= I_{sur}(\eta, \zeta, \varphi - \varphi_0, \tau_0) \end{aligned} \quad (7)$$

where I_{sur} is the intensity of radiation, multiply reflected by the underlying surface at $\tau = \tau_0$. Taking into account Eq. 1, we get the following integral expression for $I_{sur}(\eta, \zeta, \varphi - \varphi_0, \tau_0)$, as also it is given by Sobolev (1975):

$$\begin{aligned} \eta I_{sur}(\eta, \zeta, \varphi - \varphi_0, \tau_0) = & \frac{1}{2\pi} \int_0^{2\pi} d\varphi' \int_0^1 y(\eta, \eta', \varphi - \varphi_0) \\ & I(\tau_0, \eta', \zeta, \varphi' - \varphi_0, \tau_0) \eta' d\eta' \\ & + \frac{S}{2} y(\eta, \zeta, \varphi - \varphi_0) \zeta \exp\left(-\frac{\tau_0}{\zeta}\right) \\ & \eta \in [0, 1], \zeta \in [0, 1] \end{aligned} \quad (8)$$

The formal solutions of the radiative transfer Eq. 5, taking into account the expression for the source function

Eq. 6, can be written directly in integral form, satisfying the boundary conditions Eq. 7:

$$\begin{aligned} I(\tau, \eta, \varphi - \varphi_0, \tau_0) = & \int_0^\tau B(\tau', \eta, \zeta, \varphi - \varphi_0, \tau_0) \\ & \exp\left(-\frac{\tau - \tau'}{\eta}\right) \frac{d\tau'}{\eta} \end{aligned} \quad (9)$$

$$\begin{aligned} I(\tau - \eta, \varphi - \varphi_0, \tau_0) = & \int_0^\tau B(\tau', -\eta, \zeta, \varphi - \varphi_0, \tau_0) \\ & \exp\left(-\frac{\tau' - \tau}{\eta}\right) \frac{d\tau'}{\eta} \\ & + I_{sur}(\eta, \zeta, \varphi - \varphi_0, \tau_0) \exp\left(-\frac{\tau_0 - \tau}{\eta}\right) \\ & \tau \in [0, \tau_0], \eta \in [0, 1], \zeta \in [0, 1] \end{aligned} \quad (10)$$

Substituting Eqs. 9 and 10 in Eq. 6 and taking into account different mathematical aspects of upwelling and downwelling radiation, we can obtain the well-known system of exact integral equations for the source function B.

On the contrary, by substituting Eq. 6 in Eqs. 9 and 10, the appropriate exact integral equations for upwelling and downwelling intensities can be obtained.

Fourier series expansions

Since in the theory of light scattering the phase function is frequently expanded in Legendre polynomials, we can separate the azimuthal dependence on I and B , expanding these quantities in a Fourier series. Then the system of Eqs. 5 and 6 can be separated into distinct pairs of equation determining the coefficient of this expansion. Then we may use azimuth's harmonics of Fourier series expansions for the following optical quantities:

$$\begin{aligned} \chi(\tau, \gamma) = & \sum_{i=0}^{M_1} x_i(\tau) P_i(\cos \gamma) = p^0(\tau, \eta, \zeta) \\ & + 2 \sum_{m=1}^{M_1} p^m(\tau, \eta, \zeta) \cos m(\varphi - \varphi_0) \end{aligned} \quad (11)$$

$$\begin{aligned} y(\eta', \eta'', \varphi' - \varphi'') = & y^0(\eta', \eta'') \\ & + 2 \sum_{m=1}^{M_2} y^m(\tau, \eta', \eta'') \cos m(\varphi - \varphi'), \end{aligned} \quad (12)$$

$$\begin{aligned} I(\tau, \eta, \zeta, \varphi - \varphi_0, \tau_0) = & I^0(\tau, \eta, \zeta, \tau_0) \\ & + 2 \sum_{m=1}^{[M_1, M_2]} I^m(\tau, \eta, \zeta, \tau_0) \cos m(\varphi - \varphi_0) \end{aligned} \quad (13)$$

$$I(\tau, -\eta, \zeta, \varphi - \varphi_0, \tau_0) = I^0(\tau, -\eta, \zeta, \tau_0) + 2 \sum_{m=1}^{[M_1, M_2]} I^m(\tau, -\eta, \zeta, \tau_0) \cos m(\varphi - \varphi_0) \quad (14)$$

with $m = 0, 1, 2, \dots, M_1$ and $m = 0, 1, 2, \dots, M_2$ and where $P_i(\cos \gamma)$ are Legendre polynomials. From here forward, only azimuth's number $M = \max[M_1, M_2]$ will be used for the Fourier analysis of the optical atmosphere-surface quantities. The functions $p^m(\tau, \eta, \zeta)$ are calculated on the basis of the well-known series expansion or with the help of traditional Fourier representation:

$$p^m(\tau, \eta, \zeta) = \sum_{i=m}^{M_i} x_i(\tau) \frac{(m-i)!}{(m+i)!} P_i^m(\eta) P_i^m(\zeta) \quad (15)$$

$$p^m(\tau, \eta, \zeta) = \frac{1}{2\pi} \int_0^{2\pi} \chi(\tau, \eta, \zeta, \varphi - \varphi_0) \cos m \times (\varphi - \varphi_0) d(\varphi - \varphi_0) \quad (16)$$

The functions $P_i^m(\eta)$ are the associated Legendre's polynomials, and coefficients x_i are calculated according to:

$$x_i(\tau) = \frac{2i+1}{2} \int_0^{2\pi} \chi(\tau, \gamma) P_i(\cos \gamma) \sin \gamma d\gamma |x_i(\tau)| \leq 2i+1; i=0, 1..M \quad (17)$$

Of course, the atmospheric phase functions $\chi(\tau, \gamma)$ will be normalized in accordance with the usual conditions:

$$\frac{1}{2} \int_0^\pi \chi(\tau, \gamma) \sin \gamma d\gamma = 1 \quad (18)$$

Taking into account Eqs. 11, 12, 13, and 14, we obtain the basic boundary value problem for the determination of azimuth's harmonics radiation fields:

$$\eta \frac{dI^m(\tau, \eta, \zeta, \tau_0)}{d\tau} = -I^m(\tau, \eta, \zeta, \tau_0) + B^m(\tau, \eta, \zeta, \tau_0) \quad \tau \in [0, \tau_0], \eta \in [-1, 1], \zeta \in [0, 1] \quad (19)$$

$$B^m(\tau, \eta, \zeta, \tau_0) = \frac{\Lambda(\tau)}{4} \int_{-1}^1 p^m(\tau, \eta, \eta', \tau_0) I^m(\tau, \eta, \zeta, \tau_0) d\eta' + \frac{S}{4} \Lambda(\tau) p^m(\tau, \eta, \zeta) \exp\left(-\frac{\tau}{\eta}\right) \quad \tau \in [0, \tau_0], \eta \in [-1, 1], \zeta \in [0, 1] \quad (20)$$

with the boundary conditions

$$I^m(0, \eta, \zeta, \tau_0) = 0 \quad \eta \in [0, 1], \zeta \in [0, 1] \quad (21)$$

$$I^m(\tau_0, -\eta, \zeta, \tau_0) = I_{sur}^m(\eta, \zeta, \tau_0)$$

The azimuth's harmonics of the surface brightness I_{sur} can be expanded as

$$\eta I_{sur}^m(\eta, \zeta, \tau_0) = \frac{S\zeta}{2} y^m(\eta, \zeta) \exp\left(-\frac{\tau_0}{\zeta}\right) + \int_0^1 y^m(\eta, \eta') I^m(\tau_0, \eta', \zeta, \tau_0) \eta' d\eta' \quad (22)$$

where y^m has been obtained by expanding it in the same way of P^m .

Then, the general integral forms with the previous boundary conditions are

$$I^m(\tau, \eta, \zeta, \tau_0) = \int_0^\tau B^m(\tau', \eta, \zeta, \tau_0) \exp\left(-\frac{\tau - \tau'}{\eta}\right) \frac{d\tau'}{\eta} \quad (23)$$

$$I^m(\tau, -\eta, \zeta, \tau_0) = \int_0^\tau B^m(\tau', -\eta, \zeta, \tau_0) \exp\left(-\frac{\tau' - \tau}{\eta}\right) \frac{d\tau'}{\eta} + I_{sur}^m(\eta, \zeta, \tau_0) \exp\left(-\frac{\tau_0 - \tau}{\eta}\right) \quad (24)$$

According to the classical approach, substituting Eqs. 23 and 24 into Eq. 20, we can obtain the exact integral equations for the azimuth's harmonics of the source function $B^m(\tau, \eta, \zeta, \tau_0)$ for upward and downward directions:

$$B^m(\tau, \eta, \zeta, \tau_0) = \frac{\Lambda(\tau)}{2} \left[\int_0^1 p^m(\tau, \eta, \eta') I^m(\tau, \eta', \zeta, \tau_0) d\eta' + \int_0^1 p^m(\tau, -\eta, \eta') I^m(\tau, -\eta, \zeta, \tau_0) d\eta' \right] + \frac{S}{4} \Lambda(\tau) p^m(\tau, \eta, \zeta) \exp\left(\frac{-\tau}{\zeta}\right) \quad (25)$$

$$B^m(\tau, -\eta, \zeta, \tau_0) = \frac{\Lambda(\tau)}{2} \left[\int_0^1 p^m(\tau, -\eta, \eta') I^m(\tau, \eta', \zeta, \tau_0) d\eta' + \int_0^1 p^m(\tau, \eta, \eta') I^m(\tau, -\eta, \zeta, \tau_0) d\eta' \right] + \frac{S}{4} \Lambda(\tau) p^m(\tau, -\eta, \zeta) \exp\left(\frac{-\tau}{\zeta}\right) \quad (26)$$

From an applied point of view, it is better to obtain the proper exact integral equation from azimuth's harmonics $I^m(\tau, \pm\eta, \zeta, \tau_0)$. Substituting Eqs. 25 and 26 into Eqs. 23 and 24, we obtain the integral forms for the radiative transfer equations:

$$I^m(\tau, \eta, \zeta, \tau_0) = \int_0^{\tau_0} \frac{\Lambda(\tau')}{2} \left\{ \left[\int_0^1 p^m(\tau, \eta, \eta') I^m(\tau, \eta', \zeta, \tau_0) d\eta' \right. \right. \\ \left. \left. + \int_0^1 p^m(\tau, -\eta, \eta') I^m(\tau, -\eta, \zeta, \tau_0) d\eta' \right] \right. \\ \left. + \frac{S}{2} p^m(\tau, \eta, \zeta) \exp\left(-\frac{\tau'}{\zeta}\right) \right\} \exp\left(-\frac{\tau - \tau'}{\eta}\right) \frac{d\tau'}{\eta} \quad (27)$$

and

$$I^m(\tau, -\eta, \zeta, \tau_0) = \int_0^{\tau_0} \frac{\Lambda(\tau')}{2} \left\{ \left[\int_0^1 p^m(\tau, -\eta, \eta') I^m(\tau, \eta', \zeta, \tau_0) d\eta' \right. \right. \\ \left. \left. + \int_0^1 p^m(\tau, -\eta, \eta') I^m(\tau, -\eta, \zeta, \tau_0) d\eta' \right] \right. \\ \left. + \frac{S}{2} p^m(\tau, -\eta, \zeta) \exp\left(-\frac{\tau'}{\zeta}\right) \right\} \exp\left(-\frac{\tau - \tau'}{\eta}\right) \frac{d\tau'}{\eta} \\ + I_{sur}^m(\eta, \zeta, \tau_0) \exp\left(-\frac{\tau_0 - \tau}{\eta}\right) \quad (28)$$

These are the integral equations useful for the calibration. Unfortunately, classical analytical and semi-analytical approaches cannot provide a complete numerical analysis of radiation fields existing in the environment systems. Nevertheless, with the help of precise analytical and highly accurate semi-analytical methods and algorithms, we are able to calibrate the actual spatial-angular distributions of radiation fields in order to estimate the precision of the input environment optical models. In fact, the application of precise calibrating models of radiation fields is necessary in order to estimate the accuracy of different approximate algorithms, used in atmospheric correction and in the thematic interpretation of modern multispectral and hyperspectral satellite information.

It should be noted that functions $p^m(\tau, \eta, \zeta)$ can also be calculated without any information about coefficients x_i . In fact, with the help of known scattering functions $A^m(\tau, \eta, \zeta)$,

$$p^m(\tau, \eta, \zeta) = A^m(\tau, \eta, \zeta) \quad \text{for } \Lambda = 0 \quad (29)$$

$A^m(\tau, \eta, \zeta)$ can be calculated on the basis of the expansion series given by Sobolev (1975)

$$A^m(\tau, \eta, \zeta) = P_m^m(\eta) \sum_{i=m}^M x_i(\tau) \frac{(m-i)!}{(m+i)!} P_i^m(\zeta) R_{i,m}^m(\eta, \zeta) \quad (30)$$

where functions $R_{i,m}^m$ are Sobolev's polynomials, which can be calculated on the basis of recursive formulas:

$$(i-m+1)R_{i+1,m}^m(\eta) + (i+m)R_{i-1,m}^m(\eta) \\ = (2i+1\Lambda x_i)R_{i,m}^m(\eta) d\eta \quad (31)$$

where

$$R_{i,m}^m(\eta) = 0 \quad m > i \quad (32)$$

$$R_{i,m}^m(\eta) = 1 \quad m > i \quad (33)$$

It should be noted that in case of large $m \gg 1$ and for $\eta \approx 1$, $\eta \rightarrow 1$, $\zeta \rightarrow 1$, $A^m(\tau; \eta, \zeta)$ losses of accuracy due to significant oscillations of small value used for calculating the functions.

Successive approximation methods and the iterative scheme

The system of exact integral Eqs. 27 and 28 can be solved numerically on the basis of successive approximations method according to an iterative scheme. We have the downwelling radiation as

$$I_{n+1}^m(\tau, \eta, \zeta, \tau_0) = \int_0^{\tau_0} \frac{\Lambda(\tau')}{2} \left\{ \left[\int_0^1 p^m(\tau', \eta, \eta') I_n^m(\tau', \eta', \zeta, \tau_0) d\eta' \right. \right. \\ \left. \left. + \int_0^1 p^m(\tau', -\eta, \eta') I_n^m(\tau', -\eta, \zeta, \tau_0) d\eta' \right] \right. \\ \left. + \frac{S}{2} p^m(\tau', \eta, \zeta) \exp\left(-\frac{\tau'}{\zeta}\right) \right\} \exp\left(-\frac{\tau - \tau'}{\eta}\right) \frac{d\tau'}{\eta} \quad (34)$$

While for the upwelling intensity, the iterative scheme is

$$I_{n+1}^m(\tau, -\eta, \zeta, \tau_0) = \int_0^{\tau_0} \frac{\Lambda(\tau')}{2} \left\{ \left[\int_0^1 p^m(\tau', -\eta, \eta') I_n^m(\tau', \eta', \zeta, \tau_0) d\eta' \right. \right. \\ \left. \left. + \int_0^1 p^m(\tau', \eta, \eta') I_n^m(\tau', -\eta, \zeta, \tau_0) d\eta' \right] \right. \\ \left. + \frac{S}{2} p^m(\tau', -\eta, \zeta) \exp\left(-\frac{\tau'}{\zeta}\right) \right\} \exp\left(-\frac{\tau - \tau'}{\eta}\right) \frac{d\tau'}{\eta} \\ + I_{sur}^m(\eta, \zeta, \tau_0) \exp\left(-\frac{\tau_0 - \tau}{\eta}\right) \quad (35)$$

The iterative brightness of underlying surface is

$$\eta I_{sur,n}^m(\eta, \zeta, \tau_0) = \frac{S\zeta}{2} y^m(\eta, \zeta) \exp\left(-\frac{\tau_0}{\zeta}\right) \quad (36)$$

$$+ \int_0^1 y^m(\eta, \eta') I_n^{*m}(\tau_0, \eta', \zeta) \eta' d\eta' \quad (37)$$

with $\tau \in [0, \tau_0]$ $\eta \in [0, 1]$ $\zeta \in [0, 1]$ and $m = 0, 1 \dots M$, $n = 1, 1, 2 \dots, K$.

The starting approximations for $I^m(\tau; \eta, \zeta, \tau_0)$ and $I^m(\tau, -\eta, \zeta, \tau_0)$ can be chosen equal, for example, according to the following scheme:

$$I_0^m(\tau, \eta, \zeta, \tau_0) = 0 \quad (38)$$

$$I_0^m(\tau, -\eta, \zeta, \tau_0) = 0 \quad (39)$$

In particular case, we can obtain the corresponding approximate expressions for the primary light scattering by the atmosphere and the single light reflection from the bottom as a result of the first iterative step. In order to get precise values of the primary atmospheric light reflection and the single light reflection coming from the bottom determined by the brightness $I_{sur,1}^m(\tau, \eta, \zeta, \tau_0)$ and $I_{sur,1}^m(\tau, -\eta, \zeta, \tau_0)$, we need to use this starting approximation:

$$I_0^m(\tau, \eta, \zeta, \tau_0) = 0 \quad (40)$$

$$I_0^m(\tau, -\eta, \zeta, \tau_0) = I_{sur,1}^m(\eta, \zeta, \tau_0) \exp\left(-\frac{\tau_0 - \tau}{\eta}\right) \quad (41)$$

where the bottom brightness $I_{sur,1}^m(\eta, \zeta, \tau_0)$ is determined by proper approximation for I_{sur}^m selected from the boundary condition Eq. 21, taking into account all processes of the primary atmospheric light scattering before and after single light reflection from the underlying surface. We emphasize that, especially from the point of view of calibration, the starting approximations must be chosen according to some arbitrary but exact or highly precise solutions of the radiative transfer equation. In particular, we can use, as the first starting step, the precise expressions that take into account exactly the primary atmospheric light scattering and single bottom light reflection:

$$I_0^m(\tau, \eta, \zeta, \tau_0) = I_1^m(\tau, \eta, \zeta, \tau_0) \quad (42)$$

$$I_0^m(\tau, -\eta, \zeta, \tau_0) = I_1^{*m}(\tau, \eta, \zeta, \tau_0) \quad (43)$$

Of course, we can select arbitrary starting iterations, for example, by using some approximate analytical, semi-analytical, or numerical solutions of the initial boundary value problem. In this case, the primary atmospheric light scattering and the single surface light reflection have to be estimated exactly. At the same fixed iterative step, the multiple light scattering can be only calculated approximately, but the final resulting radiation field will be estimated sufficiently precise.

Primary light scattering

The exact primary scattering for a vertically nonuniform atmosphere, bounded by a reflecting non-orthotropic surface, can be described by

$$I_1^m(\tau, \eta, \zeta, \tau_0) = \int_0^{\tau_0} \frac{\Lambda(\tau')}{2} \left\{ \int_0^1 p^m(\tau', -\eta, \eta') I_{sur,1}^m(\eta', \zeta, \tau_0) \times \exp\left(\frac{\tau_0 - \tau'}{\eta'}\right) d\eta' + \frac{S}{2} p^m(\tau, \eta, \zeta) \exp\left(-\frac{\tau'}{\zeta}\right) \right\} \times \exp\left(-\frac{\tau - \tau'}{\eta}\right) \frac{d\tau'}{\eta} \quad (44)$$

$$I_1^m(\tau, -\eta, \zeta, \tau_0) = \int_0^{\tau_0} \frac{\Lambda(\tau')}{2} \left\{ \int_0^1 p^m(\tau', \eta, \eta') I_{sur,1}^m(\eta', \zeta, \tau_0) \times \exp\left(-\frac{\tau_0 - \tau'}{\eta'}\right) d\eta' + \frac{S}{2} p^m(\tau, -\eta, \zeta) \exp\left(-\frac{\tau'}{\zeta}\right) \right\} \times \exp\left(-\frac{\tau - \tau'}{\eta}\right) \frac{d\tau'}{\eta} + I_{sur,1}^m(\eta, \zeta, \tau_0) \exp\left(-\frac{\tau_0 - \tau}{\eta}\right) \quad (45)$$

The brightness of an arbitrary non-orthotropic underlying surface for single reflection has the following expression:

$$\eta I_{sur,1}^m(\eta, \zeta, \tau_0) = \frac{S\zeta}{2} y^m(\eta, \zeta) \exp\left(-\frac{\tau_0}{\zeta}\right) + \int_0^1 y^m(\eta, \eta') I_1^{*m}(\tau_0, \eta', \zeta) \eta' d\eta' \quad (46)$$

with $\tau \in [0, \tau_0]$, $\eta \in [0, 1]$, $\zeta \in [0, 1]$ and $m = 0, 1, 2, \dots, M$. In this formula the I_1^{*m} denotes the intensity of primary scattering in a nonuniform atmosphere illuminated by the sun from the side of the top of the atmospheric boundary without the light reflecting from surface placed at the lowest atmosphere boundary. If we substitute Eq. 46 into Eqs. 44 and 45, we obtain

$$I_1^m(\tau, \eta, \zeta, \tau_0) = I_1^{*m}(\tau, \eta, \zeta, \tau_0) + \int_0^1 I_{*1}^m(\tau, \eta, \eta', \tau_0) \zeta \exp\left(-\frac{\tau_0}{\zeta}\right) y^m(\eta', \zeta) \frac{d\eta'}{\eta'} + 2 \int_0^1 I_{*1}^m(\tau, \eta, \eta', \tau_0) \frac{d\eta'}{\eta'} \int_0^1 I_1^{*m}(\tau, \eta'', \zeta, \tau_0) y^m(\eta', \eta'') \eta'' d\eta'' \quad (47)$$

and

$$I_1^m(\tau, -\eta, \zeta, \tau_0) = I_1^{*m}(\tau, -\eta, \zeta, \tau_0) + \int_0^1 I_{*1}^m(\tau, -\eta, \eta', \tau_0) \zeta \exp\left(-\frac{\tau_0}{\zeta}\right) y^m(\eta', \zeta) \frac{d\eta'}{\eta'} + 2 \int_0^1 I_{*1}^m(\tau, -\eta, \eta', \tau_0) \frac{d\eta'}{\eta'} \int_0^1 I_1^{*m}(\tau, \eta'', \zeta, \tau_0) y^m(\eta', \eta'') \eta'' d\eta'' + I_{sur,1}^m(\eta, \zeta, \tau_0) \exp\left(-\frac{\tau_0 - \tau}{\eta}\right) \quad (48)$$

where I_1^m is the brightness in a vertically nonuniform atmosphere illuminated from the sun from the side of the lowest boundary. Neglecting the solar photons that are scattered by the atmosphere and only taking those reflected by the underlying surface one time, that is, only taking into account the direct photons, we can obtain the approximate solution for the intensity $I_1^m(\eta, \pm\zeta, \tau_0)$:

$$I_1^m(\tau, \eta, \zeta, \tau_0) = I_1^{*m}(\tau, \eta, \zeta, \tau_0) + \int_0^1 I_{*1}^m(\tau, \eta, \eta', \tau_0) \zeta \exp\left(-\frac{\tau_0}{\zeta}\right) y^m(\eta', \zeta) \frac{d\eta'}{\eta'} \quad (49)$$

$$I_1^m(\tau, -\eta, \zeta, \tau_0) = I_1^{*m}(\tau, -\eta, \zeta, \tau_0) + \int_0^1 I_{*1}^m(\tau, -\eta, \eta', \tau_0) \zeta \exp\left(-\frac{\tau_0}{\zeta}\right) y^m(\eta', \zeta) \frac{d\eta'}{\eta'} + I_{sur,1}^m(\eta, \zeta, \tau_0) \exp\left(-\frac{\tau_0 - \tau}{\eta}\right) \quad (50)$$

Precise expression of $I_1^{*m}(\tau, \eta, \zeta, \tau_0)$ and $I_1^{*m}(\tau, -\eta, \zeta, \tau_0)$ can be computed with the help of expression Eqs. 23 and 24 using the corresponding exact expression for the source functions that can be obtained taking the sun's position at the top or lowest atmospheric boundaries, that is,

$$B_1^{*m}(\tau, \pm\eta, \zeta, \tau_0) = \frac{S}{4} \Lambda(\tau) p^m(\tau, \pm\eta, \zeta) \exp\left(-\frac{\tau}{\zeta}\right) \quad (51)$$

$$B_{*1}^m(\tau, \mp\eta, \zeta, \tau_0) = \frac{S}{4} \Lambda(\tau) p^m(\tau, \mp\eta, \zeta) \exp\left(-\frac{\tau_0 - \tau}{\zeta}\right) \quad (52)$$

The importance of obtaining precise expression for primary scattering resides also in the need to obtain the grid point to calibrate the radiation fields in environment.

The Gauss-Seidel methods

The application of the Gauss-Seidel method to a multilayer atmosphere bounded from an arbitrary non-orthotropic reflecting surface consists of the discretization of variables τ , η , and φ and the subsequent approximation of the system with a linear algebraic equation without any series expansions (Lenoble, 1985). The atmosphere is divided in $N-1$ layers ($0 = \tau_1 < \tau_2 < \dots < \tau_N = \tau_0$) of optical thickness $\tau = \frac{\tau_0}{N-1}$. For each interval (τ, τ_{i+2}) , Eqs. 9 and 10 may be written in the following form ($\eta > 0$):

$$I(\tau_{i+2}, \eta, \zeta, \varphi - \varphi_0, \tau_0) = I(\tau_i, \eta, \zeta, \varphi - \varphi_0, \tau_0) \exp\left(-\frac{2\Delta\tau}{\eta}\right) + \int_{\tau_i}^{\tau_{i+2}} B(\tau', \eta, \zeta, \varphi - \varphi_0) \exp\left(-\frac{\tau_{i+2} - \tau'}{\eta}\right) \frac{d\tau'}{\eta} \quad i = 1, 2, \dots, N-2 \quad (53)$$

$$I(\tau_i, -\eta, \zeta, \varphi - \varphi_0, \tau_0) = I(\tau_{i+2}, -\eta, \zeta, \varphi - \varphi_0, \tau_0) \exp\left(-\frac{2\Delta\tau}{\eta}\right) + \int_{\tau_i}^{\tau_{i+2}} B(\tau', -\eta, \zeta, \varphi - \varphi_0) \exp\left(-\frac{\tau' - \tau_i}{\eta}\right) \frac{d\tau'}{\eta} \quad i = 1, 2, \dots, N-2 \quad (54)$$

The basic approximation is made according to the following expression for the source function:

$$\int_{\tau_i}^{\tau_{i+2}} B(\tau', -\eta, \zeta, \varphi - \varphi_0, \tau_0) \exp\left(-\frac{\tau_{i+2} - \tau'}{\eta}\right) \frac{d\tau'}{\eta} \approx B(\tau_{i+1}, \eta, \zeta, \varphi - \varphi_0, \tau_0) \left[1 - \exp\left(-\frac{2\Delta\tau}{\eta}\right)\right] \quad (55)$$

while the second approximation is obtained by using the following expression for the angular integral of the source term:

$$\int_{\Omega} \chi(\tau, \omega_j, \omega) I(\tau, \omega, \tau_0) d\omega \approx \sum_{k=1}^M P_k(\tau, \omega_j) I(\tau, \omega, 0) \Delta\omega_k \quad (56)$$

with $d\omega = d\eta d\varphi$. Here, the unit sphere is divided into L domains according the increments $\Delta\omega_j$ of solid angle Ω , where ω_j is the center of $\Delta\omega_j$. The weights $P_k(\tau, \omega_j)$ are defined as integral average values by means of the expression:

$$P_k(\tau, \omega_j) = \frac{1}{\Delta\omega_k} \int_{\Delta\omega_k} \chi(\tau, \omega_j, \omega) d\omega \quad j = 1, 2, 3, \dots, L \quad (57)$$

Making use of these approximations, we obtain the system of linear algebraic equations relative to the unknown values $I(\tau_i, \pm\eta_j, \zeta, \tau_N)$ with ($i = 1, 2, \dots, N; j = 1, 2, \dots, L$). Such a system is solved by the well-known one-step iterative procedure given by Gauss-Seidel's method (Lenoble, 1985). The values of down-going radiation are calculated from one layer to the subsequent layer for each iteration. Namely, on n th iterative step the values of down-going radiation at the $(i+2)$ th layer are obtained by the values of down-going radiation for the i th and $(i+1)$ th layers at the same n th iterative step and by the values of upgoing radiation for the $(i+1)$ th layer at the previous $(n-1)$ th iterative step. At the surface, one takes into account the boundary conditions (7), and then the values of upgoing radiation are calculated from one layer to the following layer upward. The main advantages of this method are:

1. The inner radiation fields are obtained without any additional calculations.
2. The method is simply extended to polarization.
3. The method takes into account the arbitrary dependence of primary optical characteristics of the atmosphere on the height and the arbitrary law of surface reflection.

4. The method with applied point of view makes it possible, in particular, to estimate the role of the nonuniform atmosphere to make the atmospheric corrections of a satellite multispectral data.

The principal disadvantage of the classical Gauss-Seidel method is the linear increase of required computer time with increase of optical thickness of the atmosphere. Therefore, this method is not sufficiently effective for optical thickness $\tau_0 \gg 1$ (Lenoble, 1985). In order to overcome this difficulty, a semi-analytical approach had been proposed to integrate optical thickness $\tau_0 \gg 0$. Until now, we have described the classical Gauss-Seidel method by the three variables τ , η , and φ . We can easily decrease the total number of angular variables using the Fourier series expansions of the phase function $\chi(\tau, \gamma)$ and the bidirectional law of surface reflectance $y(\eta', \eta'', \varphi' - \varphi'')$ according to Fourier series previously defined (Lenoble, 1985). Under these assumptions we get

$$I^m(\tau_{i+2}, \eta, \zeta, \tau_0) = I^m(\tau_i, \eta, \zeta, \tau_0) \exp\left(-\frac{2\Delta\tau}{\eta}\right) + \int_{\tau_i}^{\tau_{i+2}} B^m(\tau', \eta, \zeta, \tau_0) \exp\left(-\frac{\tau_i - \tau'}{\eta}\right) \frac{d\tau'}{\eta} \quad i = 1, 2, \dots, N-2 \quad (58)$$

$$I^m(\tau_i, -\eta, \zeta, \tau_0) = I^m(\tau_{i+2}, -\eta, \zeta, \tau_0) \exp\left(-\frac{2\Delta\tau}{\eta}\right) + \int_{\tau_i}^{\tau_{i+2}} B^m(\tau', -\eta, \zeta, \tau_0) \exp\left(-\frac{\tau' - \tau_i}{\eta}\right) \frac{d\tau'}{\eta} \quad i = 1, 2, \dots, N-1 \quad (59)$$

Thus, the Gauss-Seidel method is now given by this approximation:

$$\int_{\tau_i}^{\tau_{i+2}} B^m(\tau_i, \eta, \zeta, \tau_0) \exp\left(-\frac{\tau_{i+2} - \tau'}{\eta}\right) \frac{d\tau'}{\eta} \approx B^m(\tau_{i+1}, \eta, \zeta, \tau_0) \left[1 - \exp\left(-\frac{2\Delta\tau}{\eta}\right)\right] \quad (60)$$

The second step is now to write the form of classical Gauss quadratures:

$$\int_0^1 f(\eta) d\eta \approx \sum_{j=1}^L f(\eta_j) w_j \quad (61)$$

Then, the application of the Gauss-Seidel method for the radiation field azimuth's harmonics is reduced to the basic boundary value problem for each $m = 0, 1, \dots, M$ of the following system of linear algebraic equations to unknown values $I^m(\tau_i, \eta_j, \zeta, \tau_0)$ with $i = 1, 2, \dots, N-2$ and $j = 1, 2, \dots, L$:

$$I^m(\tau_{i+2}, \eta_j, \zeta, \tau_0) = I^m(\tau_i, \eta_j, \zeta, \tau_0) \exp\left(-\frac{2\Delta\tau}{\eta_j}\right) + B^m(\tau_{i+1}, \eta_j, \zeta, \tau_0) \left[1 - \exp\left(-\frac{2\Delta\tau}{\eta_j}\right)\right] \quad (62)$$

$$I^m(\tau_i, -\eta_j, \zeta, \tau_0) = I^m(\tau_{i+2}, -\eta_j, \zeta, \tau_0) \exp\left(-\frac{2\Delta\tau}{\eta_j}\right) + B^m(\tau_{i+1}, -\eta_j, \zeta, \tau_0) \left[1 - \exp\left(-\frac{2\Delta\tau}{\eta_j}\right)\right] \quad (63)$$

$$\eta_j I^m(\tau_N, -\eta_j, \zeta, \tau_0) = \sum_{k=1}^L y^m(\eta_j, \eta_k) I^m(\tau_N, \eta_k, \zeta, \tau_0) \eta_k \omega_k + \frac{S}{2} y^m(\eta_j, \zeta) \exp\left(-\frac{\tau_N}{\zeta}\right) \quad (64)$$

where

$$B^m(\tau_i, \eta_j, \zeta, \tau_0) = \frac{S}{4} \Lambda(\tau_i) p^m(\tau_i, \eta_j, \zeta) \exp\left(-\frac{\tau_i}{\zeta}\right) + \frac{\Lambda(\tau_i)}{2} \sum_{k=1}^L \omega_k \left[p^m(\tau_j, \eta_j, \eta_k) I^m(\tau_i, \eta_k, \zeta, \tau_0) + p^m(\tau_i, -\eta_j, \eta_k) I^m(\tau_i, -\eta_k, \zeta, \tau_0) \right] \quad (65)$$

$$B^m(\tau_i, -\eta_j, \zeta, \tau_0) = \frac{S}{4} \Lambda(\tau_i) p^m(\tau_i, -\eta_j, \zeta) \exp\left(-\frac{\tau_i}{\zeta}\right) + \frac{\Lambda(\tau_i)}{2} \sum_{k=1}^L \omega_k \left[p^m(\tau_j, -\eta_j, \eta_k) I^m(\tau_i, \eta_k, \zeta, \tau_0) + p^m(\tau_i, \eta_j, \eta_k) I^m(\tau_i, -\eta_k, \zeta, \tau_0) \right] \quad (66)$$

It should be noted that now we have only two variables, τ and η , while the values ζ and τ_0 are parameters. This system is solved by means of the direct iterative procedure analogously to the previously defined iterative schemes:

$$I_{n+1}^m(\tau_{i+2}, \eta_j, \zeta, \tau_i) = I_n^m(\tau_i, \eta_j, \zeta, \tau_0) \exp\left(-\frac{2\Delta\tau}{\eta_j}\right) + B_n^m(\tau_{i+1}, \eta_j, \zeta, \tau_0) \left[1 - \exp\left(-\frac{2\Delta\tau}{\eta_j}\right)\right] \quad (67)$$

$$I_{n+1}^m(\tau_i, -\eta_j, \zeta, \tau_i) = I_n^m(\tau_{i+2}, -\eta_j, \zeta, \tau_0) \exp\left(-\frac{2\Delta\tau}{\eta_j}\right) + B_n^m(\tau_{i+1}, -\eta_j, \zeta, \tau_0) \left[1 - \exp\left(-\frac{2\Delta\tau}{\eta_j}\right)\right] \quad (68)$$

$$\eta_j I_{n+1}^m(\tau_N, -\eta_j, \zeta, \tau_0) = \sum_{k=1}^L y^m(\eta_j, \eta_k) I_n^m(\tau_N, \eta_k, \zeta, \tau_0) \eta_k \omega_k + \frac{S}{2} y^m(\eta_j, \zeta) \exp\left(-\frac{\tau_N}{\zeta}\right) \quad (69)$$

with $n = 0, 1, \dots, K; i = 1, 2, \dots, N-2; j = 1, 2, \dots, L$.

The azimuth harmonics of the source function are given by

$$B_n^m(\tau_i, \eta_j, \zeta, \tau_0) = \frac{S}{4} \Lambda(\tau_i) p^m(\tau_i, \eta_j, \zeta) \exp\left(-\frac{\tau_i}{\zeta}\right) + \frac{\Lambda(\tau_i)}{2} \sum_{k=1}^L w_k [p^m(\tau_i, \eta_j, \eta_k) I_n^m(\tau_i, \eta_k, \zeta, \tau_0) + p^m(\tau_i, -\eta_j, \eta_k) I_n^m(\tau_i, -\eta_k, \zeta, \tau_0)] \quad (70)$$

$$B_n^m(\tau_i, -\eta_j, \zeta, \tau_0) = \frac{S}{4} \Lambda(\tau_i) p^m(\tau_i, -\eta_j, \zeta) \exp\left(-\frac{\tau_i}{\zeta}\right) + \frac{\Lambda(\tau_i)}{2} \sum_{k=1}^L w_k [p^m(\tau_i, -\eta_j, \eta_k) I_n^m(\tau_i, \eta_k, \zeta, \tau_0) + p^m(\tau_i, \eta_j, \eta_k) I_n^m(\tau_i, -\eta_k, \zeta, \tau_0)] \quad (71)$$

Iterative process is over when the following conditions are satisfied:

$$\max \left| \frac{I_{n+1}^m(\tau_i, \pm \eta_j, \zeta, \tau_0) - I_n^m(\tau_i, \pm \eta_j, \zeta, \tau_0)}{I_n^m(\tau_i, \pm \eta_j, \zeta, \tau_0)} \right| \leq \epsilon \quad (72)$$

$i = 1, \dots, N; \quad j = 1, \dots, L$

In such a way, the classical Gauss-Seidel method has been modified by the Fourier expansions of the phase functions and by the law of surface reflectance, which reduce the total number of variables. Finally, let us note that the values of intensity in the horizontal direction $\eta = 0$ may be easily calculated by the intensities at Gaussian points obtained above. Namely, at $\eta = 0$ we get for any optical depth τ :

$$I^m(\tau_i, 0, \zeta, \tau_0) = \frac{\Lambda(\tau)}{2} \int_{-1}^1 p^m(\tau, 0, \eta') I^m(\tau, \eta', \zeta, \tau_0) d\eta' + \frac{S}{4} \Lambda(\tau) p^m(\tau, 0, \zeta) \exp\left(-\frac{\tau}{\zeta}\right) \quad (73)$$

$$\approx \sum_{k=1}^L \omega_k p^m(\tau, 0, \eta_k) [I^m(\tau, \eta_k, \zeta, \tau_0)] + I^m(\tau, -\eta_k, \zeta, \tau_0)] + \frac{S}{4} \Lambda(\tau) p^m(\tau, 0, \zeta) \exp\left(-\frac{\tau}{\zeta}\right) \quad (74)$$

The input optical models for the earth's atmosphere

One important piece of information comes from the models of atmospheric aerosol that enter into the mathematics and algorithms previously described. The World Climate Programme (1982) selected a certain number of aerosol models with their optical properties. Levoni et al. (1997) expanded the number of aerosols and clouds selected by WMP, giving all the optical properties and the algorithms to calculate them and also including the computation to obtain the Legendre's polynomials.

Of course, the atmospheric phase functions have to be normalized according to the already-mentioned rules, and $\chi(\tau, \eta, \zeta, \varphi - \varphi_0)$ and $\chi^m(\tau, \eta, \zeta)$, and must be placed under the condition of reciprocal angular symmetry:

$$\chi(\tau, \eta, \zeta, \varphi - \varphi_0) = \chi(\tau, \eta, \varphi, -\varphi_0) \quad (75)$$

$$\chi^m(\tau, \eta, \zeta) = \chi^m(\tau, \zeta, \eta) \quad (76)$$

The parameterization and approximation of atmospheric phase function can be done, for example, with the help of some of following imitative models:

$$\chi(\tau, \gamma) \cong \frac{1 - g^2(\tau)}{(1 + g^2(\tau) - 2g(\tau)\cos\gamma)^{\frac{3}{2}}} |g(\tau)| < 1 \quad (77)$$

$$\chi(\tau, \gamma) \cong \frac{4\alpha g(\tau)(1 - g^2(\tau))^{2\alpha}}{r \left[(1 + g^2(\tau))^{2\alpha} - (1 - g^2(\tau))^{2\alpha} \right] (1 + g^2(\tau) - 2g(\tau)\cos\gamma)^{\alpha+1}} \quad (78)$$

$\alpha > -\frac{1}{2}, \quad |g(\tau)| < 1$

$$\chi(\tau, \gamma) \cong \alpha \frac{1 - g_1^2(\tau)}{(1 + g_1^2(\tau) - 2g_1(\tau)\cos\gamma)^{\frac{3}{2}}} + (1 - \alpha) \frac{1 - g_2^2(\tau)}{(1 + g_2^2(\tau) - 2g_2(\tau)\cos\gamma)^{\frac{3}{2}}} \quad (79)$$

$|g_1(\tau)| < 1 \quad |g_2(\tau)| < 1$

$$\chi(\tau, \gamma) \cong a \frac{1 - g^2(\tau)}{(1 + g^2(\tau) - 2g(\tau)\cos\gamma)^{\frac{3}{2}}} + (1 - a) \sum_{i=0}^{\tilde{M}} x_i(\tau) P_n(\cos\gamma) \quad (80)$$

$$|g(\tau)| < 1; \quad |x_i(\tau)| < 2i + 1; \quad \tilde{M} < M$$

where g is the Heney-Greenstein parameter. The problem of the approximation of atmospheric phase function $\chi(\tau, \gamma)$ with the help of parameterized phase functions $\tilde{\chi}(\tau, \gamma)$ is a typical problem of optimal choosing

of parameters $g(\tau)$, $g_1(\tau)$, $g_2(\tau)$, a , $x_i(\tau)$, and α according to the well-known condition of the optimization:

$$\min_{(i,j)} \left| \sum_{i=0}^K \sum_{j=0}^L \chi(\tau_j, \gamma_i) - \tilde{\chi}(\tau_j, \gamma_i, g, g_1, g_2 \dots) \right|^2 = \varepsilon^2 \quad (81)$$

where ε is the level of error. It should be remarked that the principal disadvantages arising for the Fourier harmonics $p^m(\eta, \zeta)$ are the non-stability of numerical schemes and the accuracy loss for calculated values in the case of a large numbers $m \gg 1$.

We can now define our strategy on the level of the informational contents of input optical models by the following statements:

1. The input phase function is given according to initial grid point $G(i, j, \dots k)$ and error level of ε . This is the first level of informational content that is determined by the calculation according to Mie theory (Levoni et al., 1997).
2. The problems of the determination of structured coefficients x_n and polynomials functions p^m in the points γ_i of the chosen initial grid are performed by the determination of unknown spectra for known function $\chi(\gamma)$ given in the abovementioned grid point only. It is well known, from spectral theory of signals, that discretization levels cannot be arbitrary.

According to the Nyquist-Kotelnikov theorem, the current frequency of discretization L should exceed at least twice that of the high signal frequency M :

$$L \geq 2M \quad (82)$$

However, we emphasize that high discretization levels of input phase function $\chi(\tau_l, \gamma_i)$, needed for stable and reliable determination of their high Fourier azimuth's harmonics, cannot be achieved practically. Therefore, for numerical interpolations of phase function $\chi(\tau_l, \gamma_i)$ between knots of initial grid points, taking into account the interpolation's accuracy $\tilde{\varepsilon}$, the determination of x_n and p^m provides a good numerical approach. As a result, we obtain a second level of information that is interpolated with a new grid point $\tilde{g}$ and a second level of error ε^* . According to recommendations given, the spline interpolation could provide good computational accuracy for interpolated phase function.

3. A third information content level arises after summing structured coefficients x_n and function p^m in the knots of interpolated grid points, and the determination of its total number N and M according to conditions of minimization is needed:

$$\sum_{j=0}^L \left| \chi_{\tilde{g}}(\tau_l, \gamma_i) - \sum_{i=0}^M x_i P_i(\cos \gamma_j) \right|^2 = \sigma^2 = \min \quad (83)$$

$$\sum_{j=0}^L \left| \chi_{\tilde{g}}(\tau_l, \gamma_i) - \sum_{i=0}^M p_{\tilde{g}}^m(\eta_i, \zeta_i, \tau_l) \cos m \varphi_k \right|^2 = \sigma^2 = \min \quad (84)$$

It must be clear that the previous sums will be carried out only after calibration procedures for coefficients x_n and function p^m . Naturally, the procedures mentioned cannot change the grid points $\tilde{g}$ but only correct values of x_n and p^m .

4. Finally, the final informational level arises after the compression of total numbers of coefficients x_n and azimuth's harmonics p^m on the basis of new approaches connected with mutual estimation of azimuth harmonics radiation fields of primary atmospheric scattering and single-bottom reflection from one side and multiple scattered and reflected radiation field from another side.

This contribution is increased when the number of harmonics m grows. This conclusion is a serious foundation of the compression of total number of azimuth's harmonics in the sum of Eq. 84, according to the following statement:

$$\frac{\Delta p^m(\eta, \zeta, \tau_0)}{p_{(1)}^m(\eta, \zeta, \tau_0)} < \varepsilon \quad m \Rightarrow m_{cut} \quad (85)$$

Further, the parameter L determines the accuracy of calibrated coefficients and functions, while the parameter M influences the approximation's accuracy determined with the help of series Eq. 84. According to Nyquist-Kotelnikov's theorem, both parameters are subjected to relation Eq. 82.

This estimation, in accordance with Nyquist-Kotelnikov's theorem, shows clearly that initial total number of radiation fields azimuth's harmonics M can be compressed significantly in the frame of accuracy estimation given by Eq. 85 lossless of general information content for calculating radiation intensities. Here, the unique parameter needed to approximate the input atmospheric phase function $\chi(\tau, \gamma)$ with help of coefficients x_n and functions $p^m(\eta, \zeta)$, taking into account beforehand approximation accuracy ε , is M :

$$\max_{(\tau_l, \gamma_s)} \left| \frac{\chi(\tau_l, \gamma_s) - \sum_{n=0}^M x_n(\tau_l) P_n(\cos \gamma_s)}{\chi(\gamma_s)} \right| = \tilde{\varepsilon}_1 \quad (86)$$

$$\max_{(\gamma_i, \eta_i, \zeta_j, \varphi_k)} \left| \frac{\chi_{\tilde{g}}(\tau_l, \eta_i, \zeta_j, \varphi_k) - \sum_{m=0}^M p_{\tilde{g}}^m(\tau_e, \eta_i, \zeta_j) \cos m \varphi_k}{\chi_{\tilde{g}}(\gamma_i, \eta_i, \zeta_j, \varphi_k)} \right| = \tilde{\varepsilon}_2 \quad (87)$$

The input optical models for the ground surface

Analogous considerations for the input optical models of the atmosphere may be carried out for input optical models of the ground surface. However, in the case of underlying

surfaces, there are some differences. Atmospheric optical models connect directly chemical and physical parameters of atmospheric aerosol's particles with appropriate atmospheric optical parameters on the basis of Mie theory independently from their influence of natural underlying surfaces. The ideal for surface optical models should be to use appropriate surface diffraction theory. Unfortunately, in real situations the correct approach is replaced by measurements or imitative modeling linking the scattering and absorbing atmosphere. In this case, the final determination of surface optical parameters will significantly depend on the atmospheric optical state. Publications, dedicated to analysis of empirical, semiempirical, and theoretical data, show that differently from the atmosphere the problem of representative and classified optical models of ground surface have not been yet fully solved. Nevertheless, we will take into account real situations with proper parameterization models applied to empirical and semiempirical data. Most representative optical models of the ground surface can be described using the bidirectional reflectance. However, in this case, some problems concerning the bidirectional surface reflectance $r_{sur}(\eta, \zeta, \varphi)$ arise. This is determined as ratio of reflected radiation to the incident flux under the same conditions, with corresponding surface phase function $y(\eta, \zeta, \varphi - \varphi_0)$. Usually, empirical and semiempirical values of a surface bidirectional reflectance are represented by

$$r_{sur} = A(\zeta)\chi_{sur}(\eta, \zeta, \varphi - \varphi_0) \quad (88)$$

where $A(\zeta)$ is the albedo of the surface. By simple considerations we can establish obvious relation between surface phase function $\chi_{sur}(\eta, \zeta, \varphi)$ and probabilistic function $y(\eta, \zeta, \varphi)$, making use of the normalized condition:

$$y(\eta, \zeta, \varphi) = 2\eta\chi_{sur}(\eta, \zeta, \varphi) \quad (89)$$

In order to represent the probabilistic function $y(\eta, \zeta, \varphi)$, the following models can be used as a basic parameterization model for numerical approximations of empirical and semiempirical surface bidirectional brightness coefficients:

1. Orthotropic case

$$y(\eta, \zeta, \varphi) = 2\eta A(\zeta) \quad (90)$$

2. Lambertian surface

$$y(\eta, \zeta, \varphi) = 2\eta A \quad (91)$$

3. Minnaert model

$$y(\eta, \zeta, \varphi) = C\eta^q\zeta^{q-1} \quad (92)$$

4. Mirror surface

$$y(\eta, \zeta, \varphi) = 2\pi\delta(\eta - \zeta)\delta(\varphi)r(\eta) \quad (93)$$

Where $r(\eta)$ is Fresnel's coefficient of mirror reflection

5. Panfilov model (cited by Kondratiev et al., 1992)

$$y(\eta, \zeta, \varphi) = \frac{2\eta d}{1+d} \left[1 + \frac{1-g^2}{d(1+g^2-2g\cos\gamma)^{\frac{3}{2}}} \right] \quad (94)$$

Where g is known as the Heney-Greenstein parameter and d depends on the kind of underlying surface

6. Pinty-Dickinson-Verstraete model (Verstraete et al., 1990) in which bidirectional reflectance of a canopy normalized with respect to the reflectance of a perfectly reflecting Lambertian surface under the same conditions of the sun's illumination and observation is equal to:

$$r_{sur} = \frac{\Lambda_{sur}}{4} \frac{k_1(\zeta)\zeta}{k_1(\zeta)\eta + k_2(\eta)\zeta} \left[P(\pi - \gamma)P_{rel}(\pi - \gamma) + H\left(\frac{\zeta}{k_1(\zeta)}\right)H\left(\frac{\eta}{k_1(\eta)}\right) - 1 \right] \quad (95)$$

where the following symbols are used:

$$k_1(\zeta) = \Phi_1 + \Phi_{2\zeta} \quad (96)$$

$$k_2(\eta) = \Phi_1 + \Phi_{2\eta}$$

$$\Phi_1 = 0.5 - 0.6\chi - 0.033\chi^2 \quad (97)$$

$$\Phi_2 = 0.877(1 - 2\Phi_1) \quad (98)$$

The semiempirical parameter χ is varied in the interval $[-0.4, 0.6]$, accepting the following magnitudes for real canopy's kind:

- (a) 0 for a canopy with uniform leaf orientation distribution (equal probability for all leaf orientations).
- (b) 0.6 for a planophile canopy (mostly horizontal leaves).
- (c) -0.4 for an erectophile canopy (mostly vertical leaves).

The modeling auxiliary function $P_{rel}(\pi - \gamma)$ is given by:

$$P_{rel}(\pi - \gamma) = 1 + \frac{1}{1 + F(\pi - \gamma)} \quad (99)$$

where

$$F(\pi - \gamma) = 4 \left(1 - \frac{4}{3\pi} \right) \frac{\eta}{k_2(\eta)} G(\eta, \zeta, \varphi) \quad (100)$$

and

$$G(\eta, \zeta, \varphi) = \frac{1}{2\rho\Lambda} \left[\frac{1-\zeta^2}{\zeta^2} + \frac{1-\eta^2}{\eta^2} + 2 \frac{\sqrt{(1-\zeta^2)(1-\eta^2)}}{\eta\zeta} \cos(\varphi - \varphi_0) \right] \quad (101)$$

The empirical parameters ρ varied in interval $0.01 \leq \rho \leq 2$. The function $P(\pi - \gamma)$ represents the modeling surface phase function for given semiempirical model by using, for example, the known Heney-Greenstein phase function of Eq. 80 for $\tilde{\gamma} = \pi\gamma$.

Now let us represent the bidirectional reflectance given by Eq. 61 with a help from Eq. 62:

$$2\eta r_{sur}(\eta, \zeta, \varphi) = A(\zeta)y(\eta, \zeta, \varphi) \quad (102)$$

Taking into account normalized condition 3, we obtain the following correlation:

$$y(\eta, \zeta, \varphi) = \frac{4\pi\eta r_{sur}(\eta, \zeta, \varphi)}{\int_0^{2\pi} d\varphi \int_0^1 r_{sur}(\eta, \zeta, \varphi)\eta d\eta} \quad (103)$$

It should be noted that replacing surface phase function $\chi_{sur}(\eta, \zeta, \varphi)$ with the appropriate probabilistic functions $y(\eta, \zeta, \varphi)$ is not quite correct because the transformation, although having some advantages, simultaneously violates the fundamental physical properties of reciprocal angular symmetry $\chi_{sur}(\eta, \zeta, \varphi) = \chi_{sur}(\zeta, \eta, \varphi)$. Thus, the input optical models for the atmosphere we can enter into the analysis of appropriate informational levels are connected with the parameterization and structuring of surface optical quantities. The parameterization of the bidirectional surface reflectance is given the minimization's condition:

$$\min_{i,j,k} \sum_i \sum_j \sum_k |y(\eta_i, \zeta_j, \varphi_k) - \tilde{y}(\eta_i, \zeta_j, \varphi_k)|^2 = \sigma^2 \quad (104)$$

Afterward, the previous procedures of structuring, due to the use of Legendre's polynomials series expansion and Fourier series expansion, can be repeated for the discussed surface case without any great difficulty. The same remarks hold for the procedure of calibration and the sum of structured elements. The main point is the necessity of connecting the total number of the coefficients and functions calculated separately for the atmosphere and underlying surfaces. Thus, as results we have input a unified optical model for an atmosphere-surface system with four levels of informational content, which is needed to accurately define successive radiation fields modeling.

Discrete ordinate method

The discrete ordinate method isolates the azimuth dependence of Eqs. 5 and 6, expanding the phase function into the Legendre polynomial. Using the addition theorem for spherical harmonics and taking into account the orthogonality properties of the Legendre polynomials, we obtain that the phase function can be written as:

$$\chi(\tau, \gamma) = \sum_{m=0}^{2N-1} (2 - \delta_{0m}) p^m(\tau, \eta, \zeta) \cos m(\varphi - \varphi_0) \quad (105)$$

where p^m is given by Eq. 15 and δ_{0m} is the Kronecker delta where $\delta_{0m} = 1$ for $m = 0$ and $\delta_{0m} = 0$ otherwise. Expanding the radiation in the similar way, we obtain:

$$I(\tau, \eta, \zeta, \varphi - \varphi_0) = \sum_{m=0}^{2N-1} I^m(\tau, \eta) \cos m(\varphi - \varphi_0) \quad (106)$$

The procedure is similar to that described in the Fourier expansion section.

The application to the multilayer atmosphere-surface system requires having sufficiently large layers to resolve the radiation in terms of its angular dependence and its optical thickness. The discrete ordinate method was developed by K. Stamnes and Swanson (1981), Stamnes (1982), and Stamnes et al. (1988). Thomas and Stamnes (1999) extended the approach to an atmosphere-ocean system, choosing N_1 layers for the atmosphere and N_2 layers for the ocean. In such a case, Eqs. 19 and 20 can be solved approximating the integral over polar angles by a quadrature sum consisting of $2N_1$ terms in the atmosphere, N_1 terms in the upper hemisphere, and N_1 terms in the downward hemisphere. These last terms are refracted through the interface when the radiation penetrates into the water. Of course, in order to represent the total reflection, we need more terms that can be chosen, such as $2N_2$, ($N_2 > N_1$) for the radiation in water, yielding $2(N_2 - N_1)$ terms of the total reflecting region.

Thus, the solution of the discrete ordinate method applied to the atmosphere (superscripted with a) can be written for the p th layers as:

$$I_p^{\pm}(\tau, \pm\eta_i^a) = \sum_{j=1}^{N_1} \left[C_{-jp} g_{-jp}^a(\pm\eta_i^a) \exp(k_{jp}^a \tau) + C_{jp} g_{jp}^a(\pm\eta_i^a) \exp(-k_{jp}^a \tau) \right] + U_p(\tau, \pm\eta_i^a) \quad (107)$$

where $i = 1, \dots, N_1$ and $p \leq N_1$. The same is true for the p th layers in water (superscripted with w):

$$I_p^{\pm}(\tau, \pm\eta_i^w) = \sum_{j=1}^{N_1} \left[C_{-jp} g_{-jp}^w(\pm\eta_i^w) \exp(k_{jp}^w \tau) + C_{jp} g_{jp}^w(\pm\eta_i^w) \exp(-k_{jp}^w \tau) \right] + U_p(\tau, \pm\eta_i^w) \quad (108)$$

where $i = 1, \dots, N_2$ and $N_1 < p \leq N_1 + N_2$. The eigenvalues k_{jp}^a, k_{jp}^w and the eigenvectors g_{jp}^a, g_{jp}^w are determined solving the homogeneous associate of Eq. 19 with the source terms put equal to zero. The term $U_p^m(\tau, \pm\eta_i)$ is the particular solution.

The coefficients $C_{\pm jp}$ are determined by:

1. The boundary conditions at the top of the atmosphere and at the bottom of the ocean

2. Radiation continuity conditions at each interface between the layers
3. Fresnel's equations at the atmosphere water interface

This leads to a system of linear algebraic equations:

$$\mathbf{AX} = \mathbf{B} \quad (109)$$

whose solution is $\mathbf{X} = \mathbf{A}^{-1} \mathbf{B}$. Here, $\mathbf{A}$ contains information about the properties of the optical system and the bidirectional reflectance distribution function (BRDF). The order of $\mathbf{A}$ is defined by the unknown coefficient $C_{\pm jp}$. The column vector $\mathbf{X}$ contains information on $C_{\pm jp}$, the matrix $\mathbf{B}$ contains information about the particular solutions as well as the lower boundary emissivity.

Since the phase function is the sum of Rayleigh (molecular) scattering plus the Mie scattering due to the effect of aerosol in atmosphere, an improved solution was proposed by T. Nakajima and Tanaka (1981), which computes the Rayleigh scattering exactly. The theoretical approach can be found in Levoni et al. (2001). This approach improves the accuracy of the solution and reduces the computational time, which largely depends on the number of momenta used for Lagrange polynomials.

Spurr (2001) has developed a solution based on the recognition that if the integral properties of one of the layers in a system are perturbed, there is no need to repeat the entire computation from scratch. By its analysis, he deduced that the solution of the problem can be defined by a matrix form of the type:

$$\mathbf{AX}' = \mathbf{B}' \quad (110)$$

In this relation, which is similar to the previous one Eq. 109, the vector column $\mathbf{B}$ depends on the layer parameters that have been changed. Since the matrix $\mathbf{A}$, unperturbed, is solved by LU decomposition, the solution of Eq. 110 can be found by back-substitution using the LU factorized form of $\mathbf{A}$. The Spurr model, named LIDORT, also contains perturbations in layer thermal emission as well as surface albedo.

The first radiative transfer model, LOWTRAN (Kneizys et al., 1988), and the successive version, MODTRAN (Berk et al., 1989), use the discrete ordinate methods, even with a limited number of momenta of Legendre polynomials. The success of the discrete ordinate methods is due to their flexibility, at least in the frame of remote sensing, so various other authors have adopted this approach, dressing the solutions with the optical features of the atmosphere and the surface to obtain a suitable model. These include the SBDART (Ricchiazzi et al., 2007), libRadtran (Mayer et al., 2005), and, in the IR, HARTCODE (Miskolczi et al., 1998).

Statistical modeling or Monte Carlo methods

Monte Carlo methods provide approximate solutions to the radiative transfer equation by sampling the trajectories

of a large number of photons. There are at least three Monte Carlo methods:

1. Forward with bin averaging, where the photons are averaged over various chosen ranges of solid angles.
2. Forward with discrete angles, where the radiation is estimated at each collision for particular predetermined angles.
3. Backward or adjoint with discrete angles, where the photons start at particular angles at the sensor and retrace back the path. Such a method is the most useful for spherical atmospheres.

In solar radiation problems, the photons are introduced with random initial position at the boundary of the domain. Their directions are chosen according to the illumination conditions. The photons then begin their flight. In an efficient Monte Carlo program, a statistical weight is associated with each photon. In practice, a sample transmission is chosen uniformly between 0 and 1. The photon travels along its path until the cumulative extinction along the photon's path reaches the value that corresponds to this transmission. The photon experiences a scattering event in which the scattering angle is determined by choosing a random number and comparing this to the cumulative phase function. After a photon's new direction is determined with a new transmission, this process repeats until the photon leaves the domain or is absorbed. During scattering the absorption is normally modeled by multiplying the photon weight (initially 1) by the single scattering albedo of the medium doing the scattering. At each collision this weight is multiplied by the ratio of the total scattering cross section to the total cross section for all processes, corrected for the absorption probability. The photon trajectory is terminated when the statistical weight falls below a preassigned value (usually 10^{-5}). In highly variable media, a technique called maximum cross section is often used to reduce the per-photon variance of flux. The cumulative extinction at each step is scaled by the maximum extinction within the domain, and the likelihood of scattering at the end of each step depends on the ratio of the local to the maximum extinction. Radiative quantities are computed by these weighted photons.

The atmosphere may contain more than one optically active component (e.g., aerosols, gases, and clouds often coexist). The extinction accumulated along the photon trajectory is the extinction due to all components. Scattering may be treated either by averaging the single scattering phase functions (weighted by the extinction and single scattering albedo) or by choosing the phase function for a single component based on the relative amounts of extinction.

A technique called Russian roulette can help to speed up calculations in absorbing media. At each scattering event, the photon weight is compared with a random number. If the weight exceeds the random number, the photon trajectory is terminated, otherwise the photon weight is reset to 1. In Cornish-Gilliflower release, for instance (<http://code.google.com/p/i3rc-monte-carlo-model/>), the

implementation Russian roulette is performed only when the photon weight is less than one-half. Intensity is computed using a technique called local estimation. At each scattering event, the total extinction to the boundary from the scattering location is computed in each direction at which intensity is desired. The intensity at the exiting location is then incremented by the product of the transmission along that direction, the phase function of the scattering particle evaluated at the angle between the direction the photon is traveling and the intensity direction, and the photon weight. The phase functions of large particles (i.e., those much larger than the wavelength of light being simulated) have large forward peaks due to diffraction. These peaks may be orders of magnitude larger than the phase function, only a few degrees off-axis. If the forward peak happens to align with one of the directions at which intensity is being computed, the contribution from an individual scattering event can be very large, leading to large variance between calculations (and hence large error estimates). In order to reduce this variance, the phase function used for local estimation can be replaced by a hybrid that replaces the original phase function at small angles by a Gaussian of user-specified width. The hybrid phase function is constructed to be continuous and properly normalized.

From 1D to 3D Monte Carlo

Let us now apply the previous concepts to a homogeneous atmosphere with extinction coefficient $\beta(\mathbf{r})$ and phase function $P(\mathbf{r}, \omega \cdot \omega')$. One can calculate the 1D Monte Carlo radiative transfer using a random number generator (numerical algorithm) to produce the random numbers, r_n , between 0 and 1 with a probability distribution function $pdf = 1$. From r_n , one can generate another set of random numbers as $r_x = -\ln(r_n)$ with $pdf = \exp(-r_x)$ and r_x between 0 and ∞ . Then, in order to determine the trajectory of the photons, one can:

1. Determine the starting position of a photon given by $\mathbf{x}_0$ with direction η, ϕ .
2. Generate a photon path length using random numbers $x = r_x$ using the random numbers r_x .
3. Calculate a new photon position $\mathbf{x}_0 + \mathbf{x}$ called the event point (or collision point).
4. Analyze what can happen with the photon at this event point by generating the random number r_n and comparing it with the single scattering albedo Λ . If $r_n > \Lambda$, then the photon is absorbed and the cycle returns to point 1 for a new photon. If $r_n < \Lambda$, the photon is scattered and the process continue to the next step.
5. Find a new direction for the scattered photon using the phase function to calculate the cumulative probability function to relate the scattering angle to a random number.
6. Repeat, starting from the point 3, until all photons are analyzed.

Let us consider now the inhomogeneous atmosphere. We can split it into a homogeneous grid. The point of interaction (or event point) $r_x = \sum \Delta_j \Delta_j \beta(r)$ where $\Delta_j =$ step size in each grid and the free path length is $l = \frac{1}{\beta(r)}$.

In order to estimate the accuracy of the method with respect to the number of photons, one needs to estimate the Monte Carlo error given by the expectation and variance of random variables. They can be computed by the obtained number N of independent values $x_i (i = 1, 2, 3 \dots N)$ of a random variable r_n , each weighted by the probability with which the value is taken. A detailed analysis is described in Marshak and Davis (2005).

In order to obtain a 3D radiative transfer equation, one needs to reconvert the plane-parallel radiative transfer Eqs. 5 and 6 into one equation, taking into account three spatial dimension (x, y , and z) and two angular dimensions (θ, ϕ). This procedure is different than the one we have used in the plane-parallel system previously described, where the azimuth angles and zenith were, respectively, represented by the Fourier series and discrete ordinates. Since in 3D radiative transfer the spatial dimensions cannot be solved analytically, as the optical depth is in plane-parallel transfer, they must be solved in other way. One way is to use the so-called spherical harmonics discrete ordinate method (SHDOM) developed by Pincus and Evans (2009). We do not go into such a method because our purpose here is to describe the solution for the Monte Carlo method.

Let us now assume a cylinder to be infinitesimally small and located somewhere in the atmosphere. It is oriented along an axis ω that is not pointing directly at the target. Rewrite now the integrodifferential radiative transfer radiation Eq. 5 for an unpolarized beam that describes the change of radiation $I(\mathbf{r}, \omega)$ into direction ω as

$$\omega \nabla I(\mathbf{r}, \omega) = -\beta(\mathbf{r})I(\mathbf{r}, \omega) + \frac{\beta_s(\mathbf{r}, \omega)}{4\pi} \int_{4\pi} I(\mathbf{r}, \omega') P(\mathbf{r}, \omega \cdot \omega') d\omega' + S(\mathbf{r}, \omega) \quad (111)$$

where ω is the direction vector with component $(\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta)$ and θ and ϕ are zenith and azimuth angles; $\beta(\mathbf{r})$ is the extinction coefficients; and $\beta_s(\mathbf{r})$ is the scattering coefficient.

Let us rearrange this equation into an integral equation:

$$\left(1 + \frac{1}{\beta(\mathbf{r})} \omega \nabla\right) I(\mathbf{r}, \omega) = -\frac{\beta_s(\mathbf{r})}{\beta(\mathbf{r})} \frac{1}{4\pi} \int_{4\pi} I(\mathbf{r}, \omega') P(\mathbf{r}, \omega \cdot \omega') d\omega' + S(\mathbf{r}, \omega) \frac{1}{\beta(\mathbf{r})} \quad (112)$$

where the ratio $\frac{\beta_s(\mathbf{r})}{\beta(\mathbf{r})}$ is the single scattering albedo. Such integral equation can be solved with the aid of Green's function. In fact, let us transform it into a simple form:

$$L_x f(x) = u(x) \quad (113)$$

where

$$L_x = \left(1 + \frac{1}{\alpha(x)} \frac{d}{dx}\right)$$

is the operator of the left part of the equation, $f(x)$ is the radiance, and $u(x)$ is the right part of Eq. 112, continuous function in the D domain selected. The extinction coefficient $\beta(\mathbf{r})$ has been replaced by $\alpha(x)$. In order to solve the Eq. 113, we look for a function $g: C^1(D) \rightarrow C(D)$ such that $\tilde{L}(g(h)) = h$ where $y(t) = g(h(t))$. This is a convolution equation of the form $y = g \otimes h$ so that the solution is

$$y(t) = \int_a^b g(t-x) h(x) dx$$

where $g(t)$ is the Green's function for $\tilde{L}$ on D . Note that if we take $h(t) = \delta(t)$

$$y(t) = \int_a^b g(t-x) \delta(x) dx = g(t)$$

so the Green's function $g(t)$ can be defined as

$$\tilde{L}_g(t) = \delta(t)$$

Let us assume now that

$$f(x) = \int_a^b k(x, x') u(x') dx' \quad (114)$$

where $x = a$ is the position at the boundary along $-\omega$. Applying the previous assumptions to Eq. 113, we obtain

$$\alpha(x) k(x, x') + \frac{d}{dx} k(x, x') = \alpha(x) \delta(x - x') \quad (115)$$

for $x \neq x'$ the right side is zero and, therefore,

$$k(x \neq x', x') = c. \exp\left(-\int_{x'}^x \alpha(t) |dt|\right) \quad (116)$$

with c is a constant in the regions $x < x'$ and $x > x'$ where the solution is expected to be continuous. The δ function implies a step function in c for which the Green's function of the operator L_x is

$$G_w(x, \mathbf{r}') \begin{cases} 0 & \text{if } x < x' \\ \beta(\mathbf{r}') \exp\left(-\underbrace{\int_{x'}^x \beta(\mathbf{r}' + (t-x')\omega) dt}_{-\tau(\mathbf{r}, \mathbf{r}')} \right) & \text{otherwise} \end{cases} \quad (117)$$

with the optical density $\tau(\mathbf{r}, \mathbf{r}')$ between $\mathbf{r}$ and $\mathbf{r}'$. We obtain the convolution for by integrating $x \in [a, b]$ where b is the distance from $\mathbf{r}'$ to the boundary of the medium along the direction ω . Then,

$$G_\omega(\mathbf{r}, \mathbf{r}') = \beta(\mathbf{r}') \exp(-\tau(\mathbf{r}, \mathbf{r}')) \frac{\delta\left(\omega - \frac{\mathbf{r}-\mathbf{r}'}{|\mathbf{r}-\mathbf{r}'|}\right)}{|\mathbf{r}-\mathbf{r}'|^2} \quad (118)$$

The δ function selects $\mathbf{r}$ that fits to the direction ω and the reference point $\mathbf{r}'$. Then, Eq. 112 can be written in terms of the collision density $f(\mathbf{r}, \omega) = \beta(\mathbf{r})I(\mathbf{r}, \omega)$ by the convolution with $G_\omega(\mathbf{r}, \mathbf{r}')$ and multiplication with $\beta(\mathbf{r})$:

$$f(\mathbf{r}, \omega) = \int_A \int_{4\pi} \frac{\Lambda(\mathbf{r}')}{4\pi} P(\mathbf{r}', \omega \cdot \omega') \times f(\mathbf{r}', \omega') \beta(\mathbf{r}) \exp(-\tau(\mathbf{r}, \mathbf{r}')) \times \frac{\delta\left(\omega - \frac{\mathbf{r}-\mathbf{r}'}{|\mathbf{r}-\mathbf{r}'|}\right)}{|\mathbf{r}-\mathbf{r}'|^2} d\omega' d\mathbf{r}' + \Psi(\mathbf{r}, \omega) \quad (119)$$

where $\Psi(\mathbf{r}, \omega) = \Psi_{thermal}(\mathbf{r}, \omega) + \Psi_{solar}(\mathbf{r}, \omega)$

$$\Psi_{thermal}(\mathbf{r}, \omega) = \beta(\mathbf{r}) \int_A \beta_a(\mathbf{r}') B_\lambda(T(\mathbf{r}')) \times \exp(-\tau(\mathbf{r}, \mathbf{r}')) \frac{\delta\left(\omega - \frac{\mathbf{r}-\mathbf{r}'}{|\mathbf{r}-\mathbf{r}'|}\right)}{|\mathbf{r}-\mathbf{r}'|^2} d\mathbf{r}' \quad (120)$$

and

$$\Psi_{solar}(\mathbf{r}, \omega) = F_0(\lambda) \beta(\mathbf{r}) \int_A \Theta_{sun}(\mathbf{r}') \times \exp(-\tau(\mathbf{r}, \mathbf{r}')) \frac{\delta\left(\omega - \frac{\mathbf{r}-\mathbf{r}'}{|\mathbf{r}-\mathbf{r}'|}\right)}{|\mathbf{r}-\mathbf{r}'|^2} d\mathbf{r}' \quad (121)$$

Then the transformation of the radiative transfer equation (RTE) into an integral equation (IRTE) yields

$$f(\mathbf{r}, \omega) \int_A \int_{4\pi} k[(\mathbf{r}', \omega') \rightarrow (\mathbf{r}, \omega)] f(\mathbf{r}', \omega') d\omega' d\mathbf{r}' + \Psi(\mathbf{r}, \omega) \quad (122)$$

where the transport kernel k is

$$k[(\mathbf{r}', \omega') \rightarrow (\mathbf{r}, \omega)] = k_p[(\mathbf{r}', \omega') \rightarrow (\mathbf{r}, \omega)] \frac{\delta\left(\omega - \frac{\mathbf{r}-\mathbf{r}'}{|\mathbf{r}-\mathbf{r}'|}\right)}{|\mathbf{r}-\mathbf{r}'|^2} \quad (123)$$

with the transport transition density $k_p[(\mathbf{r}', \omega') \rightarrow (\mathbf{r}, \omega)]$ given by

$$k_p[(\mathbf{r}', \omega') \rightarrow (\mathbf{r}, \omega)] = \frac{\Lambda(\mathbf{r}')}{4\pi} P(\mathbf{r}', \omega \cdot \omega') f(\mathbf{r}', \omega') \beta(\mathbf{r}) \exp(-\tau(\mathbf{r}, \mathbf{r}')) \quad (124)$$

which can be interpreted as a probability density of photons to perform the transition $(\mathbf{r}', \omega') \rightarrow (\mathbf{r}, \omega)$. The factor k and k_p can be found by integration over the medium.

Let us rewrite Eq. 122 in operator form as

$$f = Kf + \Psi \quad (125)$$

whose solution can be represented as a Neumann series (i.e., by the order of scattering):

$$f = \Psi + K\Psi + K^2\Psi + K^3\Psi + \dots = \sum_{n=0}^{\infty} K^n \Psi \quad (126)$$

which converges for all bounded media with $0 \leq \Lambda \leq 1$.

If the forward Monte Carlo for radiative transfer is based on IRTE, the backward Monte Carlo is based on the *principle of reciprocity* that describes the radiative process in the reverse direction. Applying the time reversal operator, that is, introducing the minus sign before the direction ω in Eq. 112, we obtain the so-called *adjoint RTE* containing the adjoint transport operator K^+ . Thus, the solution for an adjoint integrodifferential equation with delta function source and homogeneous boundary condition is

$$f^+ = K^+ f^+ + \Psi \quad (127)$$

where Ψ is the detector function. The solution of Eq. 127 can be found as for forward time direction:

$$f^+ = \sum_{\eta=0}^{\infty} K^{+\eta} \cdot \Psi \quad (128)$$

showing the solution of the RTE in the form of Newman series can be expressed by nested integrals.

Monte Carlo methods are ideal for computing numerical solutions of previous integrals. Considering a natural event, the set of possible results can be continuous or discrete. The probability of an event can be measured using the so-called probability density function *pdf*, while the cumulative distribution function *cdf* is the integral of *pdf*. All the terms we have introduced, that is, the phase function and the free path length, can be computed using the *pdf* and *cdf* from which it is also possible to derive the expectation value, higher momentum, variance, and standard deviation of a random variable. The physics of radiation transport is merged with stochastic methods to create

numerical algorithms that estimate the collision density of the radiance. The methods described are based on the principle of reciprocity, either to simulate the natural process in forward direction, the photon source in the sun, or to describe the backward or adjoint process, the trajectory originating at the detector's position. In this case, the initial distribution of propagation corresponds to the field of view (FOV) of the detector. One key for the implementation of Monte Carlo simulation is the ray tracer simulating the propagation of light. A ray tracer uses random numbers to decide over the occurrence of events like extinction of light, scattering, and absorption, according to the local physical conditions. The trajectory is completed when the photon is absorbed or leaves the atmosphere.

Monte Carlo methods are exhaustively described in books by Marchuck et al. (1980) and Marshak and Davis (2005). A series of different papers deals with different aspects of Monte Carlo methods; among the others we cite Iwabuchi (2006) and Baker et al. (2003), which describe numerical techniques to reduce the computational demands of Monte Carlo simulations; O'Hirok and Gautier (1998), which describes techniques for broadband Monte Carlo simulations; and Cornet et al. (2010) and Battaglia and Mantovani (2005), which describes techniques to include polarization into Monte Carlo simulations. The latter also focuses on microwave radiation and anisotropic media. Tanaka and Ellison (1996; 2000) describe thermal infrared Monte Carlo simulations.

Summary

The radiative transfer equations in an atmosphere-surface coupled system are a complex integrodifferential equations system requiring proper solution techniques. Despite advances in computer science, solutions remain time consuming and, to ensure the required accuracy, they require proper selection. This entry deals with some possible solution techniques. In the Introduction, we cite the classical texts and have selected the most advanced one in order to give the most effective overview. Further, we describe the selected methods by a cascade process by which the different techniques can be used singly or all together. The methods we have selected are the Fourier expansion, the iterative method, primary scattering, Gauss-Seidel, Discrete Ordinate, and Monte Carlo. All these methods are interconnected; the solution of one method can be also used for another method, as will be explained in the text. Even the statistical approach or Monte Carlo uses some solutions described by the other numerical selected methods. We introduce the rigorous analytical approach by the solutions embedded into the iterative and Fourier approach. In order to give a complete picture, we also introduce the input models of atmosphere and surface and how to use them. The bibliography provides sources for some of the software, which is usually in the public domain.

Definition

The radiative transfer theory, also called transport theory, is the theory describing the wave propagation through a medium characterized by a random distribution of scatterers. It usually applies to electromagnetic radiation, but it can be generalized to acoustic radiation. The radiative transfer theory is one of the two theories developed to deal with radiation absorption and multiple-scattering problems: the other approach is the so-called wave analytical theory. It is generally formulated in terms of specific intensity and can be extended to polarized radiation. The radiative transfer theory constitutes the physical basis of several remote sensing techniques due to its relative simplicity and capability to deal with multiple-scattering effects.

Introduction

The subject of radiative transfer is very transversal and, indeed, covers several research fields, including astrophysics, applied physics, optics, planetary sciences, atmospheric sciences, meteorology, and engineering. Generally speaking, we can define the *radiative transfer theory* (RTT), also called *transport theory*, as the theory describing the wave propagation through a medium characterized by a *random distribution of scatterers* (Chandrasekhar, 1960). It usually applies to electromagnetic radiation, but it can be generalized to acoustic radiation (Ishimaru, 1978; Tsang et al., 2000).

The RTT is one of the two distinct theories developed to deal with radiation absorption and multiple-scattering problems: the other approach is the so-called wave analytical theory (WAT). The latter starts, in case of electromagnetic waves, from the basic *Maxwell differential equations* which are usually transformed into an equivalent wave equation (Ishimaru, 1978; Tsang et al., 1985). The wave analytical theory is, in principle, able to treat absorption and scattering to any order together with diffraction and interference effects. However, as intuitive, the detailed approach of the WAT is very cumbersome and mathematically complicated,

so that a formulation which includes all multiple-scattering terms is practically impossible to derive.

The RTT, conversely, does not start with the wave equation, but simplifies the problem dealing with the *transport of energy* through a medium containing scatterers (Chandrasekhar, 1960; Ishimaru, 1978; Ulaby et al., 1986). The development of theory is almost heuristic as it is not rigorously derived from the wave equation as the wave analytical theory. Although diffraction and interference effects are included in the description of the absorption and scattering properties of a single scatterer, RTT does not actually include the *interferential effects* of the ensemble of the scatterers. As a matter of fact, RTT assumes that there is no correlation between the fields scattered by each particle (so-called independent-scattering assumption), so that the addition of the scattered power, rather than the addition of the scattered fields, holds. Indeed, RTT carries information on the mutual coherence of the diffuse field, as it will be introduced later on dealing with the assumptions and limitations of RTT at the end of this section (Ishimaru, 1975; Furutsu, 1975).

The RTT can be expressed in terms of specific intensity which expresses the radiant power per unit area, solid angle, and frequency. If the specific intensity is scalar, as for the case of totally unpolarized light, the *radiative transfer equation* (RTE) becomes a single differential equation which is usually called the *scalar RTE* (Ulaby and Elachi, 1990). For vector fields, the scalar specific intensity can be generalized using the four Stokes parameters which lead to four coupled differential equations. The latter is sometimes called the *vector RTE* (Tsang et al., 1985). In the following sections, we will briefly introduce both scalar and vector RTEs.

Brief history of radiative transfer theory

The RTT was pioneered by astrophysicists who opened the field at the beginning of the twentieth century. The work of Schuster (1905) on the investigation of the light radiation transfer through a foggy atmosphere appears to be the first paper discussing the importance of multiple scattering. Schuster basically formulated the problem in terms of upward and downward light beams, the basic assumption for the so-called two-stream approximation of radiative transfer. The latter was also employed by Schwarzschild (1906) to explain the limb darkening of the sun. In his effort to understand the physical interior of a star, Eddington (1916) developed a first-order expansion of intensity in terms of Legendre polynomials, leading to the so-called Eddington approximation of radiative transfer. In the same years, Schwarzschild introduced the concept of the medium emission as well as absorption within the context of thermodynamic equilibrium, a subject widely used to deal with thermal infrared radiation in molecular atmosphere with negligible scattering. These pioneering works were collected in a volume by Menzel in the middle of the 1960s (1966).

In the 1950s, in his landmark book, Chandrasekhar presented the subject of radiative transfer in plane-parallel atmospheres as a branch of mathematical physics and developed numerous solution methods and techniques, including the consideration of polarized radiation (Chandrasekhar, 1960). An equally fundamental treatise is the one of Sobolev (1975). In the 1960s and 1970s, many efforts were carried out to provide a robust physical basis of the RTT and its relation with the wave analytical theory (Ishimaru, 1978; Tsang et al., 1985).

The basic differential equation of RTT is equivalent to Boltzmann's equation (also known as the Boltzmann-Maxwell collision equation), used in the kinetic theory of gases (Sommerfeld, 1956). There is a noteworthy equivalence between RTT and the neutron transport theory which was well established by Davison (1958). The formulation of RTT is, indeed, flexible and capable of treating many physical problems. It has been successfully applied to the problems of atmospheric radiation, underwater visibility, marine biology, photographic optics, and wave propagation through planets, stars, and galaxies.

Specific intensity

The fundamental quantity in the RTT is the *scalar specific intensity* I , sometimes also called radiance (indicated by L) or brightness (indicated by B). The concept of the specific intensity can be introduced considering a flow of wave energy in a random medium where the frequency, phase, and amplitude of the wave undergo random variations in time and space. This implies that the magnitude and direction of its power flow density vector (also called Poynting vector in electromagnetics) vary continuously in time and space (Ishimaru, 1978; Tsang et al., 1985).

At a given point $\mathbf{r}$ and a direction defined by the unit vector $\hat{\mathbf{s}}$, the scalar specific intensity $I(\mathbf{r}, \hat{\mathbf{s}})$ is measured in $\text{W m}^{-2} \text{sr}^{-1} \text{Hz}^{-1}$ (where sr stands for steradian or solid unit angle). Referring to Figure 1, the amount of elementary power dP (in Watts) flowing within a solid angle $d\Omega$ through an elementary area dA oriented along

Radiative Transfer, Theory, Figure 1 Geometry for a specific intensity emitted by an elementary surface dA .

the direction of the unit vector $\hat{\mathbf{n}}$ in a frequency interval dv is given by

$$dP = I(\mathbf{r}, \hat{\mathbf{s}}) \cos \theta dA d\Omega dv \quad (1)$$

Indeed, Equation 1 describes the radiation flux emitted from a surface dA along $\hat{\mathbf{s}}$ and it is often referred as the *forward* (or *outward*) specific intensity $I^+ = I(\mathbf{r}, \hat{\mathbf{s}})$ (also called *surface intensity*). Conversely, if the point $\mathbf{r}$ is taken on the surface dA , we can express the *backward* (or *inward*) specific intensity $I^- = I(\mathbf{r}, -\hat{\mathbf{s}})$ incident upon the surface along $-\hat{\mathbf{s}}$ (also called *field intensity*). In space, the inward power upon dA should be identical to the outward power emitted from the same surface, so that: $I^+ = I^-$.

In electromagnetics, the specific intensity $I(\mathbf{r}, \hat{\mathbf{s}})$ can be statistically related to the Poynting vector $\mathbf{S}$. If the latter at a given point $\mathbf{r}$ is a random function of time and each component of $\mathbf{S}$ varies in time, the tip vector of $\mathbf{S}$ moves randomly in time. If this random variability is expressed by a probability density function p_S , we can then define the specific intensity as the *ensemble average value* of the random vector $\mathbf{S}$. This means that the $I(\mathbf{r}, \hat{\mathbf{s}})$ is basically the sum of all random Poynting vectors $\mathbf{S}$ whose tips are located within a solid unit angle in the direction $\hat{\mathbf{s}}$. The same interpretation can be easily extended to acoustic waves (Ishimaru, 1978).

Flux and energy density

The *forward flux density* F^+ (measured in $\text{W m}^{-2} \text{Hz}^{-1}$) passing through an elementary area dA on a finite surface A is obtained by integrating Equation 1 over a semisolid angle $2\pi^+$ in the forward interval ($0 \leq \theta \leq \pi/2$) along the direction $\hat{\mathbf{n}}$:

$$F^+(\mathbf{r}, \hat{\mathbf{n}}) = \int_{2\pi^+} I(\mathbf{r}, \hat{\mathbf{s}}) \hat{\mathbf{s}} \cdot \hat{\mathbf{n}} d\Omega \quad (2)$$

Similarly, for the *backward flux density* F^- through dA in the backward direction ($-\hat{\mathbf{n}}$) and for a semisolid angle $2\pi^-$ in the backward interval ($\pi/2 \leq \theta \leq \pi$), we can define:

$$F^-(\mathbf{r}, \hat{\mathbf{n}}) = \int_{2\pi^-} I(\mathbf{r}, \hat{\mathbf{s}}) \hat{\mathbf{s}} \cdot (-\hat{\mathbf{n}}) d\Omega \quad (3)$$

For a radiating surface, the forward flux density F^+ is often called *radiant emittance* or *radiant excitance* (Elachi, 1987). For receiving surface, the backward flux density F^- is also called *irradiance*. The net flux density can be expressed as the component of a flux density vector $\mathbf{F}(\mathbf{r})$ along $\hat{\mathbf{n}}$ equal to the difference between the forward flux density and the backward flux density. For the flux density vector $\mathbf{F}(\mathbf{r})$, it holds over the whole solid angle:

$$F(r) = \int_{4\pi} I(r, \hat{\mathbf{s}}) \hat{\mathbf{s}} d\Omega \quad (4)$$

Other useful definitions related to the specific intensity are the *energy density* $u(\mathbf{r})$ and the *average intensity* $U(\mathbf{r})$, defined by

$$u(\mathbf{r}) = \frac{1}{c} \int_{4\pi} I(\mathbf{r}, \hat{\mathbf{s}}) d\Omega = \frac{c}{4\pi} U(\mathbf{r}) \quad (5)$$

where c is the wave velocity with u measured in $\text{J m}^{-3} \text{Hz}^{-1}$ and U measured in $\text{W m}^{-2} \text{Hz}^{-1}$. Note that Equation 4 is derived considering that the energy density $du(\mathbf{r})$ can be expressed as the ratio of the energy $I dA d\Omega dv dt$ and the volume $dA c dt$ it should occupy.

As an important example, we can consider the case when the specific intensity $I(\mathbf{r}, \hat{\mathbf{s}})$ is independent of the direction $\hat{\mathbf{s}}$ so that the radiation is said to be *isotropic*. In this circumstance, the total net flux density F along $\hat{\mathbf{n}}$ can be expressed by

$$F(\mathbf{r}) = \mathbf{F}(\mathbf{r}) \cdot \hat{\mathbf{n}} = \int_{4\pi} I(\mathbf{r}, \hat{\mathbf{s}}) \cos \theta d\Omega = I_0(\mathbf{r}) \pi \quad (6)$$

where I_0 is average specific intensity value. The previous relationship is called the *Lambert law* which can be also expressed in terms of power from Equation 1 as a cosine law: $P = P_0 \cos \theta$ with P_0 the average power.

Invariance and boundary conditions

It can be proved that the specific intensity is *invariant* along the ray path in free space (Ishimaru, 1978; Tsang et al., 2000). Even though this property might seem to contradict the intuitive spreading of power flux in free space, it should be reminded that the specific intensity is defined per unit solid angle from Equation 1. The proof of the *specific intensity invariance* can be approached by considering two points $\mathbf{r}_1$ and $\mathbf{r}_2$ in free space separated by a distance r along the direction $\hat{\mathbf{s}}$ and two small areas dA_1 and dA_2 perpendicular to $\hat{\mathbf{s}}$. Let $I(\mathbf{r}_1, \hat{\mathbf{s}})$ and $I(\mathbf{r}_2, \hat{\mathbf{s}})$ be the specific intensity at $\mathbf{r}_1$ and $\mathbf{r}_2$, respectively. The power received by dA_2 can be expressed in two ways: (1) as $I(\mathbf{r}_1, \hat{\mathbf{s}}) dA_1 d\Omega_1 dv$ from Equation 1 and (2) as $I(\mathbf{r}_2, \hat{\mathbf{s}}) dA_2 d\Omega_2 dv$. The previous expression must be equal, so that $I(\mathbf{r}_1, \hat{\mathbf{s}}) dA_1 d\Omega_1 = I(\mathbf{r}_2, \hat{\mathbf{s}}) dA_2 d\Omega_2$. But it holds $dA_1 = r^2 d\Omega_2$ and $dA_2 = r^2 d\Omega_1$, so that it results $I(\mathbf{r}_1, \hat{\mathbf{s}}) = I(\mathbf{r}_2, \hat{\mathbf{s}})$.

Once dealing with applications, the random medium is very likely inhomogeneous. This means that when looking for the specific intensity within the considered volume, we need to know the *boundary surface conditions* in terms of specific intensity (Tsang et al., 1985; Tsang et al., 2000; Ulaby et al., 1986). It is customary in RTT to divide the boundary conditions into three categories: (1) isotropic surface, (2) planar surface, and (3) rough surface.

In the first case, the surface is also called *Lambertian* as the behavior of the specific intensity $I(\mathbf{r}, \hat{\mathbf{s}})$ is independent of the direction $\hat{\mathbf{s}}$ and follows that of the Lambert law. This can be expressed in terms

$$I^+(\mathbf{r}_s) = I^-(\mathbf{r}_s) \quad (7)$$

where $\mathbf{r}_s$ is the position vector belonging to the boundary surface S .

In the second case, the surface is called *Fresnelian* as the behavior of the specific intensity $I(\mathbf{r}, \hat{\mathbf{s}})$ is regulated by the Snell law (i.e., reflection angle equal to incident angle) and the relation between the reflected and transmitted wave amplitude, with respect to the incident one, follows the Fresnel coefficient (see Figure 2). If $\Gamma_{\parallel}$ and $\Gamma_{\perp}$ are the reflection coefficients of the electric field polarized parallel and perpendicular to the plane of incidence, respectively, for unpolarized (scalar) incident specific intensity I^- and reflected specific intensity I^+ , it holds

$$I^+(\mathbf{r}_s, \hat{\mathbf{s}}_r) = |\Gamma(\hat{\mathbf{s}}_i)|^2 I^-(\mathbf{r}_s, \hat{\mathbf{s}}_i) \text{ with } \hat{\mathbf{n}} \cdot \hat{\mathbf{s}}_r = \hat{\mathbf{n}} \cdot \hat{\mathbf{s}}_i \quad (8)$$

where $\hat{\mathbf{s}}_r$ and $\hat{\mathbf{s}}_i$ are the unit vector for the reflection and incident directions, whereas $|\Gamma|^2 = 0.5 (|\Gamma_{\parallel}|^2 + |\Gamma_{\perp}|^2)$ is the unpolarized reflectance (or reflectivity) of the Fresnel boundary surface (Tsang et al., 1985). For the *surface transmittance*, a similar argumentation can be carried out considering the transmission Fresnel coefficients and the power conservation at the surface so that the incident power should be equal to the sum of the reflected and transmitted ones (Ishimaru, 1978).

In the third general case, the surface may be called *natural* and there is not necessarily an analytical law relating the incident and the reflected specific intensity (Ulaby et al., 1986). If $\gamma_d(\hat{\mathbf{s}}_r, \hat{\mathbf{s}}_i)$ is the power differential reflectivity of the boundary surface, it can be written in a general way:

$$I^+(\hat{\mathbf{r}}_s, \hat{\mathbf{s}}_r) = \int_{2\pi} \gamma_d(\hat{\mathbf{s}}_r, \hat{\mathbf{s}}_i) I^-(\mathbf{r}_s, \hat{\mathbf{s}}_i) d\Omega_i \quad (9)$$

where $d\Omega_i$ is the solid angle including all incident directions in 2π ($\pi/2 \leq \theta \leq \pi$) and $\hat{\mathbf{s}}_r$ spans the forward interval ($0 \leq \theta \leq \pi/2$). The characterization of γ_d will depend on the surface geometry and composition.

Radiative transfer equation

After examining the invariance property and the boundary conditions, we are ready to analyze the propagation of the fundamental quantity in RTT, the specific intensity $I(\mathbf{r}, \hat{\mathbf{s}}_r)$, through a medium containing a random distribution of scatterers. The latter scatter, absorb, and emit the wave energy, and all these characteristics should be included into a differential equation expressed in terms of the specific intensity.

The scalar *radiative transfer equation* (RTE) can be derived by considering an unpolarized specific intensity $I(\mathbf{r}, \hat{\mathbf{s}})$ incident upon a cylindrical elementary volume dV with a cross section dA and a length ds , as in Figure 3. The volume $dV = ds dA$ contains a random distribution of scatterers with different properties described by the parameters q_i ($i = 1 - Q$). The latter can represent the size, shape, and orientation variability of the scatterers and are

Radiative Transfer, Theory, Figure 2 Boundary condition for specific intensity at the planar surface S separating two media with different refractive indexes.

Radiative Transfer, Theory, Figure 3 Propagation and interaction of the specific intensity upon an elementary volume containing a random distribution of scatterers.

usually described by a *joint* probability density function $p_q(q_1, \dots, q_Q)$, usually normalized to one. In case we refer to spherical particles with different diameters, then the Q scatterer parameters reduce to $q_1 = D$ and $p_D(D)$. In order to derive the RTE, we need (1) first, to characterize the volumetric interaction in terms of absorption and scattering and (2) then to consider the balance of the power along the ray, taking into account thermal emission, incident radiation, and multiple scattering.

Volumetric interaction parameterization

The volumetric interaction between the incident radiation and an ensemble of scatterers needs to take into account both absorption and scattering. In this respect, we can exploit the assumption of independent scattering, which is a negligible correlation among the scattered fields. This means that the absorbed and scattered power of each scatterer can be simply summed up to provide the total absorbed and scattered power (Ishimaru, 1978; Tsang et al., 2000).

For a single scatterer at a point $\mathbf{r}$ and characterized by some properties q_i , we can define the absorption cross section $\sigma_a(r, \hat{s}_i, q_1, \dots, q_Q)$ (measured in m^2) with respect to

an incident wave along the unit direction $\hat{s}_i$. The cross section σ_a is the ratio between the power dP_a , absorbed by the scatterer itself, and incident power flux density S_i and will depend on the scatterer geometry, orientation, and composition. Considering an ensemble of the previous scatterers, randomly distributed after $p_q(q_1, \dots, q_Q)$, and summing over all the absorbed powers dP_a , the *volumetric absorption coefficient* $\kappa_a(\mathbf{r}, \hat{s}_i)$ is defined as

$$\kappa_a(\mathbf{r}, \hat{s}_i) = N_q \int_{\Delta q} \sigma_a(\mathbf{r}, \hat{s}_i, q_1, \dots, q_Q) p_q(q_1, \dots, q_Q) dq_1, \dots, dq_Q \quad (10)$$

where N_q is the number of scatterers per unit volume (measured in m^{-3}) and Δq is the domain of integration. This means that κ_a is measured in m^{-1} .

A similar argument can be used to introduce the *differential scattering cross section* $\sigma_d(\mathbf{r}, \hat{s}_r, \hat{s}_i, q_1, \dots, q_Q)$ (measured in m^2) which, however, depends not only on the incident direction $\hat{s}_i$ but also on the scattering direction $\hat{s}_r$. The cross section σ_d is given by the ratio of the power flux intensity $r^2 dS_r$, scattered at a distance r in the far field by the scatterer itself, and the incident power flux density S_i

along $\hat{\mathbf{s}}_i$. Considering a scatterer ensemble and summing over all the scattered power flux intensities $r^2 dS_r$, the volumetric *differential scattering coefficient* $\kappa_d(\mathbf{r}, \hat{\mathbf{s}}_r, \hat{\mathbf{s}}_i)$ may be defined as

$$\kappa_d(\mathbf{r}, \hat{\mathbf{s}}_r, \hat{\mathbf{s}}_i) = N_q \int_{\Delta q} \sigma_d(\mathbf{r}, \hat{\mathbf{s}}_i, q_1, \dots, q_Q) \quad (11)$$

$$p_q(q_1, \dots, q_Q) dq_1 \dots dq_Q$$

From Equation 11, it is straightforward to derive the *volumetric scattering coefficient* $\kappa_s(\mathbf{r}, \hat{\mathbf{s}}_i)$, as it is the integral of κ_d over all scattering direction in 4π :

$$\begin{aligned} \kappa_s(\mathbf{r}, \hat{\mathbf{s}}_i) &= \int_{4\pi} \kappa_d(\mathbf{r}, \hat{\mathbf{s}}_r, \hat{\mathbf{s}}_i) d\Omega_r = N_q \\ &\int_q \sigma_s(\mathbf{r}, \hat{\mathbf{s}}_i, q_1, \dots, q_Q) p_q(q_1, \dots, q_Q) dq_1 \dots dq_Q \end{aligned} \quad (12)$$

where Ω_r is the scattering solid angle including all directions $\hat{\mathbf{s}}_r$ and σ_s is the *scattering cross section* of each scattered, measured in m^2 . From Equations 11 and 12, it is also derived that the scattering cross section σ_s is the integral of differential cross section σ_d over the whole solid angle. Note that the *coefficient* $\kappa_s(\mathbf{r}, \hat{\mathbf{s}}_i)$, measured in m^{-1} , is consistent with the *coefficient* $\kappa_a(\mathbf{r}, \hat{\mathbf{s}}_i)$, whereas σ_s is the ratio between the scattered power dP_r and the incident power flux density S_i .

Finally, for an ensemble of scatterers at a point $\mathbf{r}$, where both volumetric absorption and scattering take place, it is customary to define the *volumetric extinction coefficient* $\kappa_e(\mathbf{r}, \hat{\mathbf{s}}_i)$ as

$$\kappa_e(\mathbf{r}, \hat{\mathbf{s}}_i) = \kappa_a(\mathbf{r}, \hat{\mathbf{s}}_i) + \kappa_s(\mathbf{r}, \hat{\mathbf{s}}_i) \quad (13)$$

where the extinction is supposed to be sum of the absorption and scattering effects. A further important quantity is the *volumetric scattering phase function* $p(\mathbf{r}, \hat{\mathbf{s}}_r, \hat{\mathbf{s}}_i)$, defined as

$$p(\mathbf{r}, \hat{\mathbf{s}}_r, \hat{\mathbf{s}}_i) = 4\pi \frac{\kappa_d(\mathbf{r}, \hat{\mathbf{s}}_r, \hat{\mathbf{s}}_i)}{\kappa_s(\mathbf{r}, \hat{\mathbf{s}}_i)} \quad (14)$$

where its angular normalization over the whole solid angle is 4π . Sometimes, the phase function is defined with respect to κ_e , instead of κ_s , so that its angular normalization yields the product between 4π and the *volumetric albedo* (e.g., Ishimaru, 1978). The latter is defined as

$$w(\mathbf{r}, \hat{\mathbf{s}}_i) = \frac{\kappa_s(\mathbf{r}, \hat{\mathbf{s}}_i)}{\kappa_e(\mathbf{r}, \hat{\mathbf{s}}_i)} \quad (15)$$

As an example, we can consider a random distribution of spherical particles of diameter D_0 . In this case, the joint probability distribution reduces to a Dirac impulse function: $p_D(D) = \delta(D - D_0)$. From Equations 10, 11, 12, 13, 14, and 15, the volumetric interaction parameters are then simply equal to

$$\begin{aligned} \kappa_a(\mathbf{r}, \hat{\mathbf{s}}_i) &= N_D \sigma_a(\mathbf{r}, \hat{\mathbf{s}}_i); \quad \kappa_s(\mathbf{r}, \hat{\mathbf{s}}_i) = N_D \sigma_s(\mathbf{r}, \hat{\mathbf{s}}_i); \\ w(\mathbf{r}, \hat{\mathbf{s}}_i) &= \frac{\sigma_s(\mathbf{r}, \hat{\mathbf{s}}_i)}{\sigma_e(\mathbf{r}, \hat{\mathbf{s}}_i)} \end{aligned} \quad (16)$$

Differential equation formulation

Considering the geometry of Figure 3, we can then suppose the random scatterers characterized by the volumetric interaction parameters previously defined. From Equation 13, the reduction of the specific intensity $I(\mathbf{r}, \hat{\mathbf{s}})$ due to its propagation through the volume $dV = ds dA$ is equal to

$$\begin{aligned} dI(\mathbf{r}, \hat{\mathbf{s}}) &= -ds[\kappa_a(\mathbf{r}, \hat{\mathbf{s}}) + \kappa_s(\mathbf{r}, \hat{\mathbf{s}})] \\ I(\mathbf{r}, \hat{\mathbf{s}}) &= -ds\kappa_e(\mathbf{r}, \hat{\mathbf{s}})I(\mathbf{r}, \hat{\mathbf{s}}) \end{aligned} \quad (17)$$

On the other hand, the specific intensity increases because a portion of $I(\mathbf{r}, \hat{\mathbf{s}}')$, incident on dV from another direction $\hat{\mathbf{s}}'$, is scattered into the direction $\hat{\mathbf{s}}$ and is added to $I(\mathbf{r}, \hat{\mathbf{s}})$. This contribution along $\hat{\mathbf{s}}$ at a point $\mathbf{r}$ can be derived from the *differential scattering coefficient* $\kappa_d(\mathbf{r}, \hat{\mathbf{s}}_r, \hat{\mathbf{s}}_i)$ by integrating $I(\mathbf{r}, \hat{\mathbf{s}}')$, weighted by $\kappa_d(\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}')$, over all the incident directions $\hat{\mathbf{s}}'_i = \hat{\mathbf{s}}'$ within the entire solid angle:

$$dI(\mathbf{r}, \hat{\mathbf{s}}) = +ds \int_{4\pi} \kappa_d(\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}') I(\mathbf{r}, \hat{\mathbf{s}}') d\Omega' \quad (18)$$

where Ω' is the solid angle including all directions incident on the volume dV from directions different from $\hat{\mathbf{s}}$. The term in Equation 18 is often called the *multiple-scattering pseudo-source*.

Within the volume dV , if a local thermodynamic equilibrium can be supposed, the *Kirchhoff law* holds. The latter states that a medium that absorbs radiation at a given frequency, at the same time emits radiation at the same frequency. The rate at which emission takes place is a function of temperature and frequency and is related to the Planck law which for a black body (BB) gives the following isotropic specific intensity I_{BB} :

$$I_{BB}(\mathbf{r}) = \frac{hv^3}{c^2} \frac{1}{e^{hv/KT} - 1} \quad (19)$$

where h and K are the Planck and Boltzmann constants, respectively, c is wave velocity, v the frequency, and T the temperature. For $hv \ll KT$ (valid at microwaves), $I_{BB} \approx KT/\lambda^2$ with λ the wavelength. It is easy to show that for the thermal emission specific intensity, it holds:

$$dI(\mathbf{r}, \hat{\mathbf{s}}) = +ds\Xi(\mathbf{r}, \hat{\mathbf{s}}) = +ds\kappa_a(\mathbf{r}, \hat{\mathbf{s}})I_{BB}(\mathbf{r}, \hat{\mathbf{s}}) \quad (20)$$

which shows that the emission power Ξ per unit volume, solid angle, and frequency of a medium is equal to the product κ_a times I_{BB} .

Adding all the contributions in Equations 17, 18, and 20, we get the *integrodifferential equation of radiative transfer*:

$$\frac{dI(\mathbf{r}, \hat{\mathbf{s}})}{ds} = \cdot [I(\mathbf{r}, \hat{\mathbf{s}})] = -\kappa_e(\mathbf{r}, \hat{\mathbf{s}})I(\mathbf{r}, \hat{\mathbf{s}}) + \int_{4\pi} \kappa_d(\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}')I(\mathbf{r}, \hat{\mathbf{s}}')d\Omega' + \kappa_a \quad (21)$$

where the second term expresses the divergence of the specific intensity vector. Equation 21 can be also rearranged by introducing the so-called optical distance τ , defined by (Chandrasekhar, 1960)

$$\tau(\mathbf{r}, \hat{\mathbf{s}}) = \int_{4\pi} \kappa_e(\mathbf{r}, \hat{\mathbf{s}})ds \quad (22)$$

By using the definition of the scattering phase function in Equation 14, the RTE in Equation 21 is also given by

$$\frac{dI(\mathbf{r}, \hat{\mathbf{s}})}{d\tau} = -I(\mathbf{r}, \hat{\mathbf{s}}) + \frac{w(\mathbf{r}, \hat{\mathbf{s}})}{4\pi} \int_{4\pi} p(\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}')I(\mathbf{r}, \hat{\mathbf{s}}')d\Omega' + [1 - w(\mathbf{r}, \hat{\mathbf{s}})]I_{BB}(\mathbf{r}) \quad (23)$$

At microwaves, it is useful to introduce the brightness temperature $T_B(\mathbf{r}, \hat{\mathbf{s}})$, defined as

$$I(\mathbf{r}, \hat{\mathbf{s}}) = \frac{K}{\lambda^2} T_B(\mathbf{r}, \hat{\mathbf{s}}) \quad (24)$$

where the brightness temperature is also defined as the product of the body emissivity times physical temperature. Through Equation 24, the RTE becomes

$$\frac{dT_B(\mathbf{r}, \hat{\mathbf{s}})}{d\tau} = -T_B(\mathbf{r}, \hat{\mathbf{s}}) + \frac{w(\mathbf{r}, \hat{\mathbf{s}})}{4\pi} \int_{4\pi} p(\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}')T_B(\mathbf{r}, \hat{\mathbf{s}}')d\Omega' + [1 - w(\mathbf{r}, \hat{\mathbf{s}})]T(\mathbf{r}) \quad (25)$$

It is very often convenient to separate the total specific intensity into two terms, the *reduced incident* specific intensity $I_c(\mathbf{r}, \hat{\mathbf{s}})$ and *diffuse* specific intensity $I_d(\mathbf{r}, \hat{\mathbf{s}})$:

$$I(\mathbf{r}, \hat{\mathbf{s}}) = I_r(\mathbf{r}, \hat{\mathbf{s}}) + I_d(\mathbf{r}, \hat{\mathbf{s}}) \quad (26)$$

Substituting the previous equation into Equation 24, we obtain

$$\begin{cases} \frac{dI_r(\mathbf{r}, \hat{\mathbf{s}})}{d\tau} = -I_r(\mathbf{r}, \hat{\mathbf{s}}) \\ \frac{dI_d(\mathbf{r}, \hat{\mathbf{s}})}{d\tau} = -I_d(\mathbf{r}, \hat{\mathbf{s}}) + \frac{w(\mathbf{r}, \hat{\mathbf{s}})}{4\pi} \int_{4\pi} p(\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}')I_d(\mathbf{r}, \hat{\mathbf{s}}')d\Omega' + J(\mathbf{r}, \hat{\mathbf{s}}) \end{cases} \quad (27)$$

where the *source function* $J(\mathbf{r}, \hat{\mathbf{s}})$ is given by the thermal term J_t and reduced incident term J_r :

$$J(\mathbf{r}, \hat{\mathbf{s}}) = [1 - w(\mathbf{r}, \hat{\mathbf{s}})]I_{BB}(\mathbf{r}) + \frac{w(\mathbf{r}, \hat{\mathbf{s}})}{4\pi} \int_{4\pi} p(\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}')I_c(\mathbf{r}, \hat{\mathbf{s}}')d\Omega' + J_t(\mathbf{r}, \hat{\mathbf{s}}) \quad (28)$$

Note that from Equation 27, the reduced incident specific intensity is equal to the incident specific intensity reduced by the medium extinction coefficient κ_e .

The boundary conditions for the specific intensity at the surface S of medium containing random distribution scatterers may be various: (1) if no diffuse intensity is entering the medium, it holds $I_d(\mathbf{r}, \hat{\mathbf{s}}) = 0$ on S ; (2) if the incident intensity I_i is a collimated beam directed along $\hat{\mathbf{s}}_0$, then it holds $I_i(\mathbf{r}, \hat{\mathbf{s}}_0) = I_0 \delta(\hat{\mathbf{s}} - \hat{\mathbf{s}}_0)$ on S so that $I_r(\mathbf{r}, \hat{\mathbf{s}}_0) = I_0 \delta(\hat{\mathbf{s}} - \hat{\mathbf{s}}_0) \exp(-\tau)$; and (3) if the incident intensity I_i is a diffuse one itself, then it holds $I_i(\mathbf{r}, \hat{\mathbf{s}}_0) = I_0$ on S so that $I_r(\mathbf{r}, \hat{\mathbf{s}}_0) = I_0 \exp(-\tau)$.

Integral formulation and received power

The RTE for $I_d(\mathbf{r}, \hat{\mathbf{s}})$ in Equation 27 is first-order differential equation with respect to s . It is sometimes convenient to deal with the integral formulation especially for complex geometries. Supposing that at the boundary surface S in $\mathbf{r} = \mathbf{r}_0$ it holds $I_d(\mathbf{r}_0, \hat{\mathbf{s}}) = 0$ (see Figure 4), the general integral solution for $I_r(\mathbf{r}, \hat{\mathbf{s}})$ and $I_d(\mathbf{r}, \hat{\mathbf{s}})$ is

$$\begin{cases} I_r(\mathbf{r}, \hat{\mathbf{s}}) = I_i(\mathbf{r}_0, \hat{\mathbf{s}})e^{-\tau} \\ I_d(\mathbf{r}, \hat{\mathbf{s}}) = \int_0^s e^{-(\tau-\tau')} \left[\frac{w(\mathbf{r}', \hat{\mathbf{s}})}{4\pi} \int_{4\pi} p(\mathbf{r}', \hat{\mathbf{s}}, \hat{\mathbf{s}}')I_d(\mathbf{r}', \hat{\mathbf{s}}')d\Omega' + J(\mathbf{r}', \hat{\mathbf{s}}) \right] ds' \end{cases} \quad (29)$$

where $I_i(\mathbf{r}_0, \hat{\mathbf{s}})$ is the incident specific intensity and τ' is optical distance between $\mathbf{r}_0$ and $\mathbf{r}'$ with s the distance between $\mathbf{r}_0$ and $\mathbf{r}$.

In actual measurements of the specific intensity, it is necessary to take into account the characteristics of the receiver. The latter can be conveniently described by receiving equivalent area $A_e(\hat{\mathbf{s}}, \hat{\mathbf{s}}_0)$, measured in m^2 , whose maximum is supposed to be along $\hat{\mathbf{s}}_0$. If $I(\mathbf{r}, \hat{\mathbf{s}})$ is incident upon a receiver, placed at $\mathbf{r}$ and characterized by $A_e(\hat{\mathbf{s}}, \hat{\mathbf{s}}_0)$, the receiver power per unit frequency $P_R(\hat{\mathbf{s}}_0)$ (measured in W/Hz) is given by

$$P_R(\mathbf{r}, \hat{\mathbf{s}}_0) = \int_{\Delta\Omega} A_e(\mathbf{r}, \hat{\mathbf{s}}_0, \hat{\mathbf{s}})I(\mathbf{r}, \hat{\mathbf{s}})d\Omega \quad (30)$$

$$d\Omega = P_{Rr}(\mathbf{r}, \hat{\mathbf{s}}_0) + P_{Rd}(\mathbf{r}, \hat{\mathbf{s}}_0)$$

where $\Delta\Omega$ is the angular domain integration and the last term is due to the decomposition of I into I_r and I_d . The receiver equivalent area can be, for example, either a pencil beam (e.g., highly directive microwave antennas or optical detector) or a near-isotropic radiator (e.g., short dipole).

Radiative Transfer, Theory, Figure 4 Incident, coherent, and diffuse specific intensity in a volume V of random scatterers.

Radiative transfer of partially polarized radiation

The inclusion of polarization, while unnecessary for acoustic waves, may be important for electromagnetic waves. All electromagnetic waves in random media are, in general, partially polarized because, even though the incident wave is linearly polarized, the scattered wave is generally elliptically polarized and its polarization should randomly vary in time and space.

The scalar RTE can be generalized to partially polarized wave by replacing the scalar specific intensity with the *vector specific intensity* $\mathbf{I}(\mathbf{r}, \hat{\mathbf{s}})$, measured in $\text{W m}^{-2} \text{sr}^{-1} \text{Hz}^{-1}$, whose components are the Stokes parameters $I_h(\mathbf{r}, \hat{\mathbf{s}})$, $I_v(\mathbf{r}, \hat{\mathbf{s}})$, $U(\mathbf{r}, \hat{\mathbf{s}})$, and $V(\mathbf{r}, \hat{\mathbf{s}})$. The vector specific intensity can be defined starting from an elliptically polarized plane wave, representing an electrical field $\mathbf{E}(\mathbf{r}, \hat{\mathbf{s}})$:

$$\mathbf{E}(\mathbf{r}, \hat{\mathbf{s}}) = (E_h \hat{\mathbf{h}} + E_v \hat{\mathbf{v}}) e^{-j\mathbf{k} \cdot \mathbf{r}} \quad (31)$$

where $\hat{\mathbf{h}}$ and $\hat{\mathbf{v}}$ are the unit horizontal and vertical polarization vectors with E_h and E_v their complex amplitudes, j is the imaginary unit, and $\mathbf{k}$ is the propagation constant along $\hat{\mathbf{s}}$. The Stokes specific intensity vector $\mathbf{I}(\mathbf{r}, \hat{\mathbf{s}})$ is then given by

$$\mathbf{I}(\mathbf{r}, \hat{\mathbf{s}}) = \begin{bmatrix} I_v \\ I_h \\ U \\ V \end{bmatrix} = \begin{bmatrix} |E_v|^2 \\ |E_h|^2 \\ 2 \text{Re}(E_v E_h^*) \\ 2 \text{Im}(E_v E_h^*) \end{bmatrix} \quad (32)$$

Note the first two Stokes parameters are also called modified parameters, as the original ones introduced by Stokes were $I = I_v + I_h$ and $Q = I_v - I_h$. Moreover, sometimes the third term is divided by η , the medium intrinsic impedance.

An effective representation of the Stokes vector is through the so-called Poincaré sphere where in the Q , U , and V space, the I value is graphed with respect to the ellipticity and rotation angles (e.g., linear polarization shows a zero ellipticity angle and a 0° or 90° rotation angle if vertical or horizontal polarization is dealt with, respectively). For a *completely polarized* monochromatic wave,

it holds the following identity: $I^2 = Q^2 + U^2 + V^2$, whereas for partially polarized wave, it holds the inequality $I^2 > Q^2 + U^2 + V^2$. The *degree of polarization* δ_p is defined as the ratio between the square root of $(Q^2 + U^2 + V^2)$ and I^2 : If $\delta_p = 1$, the wave is *completely polarized*, whereas if $\delta_p = 0$, the wave is *completely unpolarized*. If $0 < \delta_p < 1$, the wave is said to be *partially polarized* and it corresponds to a point inside the Poincaré sphere (Ulaby and Elachi, 1990).

The vector analog of Equation 21 is the *vector RTE*:

$$\begin{aligned} \frac{d\mathbf{I}(\mathbf{r}, \hat{\mathbf{s}})}{ds} &= \kappa_e(\mathbf{r}, \hat{\mathbf{s}}) \mathbf{I}(\mathbf{r}, \hat{\mathbf{s}}) + \int_{4\pi} \kappa_d(\mathbf{r}, \hat{\mathbf{s}}') \mathbf{I}(\mathbf{r}, \hat{\mathbf{s}}') d\Omega' \\ &\quad + \kappa_a(\mathbf{r}, \hat{\mathbf{s}}) I_{BB}(\mathbf{r}) \end{aligned} \quad (33)$$

where $\mathbf{I}$ is the 4×1 Stokes column vector, $\kappa_e(\mathbf{r}, \hat{\mathbf{s}})$ is the 4×4 *extinction matrix*, $\kappa_d(\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}')$ is the 4×4 *differential scattering matrix*, and $\kappa_a(\mathbf{r}, \hat{\mathbf{s}})$ is the 4×1 *absorption column vector*. Note that very often (and unfortunately), the matrix κ_d is also called phase matrix $\mathbf{P}$ even though it does not reflect the scalar definition of the phase function in Equation 14.

The *matrix* parameters in the vector RTE of Equation 31 can be related to the single-scattering property of each scatterer contained in the random medium. In a linear medium, we can relate the scattered field $\mathbf{E}_s(\mathbf{r}, \hat{\mathbf{s}})$ by a scatterer to the incident field $\mathbf{E}_i(\mathbf{r}, \hat{\mathbf{s}}')$ through the complex scattering 2×2 matrix $\mathbf{S}(\hat{\mathbf{s}}, \hat{\mathbf{s}}')$:

$$\begin{aligned} \mathbf{E}_s(\mathbf{r}, \hat{\mathbf{s}}) &= \begin{bmatrix} E_{sv} \\ E_{sh} \end{bmatrix} = \begin{bmatrix} S_{vv} & S_{vh} \\ S_{hv} & S_{hh} \end{bmatrix} \begin{bmatrix} E_{ih} \\ E_{iv} \end{bmatrix} \\ &= \mathbf{S}(\hat{\mathbf{s}}, \hat{\mathbf{s}}') \mathbf{E}_i(\mathbf{r}, \hat{\mathbf{s}}') \end{aligned} \quad (34)$$

It is worth noting that the scattering matrix $\mathbf{S}$ can be expressed in any arbitrary orthonormal unit system, different from the one defined by the horizontal and the vertical polarizations as in Equation 34 (where usually the reference plane contains a preferential vertical axis and either the incident or scattered direction). An example is the

so-called scattering-plane orthonormal system which contains both the incidence direction and scattered direction where the polarization states are distinguished as either parallel or orthogonal to the scattering plane itself (Tsang et al., 2000). The scattering-plane reference system is convenient if the scatterer has symmetries.

By using the previous relation and Equation 32, we can easily show that, for a single scatterer, the scattered Stokes vector $\mathbf{I}_s(\mathbf{r}, \hat{\mathbf{s}})$ is related to the incident Stokes vector $\mathbf{I}_i(\mathbf{r}, \hat{\mathbf{s}}')$ by means of the so-called Stokes or Muller 4×4 matrix $\mathbf{L}(\hat{\mathbf{s}}, \hat{\mathbf{s}}')$:

$$\mathbf{I}_s(\mathbf{r}, \hat{\mathbf{s}}) = \mathbf{L}(\hat{\mathbf{s}}, \hat{\mathbf{s}}') \mathbf{I}_i(\mathbf{r}, \hat{\mathbf{s}}') \quad (35a)$$

or explicitly:

$$\begin{bmatrix} I_{sv} \\ I_{sh} \\ U_s \\ V_s \end{bmatrix} = \begin{bmatrix} |S_{vv}|^2 & |S_{vh}|^2 & Re(S_{vh}^* S_{vv}) \\ |S_{hv}|^2 & |S_{hh}|^2 & Re(S_{hh}^* S_{hv}) \\ 2Re(S_{vv} S_{hv}^*) & 2Re(S_{vh} S_{hh}^*) & 2Re(S_{vv} S_{hh}^* + S_{vh} S_{hv}^*) - Im \\ 2Im(S_{vv} S_{hv}^*) & 2Im(S_{vh} S_{hh}^*) & Im(S_{vv} S_{hh}^* + S_{vh} S_{hv}^*) Re \end{bmatrix} \quad (35b)$$

The *differential scattering matrix* is then given, in analogy to the scalar case, as the weighted average of the Muller matrix $\mathbf{L}$ over the probability density function p_q :

$$\begin{aligned} \kappa_d(\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}') &= N_q \int_q \mathbf{L}(\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}', q_1, \dots, q_Q) p_q(q_1, \dots, q_Q) \\ &\quad d_{q_1} \dots d_{q_Q} \equiv \mathbf{P}(\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}') \\ \kappa_d(\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}') &= N_q \int_q \mathbf{L}(\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}', q_1, \dots, q_Q) p_q(q_1, \dots, q_Q) \\ &\quad d_{q_1} \dots d_{q_Q} \equiv \mathbf{P}(\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}') \end{aligned} \quad (36)$$

$$\begin{aligned} \kappa_d(\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}') &= N_q \int_q \mathbf{L}(\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}', q_1, \dots, q_Q) p_q(q_1, \dots, q_Q) \\ &\quad d_{q_1} \dots d_{q_Q} \equiv \mathbf{P}(\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}') \end{aligned}$$

The previous matrix is also called the phase matrix $\mathbf{P}$, as indicated in the third term of Equation 36. The latter is essentially based on the assumption of *incoherent addition* of the diffuse Stokes parameters (Tsang et al., 2000).

In the same manner, the *extinction matrix* κ_e can be related to the complex scattering matrix $\mathbf{S}$. In particular, the optical theorem provides a useful relationship for computing the extinction cross section in terms of the field scattered in the forward direction, relative to the incident field. If the latter is t polarized, where $m = v$ or h , the p -polarized extinction cross section σ_{em} is

$$\sigma_{em}(\mathbf{r}, \hat{\mathbf{s}}) = \frac{4\pi}{k} Im[S_{mm}(\mathbf{r}, \hat{\mathbf{s}} = \hat{\mathbf{s}}', \hat{\mathbf{s}}')] \quad (37)$$

where Im is the imaginary-part operator and the scattering term S_{mm} is the mm scattering amplitude of the particle,

evaluated in the forward-scattering direction $\hat{\mathbf{s}} = \hat{\mathbf{s}}'$. The m -polarized extinction coefficient κ_{em} is given by the weighted average over the probability density function p_q :

$$\kappa_{et}(\mathbf{r}, \hat{\mathbf{s}}) = N_q \int_{\Delta q} \sigma_{et}(\mathbf{r}, \hat{\mathbf{s}}, q_1, \dots, q_Q) p_q(q_1, \dots, q_Q) d_{q_1} \dots d_{q_Q} \quad (38)$$

In the general case, for nonspherical particles, 4×4 extinction matrix κ_e is a non-diagonal matrix having the following general structure:

$$\kappa_e(\mathbf{r}, \hat{\mathbf{s}}) = \begin{bmatrix} -2Re(M_{vv}) & 0 & -Re(M_{vh}) & -Im(M) \\ 0 & -2Re(M_{hh}) & -Re(M_{hv}) & Im(M) \\ -2Re(M_{hv}) & -2Re(M_{vh}) & -Re(M_{vv} + M_{hh}) & Im(M_{vv} -) \\ -2Im(M_{hv}) & -2Im(M_{vh}) & -Im(M_{vv} + M_{hh}) & -Re(M_{vv}) \end{bmatrix} \quad (39)$$

Where

$$M_{mn} = \frac{j2\pi N_q}{k} \int_q S_{mn}(\mathbf{r}, \hat{\mathbf{s}}, q_1, \dots, q_Q) p_q(q_1, \dots, q_Q) d_{q_1} \dots d_{q_Q} \quad (40)$$

with $m, n = h, v$. The latter expressions can be derived from the theory of attenuation of the coherent wave through a random medium, adopting the so-called Foldy's approximation (Tsang et al., 1985). For the special case of a random medium with spherical particles, the 4×4 extinction matrix κ_e simplifies to a diagonal matrix with all identical elements $\kappa_{esph} = \kappa_{ehh} = \kappa_{evv}$:

$$\kappa_e(\mathbf{r}, \hat{\mathbf{s}}) = \begin{bmatrix} \kappa_{esph} & 0 & 0 & 0 \\ 0 & \kappa_{esph} & 0 & 0 \\ 0 & 0 & \kappa_{esph} & 0 \\ 0 & 0 & 0 & \kappa_{esph} \end{bmatrix} \quad (41)$$

Note that the absorption coefficient κ_a , usually due to gases, is an unpolarized quantity within the expression of the total extinction matrix κ_e . The emission vector of the random distribution of particles within the vector RTE is expressed through the absorption vector κ_a in Equation 31. Its expression might be fairly complicated in the general case and can be derived from the fluctuation-dissipation theorem for a single scatterer and the incoherent addition of Stokes parameters (Tsang et al., 1985). It can be shown that for random media of nonspherical particles, it holds

$$\kappa_a(\mathbf{r}, \hat{\mathbf{s}}) = \begin{bmatrix} \kappa_{a1}(-\hat{\mathbf{s}}) \\ \kappa_{a2}(-\hat{\mathbf{s}}) \\ \kappa_{a3}(-\hat{\mathbf{s}}) \\ \kappa_{a4}(-\hat{\mathbf{s}}) \end{bmatrix} \quad (42)$$

Where

$$\begin{aligned}
 \kappa_{a1}(\hat{s}) &= \kappa_{e11}(\hat{s}) - \int_{4\pi} [\kappa_{d11}(\hat{s}, \hat{s}') + \kappa_{d21}(\hat{s}, \hat{s}')] d\Omega' \\
 \kappa_{a2}(\hat{s}) &= \kappa_{e22}(\hat{s}) - \int_{4\pi} [\kappa_{d12}(\hat{s}, \hat{s}') + \kappa_{d22}(\hat{s}, \hat{s}')] d\Omega' \\
 \kappa_{a3}(\hat{s}) &= -2\kappa_{e13}(\hat{s}) - 2\kappa_{e23}(\hat{s}) + 2 \int_{4\pi} [\kappa_{d13}(\hat{s}, \hat{s}') + \kappa_{d23}(\hat{s}, \hat{s}')] d\Omega' \\
 \kappa_{a4}(\hat{s}) &= 2\kappa_{e14}(\hat{s}) + 2\kappa_{e24}(\hat{s}) - 2 \int_{4\pi} [\kappa_{d14}(\hat{s}, \hat{s}') + \kappa_{d24}(\hat{s}, \hat{s}')] d\Omega'
 \end{aligned} \tag{43}$$

where the elements κ_{emn} and κ_{dmn} are the mn elements of κ_e and κ_d , respectively, with $m, n = 1, 2, 3, 4$. Equations 42 and 43 state that the emission of the particle ensemble in the forward direction is related to the absorption by the particle ensemble in the backward direction.

Of course, the boundary conditions for the vector RTE need to be specified for the Stokes vectors as well. For example, in case of a planar dielectric interface, the Fresnel theory can be generalized so that the reflected Stokes vector $\mathbf{I}_r$ is given by

$$\mathbf{I}_r(\mathbf{r}, \hat{s}) = \mathbf{R}(\theta_i) \mathbf{I}_i(\mathbf{r}, \hat{s}) = \begin{bmatrix} R_v(\theta_i) & 0 & 0 & 0 \\ 0 & R_h(\theta_i) & 0 & 0 \\ 0 & 0 & \text{Re}(\Gamma_v \Gamma_h^*) & -\text{Im}(\Gamma_v \Gamma_h^*) \\ 0 & 0 & \text{Im}(\Gamma_v \Gamma_h^*) & \text{Re}(\Gamma_v \Gamma_h^*) \end{bmatrix} \tag{44}$$

where $\mathbf{R}$ is the *surface reflectance matrix* and $R_v(\theta_i) = |\Gamma_v(\theta_i)|^2$ and $R_h(\theta_i) = |\Gamma_h(\theta_i)|^2$ are the vertically and horizontally polarized, respectively, surface reflectance coefficients at the incident angle θ_i (satisfying the Snell law) with Γ_v and Γ_h , the Fresnel reflection field coefficients. For a Lambertian surface, the *surface reflectance matrix* is a matrix with all terms equal to zero except R_{11} and R_{22} both equal to 0.5.

Numerical and approximate solutions

The radiative transfer equation, in its scalar and vector form, is an integrodifferential equation which does not have analytical solutions, except in some special cases. Approximations and numerical techniques are usually adopted for solving the RTE (Chandrasekhar, 1960; Sobolev, 1975; Ishimaru, 1978; Tsang et al., 1985; Ulaby et al., 1986). Among these techniques, we enumerate (1) the *iterative solution* technique, (2) the *discrete-ordinate* technique and the *invariant imbedding* method, (3) the *invariant imbedding* technique, (4) the *two-flux* approximate solution, (5) the *Eddington* approximate solution, and (6) the *diffusion* approximate solution.

In the *iterative* solution, the radiative transfer equation is cast into an integral form and then solved iteratively to obtain the zero-, first-, and second-order solutions

(e.g., Tsang et al., 1985). This technique is applicable when the random medium is weakly scattering, that is, when the albedo w is small. The s solution is computed by ignoring scattering except for its contribution to extinction (the multiple-scattering term is disregarded). In principle, we can obtain an accurate solution by iterating many times. But, in practice, the iteration beyond the second order requires a substantial amount of computational efforts.

The *discrete-ordinate* eigen-analysis technique provides a fairly accurate numerical solution for the RTE and has been extensively used in literature (Chandrasekhar, 1960; Ishimaru, 1978). In this technique, the specific intensity and the phase matrix are first discretized into a finite number of directions by means of a quadrature, typically using a Fourier series expansion in the azimuth angle. It can be shown that for the incident plane wave case, all the Fourier components are independent of each other. Moreover, for the vertically and horizontally polarized waves, the first two terms of the Stokes vector are even functions and the last two terms are odd functions of the azimuth angle, respectively. Then, by means of the Gaussian quadrature typically, the resulting matrix differential equation for the discrete zenith angles is solved by eigen analysis. The discrete-ordinate technique is especially useful for plane-parallel media, but other methods, equally effective, should be also mentioned. Among these, the *invariant imbedding* (also called adding-doubling or matrix doubling in the scalar and vector RTE, respectively) is based on the general relationships between the reflection and transmission for a finite elementary slab and the formulation of integral equations relating them for a layered plane-parallel problem (Tsang et al., 1985).

For a one-dimensional (1D) problem, instead of using a series expansion technique or a discrete-ordinate approach, an approximate solution can be used in order to reduce the computational burden. The *two-flux theory* is, in this respect, very effective if the incident radiation is diffuse and the medium is dull (Kubelka and Munk, 1931). In this case, the RTE is reduced to two coupled differential equations expressed in terms of the forward F^+ and backward F^- fluxes. A drawback of the two-flux theory is that the equation coefficients are not constant and may depend on the angular characteristics of the intensity (they become constant only if the wave is completely diffused). In case of an incident collimated beam, the two-flux theory can be extended to the four-flux theory and successfully applied (Ishimaru, 1978).

For layered media, the *Eddington* solution is an effective approximate solution, based on the angular expansion of the specific intensity and the phase function in a series of Legendre polynomials with unknown coefficients and truncated at the first order (Eddington, 1916). Forward-scattering corrections of the basic solution can be used to improve the accuracy of the results in high albedo media (Joseph et al., 1976; Marzano, 2006).

In case of highly scattering media, the diffusion approximation can be used to reformulate the RTE. In this case,

the diffuse specific intensity is expressed as the average intensity plus a term which accounts for an increase in magnitude in the forward direction of the net flux (Ishimaru, 1978). Coupled with proper boundary conditions, the diffusion approximation takes the form of the fundamental steady-state diffusion equation. In case of *isotropic scattering*, the phase function can be assumed constant and the formulation further simplifies and can provide useful solutions when particles are much smaller than the wavelength (Menzel, 1966).

Limits and relation with the wave analytical theory

As already mentioned, the radiative transfer theory describes the power intensity balance of the transmission, absorption, and scattering processes and heuristically derived from considerations on energy conservation, as apparent in Equation 21. The RTE is based on the assumption that the correlation between the fields scattered by the different particles in the random medium is negligible and the addition of power, rather than the addition of fields, holds. However, the conventional RTE as in Equation 21 may be not valid for densely distributed media and fails to account for the backscattering enhancement effect which may be significant under certain circumstances (Kuga and Ishimaru, 1989).

Backscattering enhancement is a phenomenon in which a strong increase in the diffuse intensity can be observed in the backward direction when the random medium is illuminated by a plane wave, caused by the constructive interference of the two waves propagating in the opposite directions in the random medium. The intensity enhancement may be twice as large as the unenhanced intensity and the angular width may be much smaller than 1° . The backscattering enhancement cannot be explained by the radiative transfer theory as it does not include the phase correlation between waves. In order to explain these effects, we need to resort to the field theory. In fact, the same problem of the RTT can be cast in terms of field quantities and their statistical characterization. When this approach is followed, we can refer to the *analytical wave theory* (or multiple-scattering theory), whose general formulation is well summarized by the integral equation set of Twersky-Foldy (Twersky, 1964; Ishimaru, 1978).

The *analytical wave theory* generally starts from the Maxwell wave equation of a scalar field $\Psi(\mathbf{r})$, which can represent either a component of the electric or magnetic field or a pressure wave and describes the various processes of multiple scattering in a detailed way, usually resorting to the concise formalism of the diagram method. The general result of is that the total field $\Psi(\mathbf{r})$ is composed by (1) the incident wave, (2) multiply scattered waves involving chains of successive scattering through different scatterers, and (3) multiply scattered waves containing all the paths which go through a scatterer more than once. This general picture is consistent with that schematically shown in Figure 1. The *Twersky theory* adopts the so-called expanded representation which

retains only the previous groups (1) and (2) but disregards the effects due to group (3). When the number of scattering events becomes large, the errors associated to the Twersky approximation become very small.

Starting from the Twersky expanded representation, it is then possible to provide a statistical description of the random scalar field $\Psi(\mathbf{r})$, distinguishing between the coherent (or average) field $\Psi_c(\mathbf{r})$ and the diffuse (also incoherent or fluctuating) field $\Psi_d(\mathbf{r})$:

$$\psi(\mathbf{r}) = \psi_c(\mathbf{r}) + \psi_d(\mathbf{r}) \quad (45)$$

where $\Psi_c(\mathbf{r}) = \langle \Psi(\mathbf{r}) \rangle$ and $\langle \Psi_d(\mathbf{r}) \rangle = 0$ with the angle brackets indicating ensemble average. It can be shown that the total field intensity $\langle |\Psi(\mathbf{r})|^2 \rangle$, which can be decomposed into the sum of coherent intensity $|\langle \Psi(\mathbf{r}) \rangle|^2$ and diffusive intensity $\langle |\Psi_d(\mathbf{r})|^2 \rangle$ from Equation 45, satisfies the so-called Twersky-Foldy integral equations. The latter are, in their turn, consistent with the first-order smoothing approximation of the more rigorous Dyson and Bethe-Salpeter equations (e.g., Furutsu, 1975).

Considering that both the RTE in Equation 21 and the Twersky-Foldy integral equations describe the same multiple-scattering phenomenon, even though from two different points of view, a link between the two theories is expected (Ishimaru, 1975). Indeed, if $\Gamma_\Psi(\mathbf{r}, \Delta\mathbf{r})$ is the correlation function (or mutual coherence function) of the random field $\Psi(\mathbf{r})$ in a given position $\mathbf{r}$ and at a distance $\Delta\mathbf{r}$, it can be shown that it holds the following approximate equality (Furutsu, 1975):

$$\Gamma_\Psi(\mathbf{r}, 0) \cong \int_{4\pi} I(\mathbf{r}, \hat{s}) d\Omega \quad (46)$$

The previous relation indicates that the angular integral of the total specific intensity I (i.e., the radiation intensity) is proportional to the total field intensity $\langle |\Psi(\mathbf{r})|^2 \rangle$. Equation 46 can be generalized showing that the field correlation function Γ_Ψ is related to the Fourier transform of the specific intensity I . It shows that the description of multiple-scattering effects, based on the radiative transfer theory, does include information concerning the field quantities in the form of mutual coherence function (Ishimaru, 1978).

It is worth noting that if the particles are sparsely distributed, the extinction coefficient κ_e is linearly proportional to the particle number concentration N_q , as in Equation 13. This is a valid assumption if the fractional volume density is less than 1 %. Beyond 1 %, the extinction coefficient is no longer linearly proportional to the number concentration, but starts decreasing in a way dependent on the size parameter, dielectric constant, and particle volume fraction. This behavior in dense media has been demonstrated by an extensive experimental and theoretical analysis (Kuga and Ishimaru, 1989; Tsang et al., 1985). The previously mentioned Twersky model is relatively simple, but applicable only for small particles with respect to the wavelength. For volume fractions

higher than 10 %, the quasi-crystalline approximation (QCA) with either the Percus-Yevick pair correlation function or with the coherent potential approximation has shown to be effective solutions (Tsang et al., 1985).

RADIO-FREQUENCY INTERFERENCE (RFI) IN PASSIVE MICROWAVE SENSING

Electromagnetic interference (EMI)

Definition

Radio-frequency interference (RFI) in passive microwave remote sensing occurs when anthropogenic (man-made) signals contaminate calibrated radiometric brightness temperature measurements of naturally occurring background thermal radiation resulting in anomalous measurements.

Introduction

Radio-frequency interference (RFI) to space-based passive microwave remote sensing systems became an important consideration after brightness temperature measurements from the Advanced Microwave Scanning Radiometer on NASA's Earth Observing System (AMSR-E) showed widespread contamination from anthropogenic emissions. The AMSR-E, part of NASA's Aqua mission, was launched on May 4, 2002, and was the first space-based radiometer since the scanning multichannel microwave radiometer (SMMR) (the SeaSat 7 mission ended in October 1987 and carried the last SMMR) to measure upwelling brightness temperatures near 6.8 GHz. Contamination (RFI) of brightness temperature measurements by SMMR radiometers at 6.6 GHz (ending in October 1987) was not significant over North America. However, beginning in 2002, substantial contamination of radiometric brightness temperatures near 6.9 GHz, from the AMSR-E, was found over North America as well as other populated regions of the world (Li et al., 2004). Contaminated brightness temperatures near 6.8 GHz, a spectral region important for remote sensing

of all-weather [sea surface temperature](#) and soil moisture retrievals, helped initiate the current research in RFI mitigation for passive microwave measurements and focus attention on protection of the RF spectrum for scientific uses.

Background

Passive microwave radiometers respond to the naturally occurring upwelling background radiation from the Earth's surface and atmosphere. The power contained in these emissions is a function of bandwidth and determined by the formula $P = kTB$, where k is Planck's constant, $1.038 \times 10^{-23} \text{ J}\cdot\text{s}^{-2}$, $T = T$ is the effective brightness temperature in Kelvin, and B is the effective RF bandwidth of the radiometer in Hz. When the radiometer responds to anthropogenic signals either within or outside of the radiometer's primary passband, the total RF power received by the radiometer increases; $P_T = kT_B B + P_{RFI}$ where P_{RFI} is mean power of the anthropogenic signal(s) during the radiometer's period of integration adjusted by the radiometer's antenna beam pattern and receiver passband response characteristics. As a result, the effective brightness temperature measured by the radiometer is larger than the scene brightness temperature $\delta T_B = \frac{P_{RFI}}{kB}$. This value represents the direct level of contamination.

In general, the level of contamination, δT_B , is a function of radiometer bandwidth and strength of interfering signal. Larger bandwidth radiometers may tolerate higher levels of interference; however, they are sensitive to emissions over a wider range of frequencies. It is also important to

understand that out-of-band (OOB) signals also contribute to P_{RFI} . The OOB signals can be a significant consideration especially when strong anthropogenic emissions occur in the same spectral region that the radiometer is operating.

Another form of RFI that may impose errors on measured brightness temperatures occurs when strong OOB signals are present at the receiver (radiometer) input and impact the operating characteristics of the receiver. The OOB signals may otherwise be rejected by the receiver channelization filter; however, if the signals are of sufficient strength to impact operation of the receiver low noise amplifier (LNA), errors can occur in the measured data. These "indirect" effects from strong OOB signals may result in a net decrease or increase in measured brightness temperature depending on the nature of the response of the receiver front end and RF electronics.

Examples of RFI in several microwave bands

One of the most extensive examples of contaminated brightness temperatures can be seen in measurements of over North America from AMSR-E near 6.9 GHz (Figure 1). The data indicate that widespread utilization of this spectral region by other radio services (the spectrum segment is allocated to the fixed service (FS) and mobile service (MS) according to the current NTIA allocation chart (<http://www.ntia.doc.gov/osmhome/redbook/redbook.html>)) was causing substantial contamination to brightness temperatures measured by the AMSR-E vertically and horizontally polarized channels at 6.9 GHz.

Radio-Frequency Interference (RFI) in Passive Microwave Sensing, Figure 1 RFI is displayed as the perturbation from a zero-mean (natural emission) level determined by differencing 6- and 10 GHz brightness temperatures measured by AMSR-E. Perturbations of up to 50 K are common across the USA affecting more than 50 % of the total land area with RFI > 5 K. The pervasive nature of the interference resulted in reduced quality of soil moisture retrievals using AMSR-E because 6.9 GHz data could not be used (Li et al., 2003).

Radio-Frequency Interference (RFI) in Passive Microwave Sensing, Figure 2 (Top) Passive microwave brightness temperatures at 6.6 GHz from SMMR in October 1987. Essentially no RFI is seen over the North America in this period. (Bottom) Brightness temperature data at 6.9 GHz from AMSR-E in May 2003. The *black* spots represent high levels of anthropogenic emission primarily over regions of California and Arizona that saturate the AMSR-E radiometer. The *red* spots over most of the remaining areas of the USA represent contaminated brightness temperature measurements.

Contamination of background brightness temperatures is shown by departure from the mean difference of 6.9 and 10.7 GHz brightness temperatures in the figure. Positive values indicate RFI at 6.9 GHz. Contamination of brightness temperature measurements in the 6 GHz region was not found during the period of SMMR measurements from 1978 to 1987 (Njoku et al., 1980); brightness temperatures over North America were essentially contamination free as shown by data from SeaSat Nimbus 7 in contrast to AMSR-E data from 2002 (Figure 2). The red and black

spots in the lower part of the figure represent anthropogenic sources causing localized errors in measurements. In this example there is a high correlation of contaminated brightness temperatures with population centers.

RFI contamination to passive microwave brightness measurements has been observed in the 10 GHz region by the NRL WindSat radiometer, AMSR-E, and NASA's Tropical Rainfall Measuring Mission (TRMM) Microwave Imager (TMI). Two common types of occurrences have been noted. First, land-based anthropogenic

Radio-Frequency Interference (RFI) in Passive Microwave Sensing, Figure 3 Passive microwave brightness temperatures at 6.9 GHz from AMSR-E in June 2003 over France and the UK. The *black spots* represent saturation of the AMSR-E response indicating severe RFI. In this example occurrences are correlated with national boundaries.

emissions have caused localized contamination of brightness temperature measurements (Figure 3). Second, reflections of geostationary broadcast transmissions to Earth from the ocean cause broad areas of contamination to measurements of brightness temperature (Figure 4). This contamination adversely impacts retrievals of *sea surface temperature (SST)* and sea surface wind (SSW) that rely directly on passive microwave brightness temperature data from the 10 GHz band.

Anomalies in sea surface wind retrievals near North America have also been attributed to RFI from geostationary broadcasts in the 18.6–18.8 GHz band segment. Flagging of potential anomalies in the WindSat 18.7 GHz data from NRL's retrieval algorithm is shown (Figure 5). Blue denotes fewer anomalies and red denotes a higher occurrence of anomalies. The first occurrence of these retrieval anomalies coincides with the activation of the DirecTV 10 geostationary broadcast satellite in early October 2007. The satellite operates within the band 18.3–18.8 GHz at 103° West longitude. In late July 2008, DirecTV 11 also went online at 99° West longitude with the same coverage area and down-link frequencies as DirecTV 10. The anomalies, found only during the descending phase of WindSat, are attributed to reflection of the satellite transmissions from the

ocean surface. The anomalies correlate precisely with the nationwide coverage maps of DirecTV 10 and DirecTV 11.

RFI mitigation techniques

After the AMSR-E brought RFI considerations to the forefront, development of RFI mitigation techniques has been under way by many researchers in passive microwave remote sensing. Techniques include frequency sub-banding (Gasiewski et al., 2002), detection of higher-order statistics (Ruf et al., 2006; Misra et al., 2008; De Roo et al., 2007; Piepmeier et al., 2008), and frequency-and time-domain methods (Johnson et al., 2006; Niamsuwan et al., 2005; Güner et al., 2007). Frequency sub-banding utilizes comparisons of measured brightness temperatures from each sub-band to determine if any single sub-band or multiple sub-bands are contaminated with RFI. Time-domain methods can be effective against pulsed emissions by utilizing short-duration blanking to eliminate the effect of the pulsed emissions. Higher-order statistics of the radiometric signal are generally sensitive to anthropogenic emissions (non-Gaussian) but are not sensitive to naturally occurring variations in scene brightness temperature. Therefore, measurements of higher-order statistics of the

Radio-Frequency Interference (RFI) in Passive Microwave Sensing, Figure 4 Example of RFI incurred at 10 GHz from oceanic reflections of broadcasts in bands adjacent to those observed by AMSR (areas in green and yellow). In this example AMSR-E, operating in the EESS band 10.6–10.7 GHz, is experiencing > 40 K brightness temperature perturbations, a value that greatly exceeds minimum levels that degrade environmental models using SST data derived from AMSR-E (Courtesy Li Li US NRL).

signal such as the fourth moment (kurtosis) can be used to detect the presence of anthropogenic emissions and RFI and serve to enhance effective mitigation of its impact.

Although increasingly effective RFI mitigation techniques are under development, 100 % RFI mitigation will not be possible. Limited information from the scene brightness temperatures is lost in the presence of detectable anthropogenic emissions. The impacts and observations of RFI are also continuing to increase. Concurrent growth in communications and wireless markets are driving new applications of RF transceivers along with new developments and applications in passive microwave remote sensing that require improved levels of precision or additional frequency bands have resulted in increasing reports and concerns of RFI. For example, in the post SMMR radiometer era, 10 GHz space-based brightness temperature measurements from the TMI radiometer began in 1997, 6 GHz measurements were available from AMSR-E in 2002, and currently, there are two space-based radiometers operating at 1.4 GHz and another planned for 2014. These missions require new levels of radiometric precision and stability in a region of the spectrum that has many active users. As a result, there is increasing attention on protection of the RF spectrum for scientific uses.

Frequency allocations and regulation

In the USA, the National Telecommunications and Information Administration (NTIA) and Federal

Radio-Frequency Interference (RFI) in Passive Microwave Sensing, Figure 5 Occurrence of anomalous ocean wind retrievals near the North American shore. The anomalies began with the commencement of transmissions from a new geostationary broadcast satellite near 18.7 GHz on 1 October 2007 (Courtesy Li Li US NRL).

Communication Commission regulate the licenses for government and nongovernment uses, respectively, of the radio services. Licenses are issued in a manner consistent with the international allocation of frequencies as agreed by the International Telecommunication Union (ITU) and World Radio Conference (WRC) (ITU, 2001). WRCs are currently held every 2 years in order to address international frequency-coordination issues. One of the major tasks of the ITU is to provide recommendations for regulation of radio spectrum among the various radio services including the Earth Exploration Satellite Service (EESS) (passive microwave radiometry is classified as the Earth Exploration Satellite Service (EESS) – passive), radio astronomy service, satellite broadcast service, fixed service, and mobile service, for example. Recommendations are provided for EESS by committees at the US national and international levels called working party 7C (WP7C). The WP7Cs are composed of representatives that understand the regulatory and technical issues from agencies and organizations with an interest or mission to provide microwave remote sensing data for Earth-observation applications. One of the most important ITU recommendations relevant to EESS is ITU-R SA.1028 and SA.1029. These ITU recommendations suggest the maximum allowable anthropogenic emissions within sample bandwidths utilized for passive remote sensing and EESS to ensure interference-free operation. More information on the regulatory process related to scientific uses of the spectrum can be found in the Handbook of Frequency Allocations and Spectrum Protection for Scientific Uses (NRC, 2007).

Conclusion

Interference to space-based passive microwave remote sensing systems has continued to increase after the discovery of pervasive contamination of AMSR-E 6.9 GHz brightness temperature data. Transmissions originating with broadcast satellite systems operating in geosynchronous orbit near 10.7 and 18.7 GHz as well as land-based emissions in the 6-, 10-, and 18 GHz bands have been shown to impact passive microwave measurements. Over land, weak signals originating from point-to-point communication systems (fixed service) are sensed by space-based passive microwave radiometers observing near 10.65 and 18.6 GHz. Over ocean, data from NRL's WindSat show a negative impact to retrievals of sea surface temperature and ocean winds due to RFI at 10 GHz and recently due to RFI at 18.7 GHz near North America. In the past several years, the remote sensing and radio science communities have responded with research and improvements to RFI mitigation approaches; however, the effectiveness of the approaches is limited, and contaminated brightness temperature measurements result in quantifiable data loss even with effective RFI mitigation in place. From the regulatory perspective, allocations of radio spectrum to

specific radio services are determined by international agreement and documented by the ITU. Much of the spectrum is allocated to multiple radio services and sharing is required. In many cases, the requirements for noninterference to EESS systems by other radio services is challenging and not well understood. The ITU is also a source for recommendations concerning radio regulations and sharing criteria. The increasing pervasiveness of RFI to passive microwave measurements is a growing concern among remote sensing scientists. The Earth's naturally occurring microwave emissions represent a unique resource for monitoring and understanding our planet with direct application to weather forecasting and climate.

Definition

Rainfall. A form of precipitation that reaches the Earth's surface in a liquid phase.

Introduction

The remote sensing of rainfall is a vital component to the integrated observing of precipitation on the Earth. While weather radars and rain gauges are the primary source of rainfall estimation in many areas, they are typically restricted to populated areas on the Earth and can only extend out over water bodies 150 km or so. Thus, satellites serve to fill in these huge data voids, especially over unpopulated regions and oceans. In this section, only satellite-based methods are considered (see *Water Resources; Global Earth Observation System of Systems (GEOSS)*). Additionally, this section refers to precipitation that falls at the surface in the form of liquid (see *Snowfall*).

A number of different methods are used to retrieve rainfall from satellites. The strength and weaknesses of the various methods that are described are summarized in *Table 1*, whereas details on the general classes of methods follow in the next three sections. Satellites (see *Observational Systems, Satellite*) that are used to estimate rainfall are generally categorized into LEO and GEO. Then, the various retrieval algorithms are typically classified on their observing spectrum (VIS, IR, PMW, AMW) or "multispectral" (i.e., use of one or more of these individual spectrums), whether they are objective or interactive (i.e., manual intervention) or whether they use multiple satellites or other information such as radar or gauges (e.g., "blended" algorithms).

Visible and infrared methods

Visible (VIS) and infrared (IR) techniques (see *Optical/Infrared, Radiative Transfer*) were the first to be conceived and are rather simple to apply, while at the same

time they show a relatively low degree of accuracy. On the other hand, GEO weather satellite VIS and IR imagers uniquely provide the rapid temporal update cycle (e.g., 30 min or less) needed to capture the growth and decay of precipitating clouds.

A complete overview of the early work and physical premises of VIS and thermal IR (10.5–12.5 μm) techniques is provided by Barrett and Martin (1981), while Kidder and Vonder Haar (1995) present some of the more recent results. The rainfall retrieval in these wavelengths is based on the fact that bright (optically thick) clouds are positively correlated with regions of convective rainfall (Woodley et al., 1971). On the other hand, clouds with cold tops in the IR imagery produce more rainfall than those with warmer tops (Scofield, 1987). However, the correspondence between cold tops and visible bright spots is far from perfect and is not always well correlated with surface rainfall (especially in stratiform rainfall regimes). *Figure 1* presents an example of typical VIS and IR signatures associated with different types of rainfall.

Various approaches have been developed to stress particular aspects of the sensing of cloud physics properties to settle differences between VIS and IR retrievals and measured rainfall. Following Barrett and Martin's classification, the rainfall estimation methods can be divided in the following categories: cloud indexing, bi-spectral schemes, life history, and cloud model based. In order to describe some methodologies that appear after Barrett and Martin's work, a new category that includes Numeric Weather Prediction (NWP)-adjusted schemes and multi-spectral algorithms has been added.

Cloud indexing methods

Cloud indexing techniques assign a rain rate level to each cloud type identified in the satellite imagery. The simplest and perhaps most widely used is the one developed by Arkin (1979) during the GARP (Global Atmosphere Research Program) Atlantic Tropical Experiment (GATE) on the basis of a high correlation between radar-estimated precipitation and fraction of the area colder than 235 K in the IR. The scheme, named the GOES Precipitation Index (GPI) (Arkin and Meisner, 1987), assigns these areas a constant rain rate of 3 mm h⁻¹, which is appropriate for tropical precipitation over 2.5° latitude $\times$ 2.5° longitude areas. The GPI is a standard for climatological

Rainfall, Table 1 Summary of satellite measurements and their attributes

Observation spectrum	Satellite type	Sensor examples	Strength	Weakness
Visible (VIS)	GEO	GOES imager	Cloud type	Cloud tops
	LEO	AVHRR	Cloud evolution	Indirect rain rate
Infrared (IR)	GEO	GOES imager	Cloud temperature	Cirrus contamination
	LEO	AVHRR	Cloud evolution	Indirect rain rate
Passive microwave (PMW)	LEO	SSM/I	Direct measure of rain, especially over ocean	Temporal sampling
		AMS-E		Indirect rain rate (land)
Active microwave (AMW)	LEO	TRMM PR	Direct measure of vertical structure of rain	Narrow swath width
		CloudSat CPR		Rain rate sensitivity

Rainfall, Figure 1 Comparison of VIS (left image) and IR (right image) from May 20, 2008 – 19:45Z over Central America. The red circle shows a feature with high reflectivity but high temperature (presumably low warm clouds with no rain associated), while the purple square shows a region with low temperature and very high reflectivity (large convective clouds). The last feature is related with higher rain rates.

rainfall analysis (Arkin and Janowiak, 1991) and is regularly applied and archived for climatological studies (see *Climate Monitoring and Prediction*).

A family of cloud indexing algorithms was developed at the University of Bristol. “Rain days” are identified from the occurrence of IR brightness temperatures (TB) below a threshold at a given location. The estimated rain days are combined with rain-per-rain day means that are spatially variable to produce rainfall estimations for extended periods (10 or more days). The most recent version of the Bristol technique uses variable IR rain/no-rain TB thresholds (Todd et al., 1995, 1999).

Bi-spectral methods

Bi-spectral methods are based on the very simple, although not always accurate, relationship between cold and bright clouds and high probability of precipitation, which is characteristic of cumulonimbus. Lower probabilities are associated to cold but dull clouds (thin cirrus) or bright but warm clouds (stratus). The RAINSAT technique (Lovejoy and Austin, 1979; Bellon et al., 1980) screens out cold but not highly reflective clouds or those that are highly reflective but have a relatively warm top. The number of false alarms of the pure IR techniques is reduced. The algorithm is based on a supervised classification trained by radar to recognize precipitation from both VIS brightness and IR brightness temperature.

Life-history methods

A family of techniques that specifically requires GEO satellite imagery are the life-history methods that rely upon a detailed analysis of the cloud’s life cycle, which is particularly relevant for convective clouds. An example is the Griffith-Woodley technique (Griffith et al., 1978). In this case, the increasing cloud area is treated different from

shrinking clouds. A major problem arises in the presence of cirrus anvils from neighboring clouds: they often screen the cloud life cycle underneath, leading to possible underestimates early in the day and overestimates toward the evening. Reasonable performances of this type of methods are obtained for deep convective storms, while contradictory results arise from their application to stratiform systems or weak convection (Amorati et al., 2000).

Cloud model-based techniques

Cloud model techniques aim at introducing the cloud physics into the retrieval process for a quantitative improvement deriving from the overall better physical description of the rain formation processes. A one-dimensional cloud model relates cloud-top temperature to rain rate and rain area in the Convective Stratiform Technique (CST) (Adler and Negri, 1988). Local minima in the IR brightness temperature are sought and screened to eliminate thin, nonprecipitating cirrus. To do so a slope parameter is calculated for each temperature minimum. Adler and Negri (1988) have established an empirical discrimination of thin cirrus in the temperature/slope plane using radar and visible imagery data. If the $T_{\min}$ and its slope fall to the left of the discrimination line, the $T_{\min}$ location is classified as thin cirrus (non-raining). A larger slope implies a more clearly defined minimum, corresponding to a thunderstorm.

NWP-adjusted and multispectral methods

Numerical weather prediction (NWP) outputs are being incorporated widely in satellite rainfall estimations. These correction factors range from moisture correction (Vicente et al., 1998) to orographic-driven precipitation. In the latter case, Digital Elevation Model (DEM) and low tropospheric winds are used to adjust the final

Rainfall, Figure 2 Vertical transmittance from the surface to space in the 15 °N annual atmosphere.

retrievals (Vicente et al., 2002). The Auto-Estimator technique (Vicente et al., 1998) proposed a moisture correction factor defined as the product of precipitable water (PW) in the layer from the surface to 500 mb times relative humidity (RH) (mean values between the surface and the 500 mb level) data. The PWRH factor decreases rainfall rates in very dry environments and increases them in very moist ones. The most recent version of this algorithm, called Hydro-Estimator, uses PW to adjust the power-law relation between cloud-top temperature and precipitation rates, while RH is applied to adjust the final rain rates (Scofield and Kuligowski, 2003).

The GOES Multispectral Rainfall Algorithm, GMSRA, (Ba and Gruber, 2001) combines multispectral measurements of the GEO satellites to estimate rainfall. One of the principal innovations of GMSRA relative to previous IR/VIS algorithms is that it combines several cloud properties used in a variety of techniques in a single and comprehensive rainfall algorithm. To be specific, the technique uses cloud-top temperatures as a basis of rain estimation (e.g., Arkin and Meisner, 1987; Vicente et al., 1998), and it utilizes the effective radii of cloud particles (e.g., Rosenfeld and Gutman, 1994) and spatial and temporal temperature gradients (e.g., Adler and Negri, 1988; Vicente et al., 1998) to screen out non-raining clouds.

Passive microwave methods

Unlike VIS and IR signals, microwave energy can penetrate clouds, in particular, cirrus clouds, and its signal has a strong interaction with precipitation-size drops and ice particles. This direct impact on microwave

measurements by hydrometeors allows for the quantitative detection of precipitation properties in the atmosphere as well as on the surface. It should be pointed out that passive MW (PMW) means naturally emitted radiation from the Earth's surface and atmosphere that interacts with clouds and precipitation and is measured by a radiometer onboard a satellite.

Most passive microwave radiometers launched to date operate in frequencies ranging from 6 to 190 GHz. At different frequencies, microwave radiometers observe different parts of the rain profile. Below 20 GHz, emission by precipitation-size drops dominates and ice particles above the rain layer are nearly transparent. Above 60 GHz, ice scattering dominates and the radiometers cannot sense the raindrops below the freezing layer. Both emission and scattering effects are important for frequencies between 20 and 60 GHz. In general, emission by liquid drops raises brightness temperature, while scattering by ice particles has the opposite effect. Besides the shift in dominating mechanism from emission to scattering with the increase of frequency, rain rate also plays a role by enhancing both the emission and the scattering signals. It is noted that the scattering by ice increases much more rapidly with frequency than scattering by liquid (Kidder and Vonder Haar, 1995). Other elements that have significant impacts on microwave radiation are shown in Figure 2. Window channels can measure down to the Earth's surface and are strongly influenced by surface properties (i.e., vegetation, soil moisture) (see *Land Surface Emissivity*). Other frequencies are sensitive to oxygen or water vapor/cloud droplets absorption. These microwave properties set the foundation for the development of rainfall estimation schemes.

There are two major categories in rainfall estimation using passive microwave radiometry: emission-based method and scattering-based method. They will be discussed in the following sections.

Emission-based methods

Emission-based rainfall algorithms are mostly applicable over ocean because water surfaces are relatively homogeneous and provide a cold background due to low emissivity. Below certain threshold rain intensity, emission dominates rather than scattering over water especially at lower frequencies. Brightness temperature (TB) increases rapidly with rain rate in this range and provides the basis for many emission-based precipitation retrieval methods. The primary disadvantage of emission-based techniques is that the microwave signal can saturate with moderate to heavy rain rates (which is frequency dependent), thus providing a strong nonlinear relationship between rain rate and TB.

The earliest efforts to estimate rain rate from satellite measurements used microwave data from the electrically scanning microwave radiometer (ESMR) on the Nimbus 5 and Nimbus 6 satellites and the scanning multichannel microwave radiometer (SMMR) on both Nimbus 7 and Seasat-A. Wilheit et al. (1977) employed a radiative transfer model to calculate the 19.35 GHz TB as a function of rain rate over ocean and used the 19.35 GHz measurements from ESMR-5 to retrieve rain rate. Weinman and Guetter (1977) utilized the weak polarization of 37 GHz radiances from ESMR-6 to discriminate convective rain over land from open water. Rain rate over water was expressed as a function of TB taking into consideration the polarization effects; a lower polarization was correlated to heavier rain rates. SMMR had five frequencies with both horizontal and vertical polarizations. Spencer et al. (1983) took advantage of the significant impact of raindrops on the thermal emission at lower frequencies (highest SMMR frequency is 37 GHz) and used multiple regression approach to relate SMMR TBs to rain rate.

The first of the special sensor microwave/imager (SSM/I) series was launched in 1987 and was followed by five more successful SSM/I instruments. The SSM/I has seven vertically and horizontally polarized channels and four frequencies at 19.35, 22.235, 37.0, and 85.5 GHz. This is a well-studied instrument for rainfall estimation. Ferraro and Marks (1995) developed an SSM/I algorithm linking oceanic rain rate with liquid water path (Weng and Grody, 1994) using ground-based radar measurements. The retrieval of liquid water path relies on the emission signatures at 19 and 37 GHz. This ocean scheme is part of the operational SSM/I rainfall algorithm as introduced in the next section.

Mugnai and Smith (1984) were the first to combine cloud model with radiative transfer model for estimating TBs from convective clouds. Studies along this line of thinking followed (Olson, 1989; Smith et al., 1994). The Goddard profiling algorithm (GPROF) is one of the

inversion algorithms that computes radiative transfer based on output from cloud models (Kummerow et al., 1996, 2001). GPROF is applied to the Tropical Rainfall Measuring Mission (TRMM) Microwave Imager (TMI) for the retrieval of surface rain rate and rainfall profile. A large a priori database of atmospheric profiles and TB at the TMI frequencies is constructed using output of two cloud-resolving models and a one-dimensional radiative transfer model. Then the algorithm utilizes a Bayesian inversion approach to derive instantaneous rain rate and rainfall profile by a weighted summation of all the profiles in the database. The weight is determined by how close each TB vector in the database resembles the observed vector. GPROF is also the primary rainfall algorithm being applied to the Advanced Microwave Sounding Radiometer-Earth Observing System (EOS) (AMSRE) (Wilheit et al., 2003).

Bauer et al. (2005) proposed a scheme for retrieving precipitation profiles over all surfaces by using microwave frequencies both in atmospheric windows between 18 and 150 GHz and in oxygen absorption complexes or sounding channels near 50–60 and 118 GHz. Hydrometeor profiles are created by applying cloud and convection schemes using information from European Centre for Medium-Range Weather Forecasts (ECMWF) short-range forecasts. A radiative transfer model and one-dimensional variational (1D-Var) retrieval framework are employed to achieve optimum hydrometeor profile retrievals.

Scattering-based methods

Due to the higher but more varying emissivity of the land surface, the only reliable means of detecting rainfall over land is by isolating depressed TBs as a result of scattering by millimeter-sized ice particles that exist in most rain clouds (see *Optical/Infrared, Scattering by Aerosols and Hydrometeors*). Since the signal being captured is a result of ice particles instead of raindrops, the scattering-based rainfall estimation is an indirect measure of rainfall, as it relates the magnitude of the scattering near the freezing layer to surface rainfall. The launch of the SSM/I in 1987 provided the first opportunity to retrieve rain rate through scattering at higher frequency (85 GHz). Meteorological satellites launched since then have included channels at or above 85 GHz that are sensitive to scattering, including more recent sensors that contain measurement channels at or above 150 GHz. Thus, these measurements have been exploited to develop scattering-based rainfall algorithms.

Spencer et al. (1989) first introduced the concept of polarization-corrected brightness temperature (PCT) which is a linear combination of the vertically and horizontally polarized brightness temperatures at 85.5 GHz. The coefficients in PCT can be adjusted so that PCT is only sensitive to the scattering in the upwelling microwave radiation but not to other atmospheric and land surface conditions including the contrast of land versus ocean.

An operational SSM/I rain rate product generated at Fleet Numerical Meteorology and Oceanography Center (FNMOC) (Ferraro, 1997) combines a scattering-based global algorithm with the abovementioned SSM/I emission-based ocean algorithm (Ferraro and Marks, 1995). The global algorithm calculates a scattering index (SI) (Grody, 1991) which is the difference between the vertically polarized 85.5 GHz observation and an estimate of the non-scattering contribution from this channel. The latter is a linear combination of the observations at lower channels (19.35 and 22.235 GHz). The SI algorithms are calibrated with ground-based radar measurements to produce instantaneous rain rate for both ocean and land (Ferraro and Marks, 1995). The emission-based algorithm complements the SI algorithm by detecting rain systems over ocean that has little or no ice scattering. A decision tree is included in the algorithm to screen out surface scattering sources such as snow cover and desert. This widely used algorithm is also adapted into GPROF land rain rate algorithm as described by McCollum and Ferraro (2003). The relationships between rain rate and 85 GHz brightness temperature are recalibrated using TRMM Precipitation Radar (PR) data, and a new procedure is developed to estimate convective rainfall.

Zhao and Weng (2002) took advantage of the highly scattering nature of 89 and in particular 150 GHz radiances from the Advanced Microwave Sounding Unit-B (AMSU-B) and retrieved ice water path (IWP) using scattering parameters measured at these two channels. The derived IWP is then converted into the surface rainfall rate (RR) through an IWP and rainfall rate relationship developed from cloud model results (Weng et al., 2003). This rain rate product is being operationally generated at National Environmental Satellite, Data, and Information Service (NESDIS) of National Oceanic and Atmospheric Administration (NOAA). This algorithm has also been applied to Microwave Humidity Sounder (MHS) with some modification since AMSU-B and MHS have very similar channels. Vila et al. (2008) added an emission-based component to this rainfall algorithm to account for oceanic rain systems that have little or no ice in them. Figure 3 shows this rain rate product and some of the corresponding TBs that have the emission and scattering signals of rain systems.

Active microwave methods

In contrast to passive microwave radiometers, active microwave sensors provide their own source of microwave radiation. Short pulses are transmitted at microwave frequencies; the time delay and strength of the returned echo gives the distance and intensity of the rain from space. Radar is also able to discriminate in range, that is, in altitude from space. Hence, radar measures fine-scale and vertical distribution of rainfall. In order to provide good horizontal resolution and minimize surface clutter effects for off-nadir incidence without the use of large antennas (greater than 2 m), only frequencies greater than

10 GHz are practical (Fujita and Satake, 1997). At such frequencies, attenuation is significant in moderate to heavy rain and affects the radar reflectivity measurement near the surface where rain information is most desired. Over the rain depth of kilometers, the two-way path-integrated attenuation (PIA) becomes significant even at moderate rain rates and leads to a bias in rain rate estimate, unless reflectivity is corrected for attenuation effects. Such a bias increases with frequency as a result of an increase in PIA.

Techniques have been developed to remove the effects of attenuation when they become significant. The study by Hitschfeld and Bordan (1954) was one of the first to propose a method for directly correcting measured reflectivities for attenuation. After correcting attenuation effects, estimates of non-attenuated reflectivity (Z) are related to rain rate (R) by using Z - R relations. The Hitschfeld-Bordan (HB) solution gives reasonable estimates if the attenuation is small and the radar is well calibrated. When these conditions are not met, the HB solution can become unstable. Numerous retrieval methods have been developed that incorporate this early work along with the more recent technique of constraining the retrievals using PIA derived from surface reference technique (SRT) (Iguchi and Meneghini, 1994; Marzoug and Amayenc, 1994; Amayenc et al., 1996). SRT relies on a reference measurement of the radar return from the surface in rain-free conditions. For example, if the surface returns for a particular incidence angle and surface types are fairly stable, then the difference in surface returns for rain-filled and rain-free radar beams can be ascribed to the effects of attenuation by precipitation. The SRT method provides a reasonable way to monitor PIA over the ocean. Over land, particularly at near-nadir incidence where the surface scattering cross section is usually highly variable in both space and time, the method is less reliable (Meneghini et al., 2000).

For cm-wavelength radars (such as the TRMM radar), attenuation corrections are relatively modest for most rains. For mm-wavelength radars (such as the radar on CloudSat), attenuation is strong and often becomes a dominant factor responsible for systematic reflectivity differences. Another example of rainfall retrieval technique from spaceborne radar is to use the attenuation directly caused by rainfall (Matrosov, 2007). This method takes advantage of high attenuation in rain and low variability of non-attenuated reflectivities and uses estimates of height derivatives of attenuated reflectivities. These estimates are then related to rain rate. Early result from a 94 GHz CloudSat radar indicates a possibility of rain rate profile retrieval (Matrosov, 2007; Mitrescu et al., 2008).

Current Sensors

- (a) TRMM PR In orbit since 1997, the Precipitation Radar (PR) on the TRMM satellite (Tropical Rainfall Measurement Mission) is the first instrument designed to measure rain from space (Kummerow et al., 1998).

Rainfall, Figure 3 NOAA-18 rain rate product (NOAA/NESDIS) and antenna temperatures. (a) Rain rate and antenna temperature at (b) AMSU-A 31.4 GHz, (c) MHS 89 GHz, and (d) MHS 157 GHz. The black circle in the images indicates a rain system dominated with ice cloud and characterized with gradual increase in scattering signal from 31.4 to 157 GHz and hence decreasing in antenna temperatures. The scattering-based portion of the NESDIS rain rate algorithm captures this rain system very well. The black oval shows a warm rain system in the tropical Pacific Ocean that was detected by the emission-based portion of the NESDIS algorithm. The emission signal is visible in 31.4 and 89 GHz but weak in 157 GHz images. Comparing with the nonprecipitating ocean area, the antenna temperatures in the raining zone are warmer at 31.4 and 89 GHz but have little difference at 157 GHz.

TRMM's PR provides direct, fine-scale, and vertical distribution of precipitation. PR is a cross-track radar that surveys a swath of 220 km at a horizontal resolution of 4.3 km. It gives the vertical distribution of rain, with the height resolution of 250 m. TRMM is in a low orbit, 402.5 km above the Earth's surface. Its subtrack covers latitudes of $\pm 35^\circ$. The PR rain retrieval algorithm (Iguchi et al., 2000) uses a hybrid of the HB and SRT methods to correct for attenuation. When the SRT is reliable, the radar-rain rate relations are adjusted so that the HB path-attenuated estimate is equal to that of SRT. When the SRT is unreliable, the HB method is usually used along with radar-rainfall relation derived from ground-based disdrometer measurements, conditioned on rain type, to provide vertical profiles of rain rate. Figure 4

illustrates an example of PR's ability to probe vertical rain structure. On September 28, Hurricane Lili was southeast of Cuba, but winds in the tropical storm were blowing at a steady 45 kts. Figure 4a shows PR estimated rain in colors: clouds are shown in white; light rain is shown in blue; extreme rain rates in red. Figure 4b shows the cone-shaped eye, newly developed and surrounded by moderate intensity rain clouds. Also shown is a prominent rain band feeding in toward the storm's inner core. Figure 4c reveals towering clouds that helped power Lili's growth, called "chimney clouds." The chimneys contain intense updrafts that release copious amounts of heat energy inside the storm. Such three-dimensional information on precipitation can only be measured by a spaceborne radar.

Rainfall, Figure 4 TRMM PR swath (red lines) and rain rates for Hurricane Lili on 28 September 2002 overlaid on a cloud image (top). PR vertical cross sections for line A–B (middle) and line C–D (bottom) as indicated in top image. The color shading in all images indicates the relative rain intensities (Image courtesy of NASA/GSFC).

- (b) CloudSat Launched in April 2006, CloudSat is the first millimeter-wavelength cloud radar in space (Stephens et al., 2002). The Cloud Profiling Radar (CPR) aboard CloudSat is a 94 GHz near-nadir-pointing radar with 500 m vertical resolution. The design concept of CPR is to provide vertical cross section of cloud liquid and ice water content and particle size. At the altitude of 750 km, the CPR provides vertical

profiles of radar reflectivity. Although the main objective of CPR is to provide global information on clouds, it also resolves many precipitation systems. It has been suggested that CloudSat data can be used to estimate light rainfall (L'ecuyer and Stephens, 2002). Early results have shown the potential of 94 GHz cloud radar for the detection of precipitation (Haynes et al., 2007) and rain rate profile retrievals (Matrosov, 2007). Figure 5 shows an example of CloudSat rain profiling retrieval (Mitrescu et al., 2008). Figure 5a shows the CloudSat reflectivity on 31 July 2006. The quasi-uniform cloud layer extends up to 13 km; the bright band is identifiable at 4 km. Figure 5b shows the CloudSat retrieved rain rates from two different retrieval algorithms and a ground radar measurement: solid line is retrievals by Mitrescu et al. (2008), squares are retrievals by Matrosov (2007), and triangles are rain rate estimates from the NEXRAD radar KLIX located in New Orleans. Although overall, the retrieved rain rates are comparable, there are noticeable differences.

Future sensors

- (a) GPM-DPR GPM (Global Precipitation Measurement) is a joint US-Japan mission designed to extend TRMM's observations of precipitation to higher latitudes, with more frequent sampling. The GPM core satellite will carry a dual-frequency, cross-track scanning, Ku/Ka-band (13.6/35.5 GHz) precipitation radar, i.e., the DPR (Iguchi et al., 2002). Anticipated advantages of the DPR over the single-frequency PR include enhanced sensitivity at light rain rates, information on the particle size distribution in rain and snow, and improvements in the identification of vertical layers consisting of mixed phase, frozen, and liquid particles. Particle size estimation follows from Mie scattering effects in that the difference in radar reflectivities (in dB) at the two frequencies provides an estimate of the mean particle size of the distribution (Doviak and Zrnica, 1984; Meneghini et al., 1989, 1992; Kuo et al., 2004). This dual-frequency measurement allows for recovery of at least 2 of 3 parameters needed to describe the bulk distribution of the generalized raindrop size distribution (DSD). Such measurements are important because increased knowledge of DSD factors improves the retrievals of rain rate.
- (b) EarthCARE EarthCARE is a joint Europe-Japan mission with a spaceborne 94 GHz Cloud Profiling Radar (CPR) and is scheduled to be launched in 2012. CPR on EarthCARE will have better sensitivity to cloud detection than CloudSat. One other important feature of CPR/EarthCARE will be its Doppler capability which is expected to provide vertical Doppler velocity profiles of cloud echoes, which are important for cloud physics and drizzle detection (Ohno et al., 2007).

Rainfall, Figure 5 CloudSat reflectivity in dBZ (*top*) and derived precipitation rates in mm h^{-1} (*bottom*) for 31 July 2006 for a short cross section through a storm system over the coastline of Mississippi. The upper image has the surface temperature and pressure contoured to give an indication of the height of the freezing level. The lower image shows the corresponding rain rate from two different CloudSat retrievals (*squares and triangles*) and surface radar-derived rain rates (*solid line*) (The image is courtesy of J. Turk and T. Mirtrescu, Naval Research Laboratory, Monterey, CA, USA).

Multisensor datasets

The individual sensor records discussed so far each have limitations which make them unsuitable for use in certain situations. For example, PMW estimates over the ocean might be the more accurate than GEO-IR estimates, but the latter are better suited for studies of the diurnal cycle due to the superior sampling obtained from a GEO satellite. Conveniently, the available remotely sensed estimates of precipitation have different strengths and weaknesses, so that combined datasets can be superior to estimates from individual sensors. Several efforts to intercompare and evaluate various types of precipitation algorithms using remotely sensed information were carried out during the 1990s. The WetNet (Dodge and Goodman, 1994) Precipitation Intercomparison Projects (PIP) evaluated multiple global and near-global precipitation algorithms including merged satellite datasets (Barrett et al., 1994; Kniveton et al., 1994; Smith et al., 1998; Adler et al., 2001). The Global Precipitation Climatology Project (GPCP) similarly sponsored three Algorithm Intercomparison Projects (AIP; Ebert et al., 1996) that compared precipitation estimated from satellite observations against high-resolution observations from rain gauges and radars over limited domains (Arkin and Xie, 1994;

Ebert and Manton, 1998). Among other results, these studies showed that PMW estimates were more accurate than IR estimates on an instantaneous basis, but algorithms which combine PMW and IR estimates were superior. However, these intercomparisons did not show significant differences between individual algorithms of a common type, and it remains the case that several merged satellite products exist without a clear consensus on which is superior, and it is common to see a range of similar datasets used in the literature.

Early combinations: GPCP and CMAP

The pre-TRMM (i.e., pre-1997) multisensor combinations of precipitation which included PMW as an input were restricted to combinations of VIS or IR estimates (both geosynchronous and low orbit) and estimates from SSM/I. Many of the early multisource precipitation estimates failed to progress past the research-only phase, but two datasets have endured and are both still in common use: the Global Precipitation Climatology Project (GPCP; Huffman et al., 1997; Adler et al., 2003) and the Climate Prediction Center Merged Analysis of Precipitation (CMAP; Xie and Arkin, 1997b). GPCP and CMAP are both monthly 2.5° resolution and use several common

Rainfall, Figure 6 (Continued)

inputs with somewhat similar merge algorithms and are therefore frequently considered to be similar, although they use different gauge analyses and have different corrections over the tropical oceans. Both datasets start in

1979 and have changing inputs over time as superior data records become available, such as the SSM/I estimates in 1987. The current version of the GPCP 2.5° monthly mean dataset is the version two dataset (Adler et al., 2003)

Rainfall, Figure 6 Maps of precipitation estimates from (a and b) GPCP Version 2, (c and d) CMAP with NCEP/NCAR reanalysis at high latitudes, (e and f) the TMPA, (g and h) CMORPH, and (i and j) PERSIANN. Maps show mean precipitation for (a, c, e, g, and i) July 2007; (b, d) January 1979–December 2007; (f) 10:30–13:30z, 15 July 2007; and (h and j) 12–15z, 15 July 2007. All units are scaled to mm day^{-1} for comparison.

which improved on the first version with a longer record and the addition of TOVS data for improved estimates at mid- and higher latitudes. Both CMAP and GPCP have problems with high-latitude precipitation due to the lack of reliable data: there are few gauges in these sparsely populated regions and available satellite-derived precipitation estimates are of limited use over ice- or snow-covered surfaces. Some studies suggest that model data might be superior to all other estimates at high latitudes (Serreze et al., 2005; Su et al., 2006; Sapiano et al., 2008), and a version of CMAP includes reanalysis precipitation forecasts from the NCAR NCEP reanalysis (Kalnay et al., 1997) over the high latitudes which is the version shown in Figure 6 (CMAP is also available without the reanalysis data). Figure 6 shows the substantial difference in the magnitude of tropical precipitation between GPCP and CMAP as well as the broad differences in precipitation at higher latitudes, although the broad patterns are very similar as would be expected from the use of many common inputs.

Although the monthly, 2.5° products are most commonly used, higher-resolution products also exist as part of the GPCP suite. A pentad (5 days mean) version of GPCP combines similar satellite inputs as the monthly product with a different gauge dataset (Xie et al., 2003). This experimental dataset is also produced on a 2.5° resolution grid and starts in 1979. A one-degree, daily version of the GPCP dataset is also available which starts in 1996 and combines IR from geosynchronous and low orbits with the GPCP Version 2 monthly product and AIRS and TOVS estimates (Huffman et al., 2001). This dataset does not directly use PMW data, although the SSM/I estimates are implicitly used through the inclusion of the monthly GPCP Version 2 product.

High-resolution precipitation products

While GPCP and CMAP are still commonly used for global, monthly, coarse resolution studies (including

validation of numerical model forecasts), recent increases in the availability of PMW data (SSM/I, TMI, AMSU, AMSR) have led to the emergence of several near-global, high-resolution products which have begun to supersede the pentad and one-degree daily products of the GPCP. These products are not global (extending no further than 60°N/S) but have spatial resolutions of at least 0.25° and temporal resolution of at least three hourly and are based on a variety of innovative methods for combining estimates derived from PMW observations with GEO-IR imagery. Generally speaking, these high-resolution precipitation products (HRPPs) use the high spatial and temporal resolution of IR data to resolve deficiencies in resolution of the higher-quality PMW data, although there are substantial differences between the exact methodologies employed. The HRPPs can be categorized into two broad types: adjustment-based techniques where IR data is calibrated using PMW estimates (where the two are often then combined) and motion-based techniques, where the IR data is used to interpolate between successive PMW overpasses.

The Pilot Evaluation of High-Resolution Precipitation Products (PEHRPP) was established to intercompare and validate these datasets. PEHRPP included a number of high-resolution datasets: the TRMM Multisatellite Precipitation Analysis (TMPA; Huffman et al., 2007), the CPC Morphing technique (CMORPH; Joyce et al., 2004), the Hydro-Estimator (Scotfield and Kuligowski, 2003), the NRL-Blended technique (NRL-Blended; Turk and Miller, 2005), Precipitation Estimation from Remotely Sensed Information using Artificial Neural Networks (PERSIANN; Hsu et al., 1997; Sorooshian et al., 2000), and the Global Satellite Mapping of Precipitation (GSMaP) project. Studies to compare these datasets are underway, although there is no technique that outperforms the others on a consistent basis (Gottschalck et al., 2005; Brown, 2006; Ebert et al., 2007; Ruane and Roads, 2007; Tian et al., 2007; Sapiiano and Arkin, 2009). Figure 6 shows a single three-hourly and daily accumulation for TMPA (Figure 6f), CMORPH (Figure 6h), and PERSIANN (Figure 6j). These three datasets have different properties; TMPA is a simple combination of PMW and IR starting in 1997 and is gauge adjusted; CMORPH uses IR information to advect PMW information between successive overpasses and has near-global resolution of 8 km, three hourly; PERSIANN uses a neural network (trained with PMW estimates) to translate IR only to rain rates. The different properties of these datasets are clear, with PERSIANN giving somewhat smoother estimates than the other two, which generally agree with each other, although TMPA is closer to GPCP and CMAP over land areas. Despite recent advances there is still much uncertainty in the quality of high-resolution precipitation datasets compared to coarser datasets such as GPCP and CMAP. Reconciliation between the HRPPs and the coarser datasets has still not been achieved, and the algorithm designs employed by GPCP and CMAP remove much of the inherent noise from the inputs, so that they

are considered more reliable than the HRPPs. In short, the reader is advised to use the class of dataset that has closest resolution to their needs and is cautioned against averaging high-resolution data.

Summary

There are various techniques to retrieve rainfall from satellites, each with their own set of attributes that are dictated by the particular needs for the information; for short-term, high spatial resolution applications like flash flood forecasting, the IR methods are generally preferred, while for global, climate scales, the PMW are usually preferred. In this sense, no single approach can be defined as the best one; however, in terms of accuracy on the instantaneous time scale (i.e., at the time the satellite is making its measurement), it is generally accepted that the active MW is the most accurate, followed by passive MW (ocean), passive MW (land), IR, and VIS.

Many of the early methods were developed using sensors that were not necessarily flown for rainfall retrieval but more for tracking cloud features and monitoring atmospheric temperature and moisture. As was described, more recent and near-term missions are being designed specifically for rainfall monitoring and include AMW sensors (e.g., the GPM mission). Additionally, emerging methods such as the blended techniques or multispectral (including PMW and AMW) will yield improvements to the current accuracy of the remote sensing of rainfall and will likely become the standard retrieval method as we enter into the next decade.

RANGELANDS AND GRAZING

Hunt E. Raymond, Jr.
USDA-ARS Hydrology and Remote Sensing
Laboratory, Beltsville, MD, USA

Synonyms

Grasslands; Grazing lands; Pampas; Prairie; Savanna; Shrublands; Steppes

Definition

Rangelands. Type of land cover dominated by grasses, grasslike plants, broadleaf herbaceous plants (forbs), and shrubs, where the land is managed as a natural ecosystem for multiple uses including wildlife habitat, biodiversity, recreation, and grazing by livestock.

Pasturelands. Type of land cover dominated by grasses, grasslike plants, and broadleaf herbaceous plants, where the land is managed as an agricultural system for livestock production.

Plant community. Co-occurring plant species and their relative abundance and which is usually recognized by the dominant plant species or functional type.

Ecological site. A combination of soil, climate, and hydrological factors that have the potential for a distinctive climax plant community with a given amount of net primary production.

Rangeland health. The degree to which the integrity of the soil is maintained and ecological processes are sustained.

Introduction

Rangelands encompass many different land cover types throughout the world, including grasslands, savannas, shrublands, tundras, marshes, and meadows (Holechek et al., 2004). Based upon the NASA MODIS land cover product, rangelands cover about 48 % of the Earth's land surface, not counting Antarctica (Friedl et al., 2010).

Most rangeland cover types are found in regions where the annual precipitation is low and the interannual variability of precipitation is high, which makes these regions unsuitable for forestry or agriculture. Livestock grazing is a land use that provides a sustainable means of producing food and fiber in rangeland cover types. Confusingly, many nongovernmental organizations use the term rangelands to denote a land-use category of livestock grazing (Lund, 2007).

Inventory, assessment, and management of grazing on rangelands within the USA are based on ecological sites, which are generally recognized and delimited by the historic climax plant community (NRCS, 2003). Another paradigm for management is rangeland health, which is based on prevention of soil erosion and the sustainability of ecosystem processes such as energy flow (primary production), the hydrologic cycle, and biogeochemical cycles (BLM, 2005; NRC, 1994). The concepts of rangeland health and ecological sites were developed in parallel in response to the shortcomings of "Rangeland Condition and Trend" (Briske et al., 2005).

Ecological sites

Management of rangelands was based initially on the theory of plant succession from Clements, (1916). Starting from bare substrate (primary succession) or bare soil (secondary succession), the dominant species change over time from short-lived to long-lived plants, ultimately reaching a climax plant community determined by climate. Climax plant communities were assumed to have the highest sustainable productivity, the greatest resistance to invasive species and pests, and the best protection against soil erosion; thus, rangeland management was based on maintaining or restoring the climax plant community. However, it was recognized that natural disturbances such as drought, grazing, and fire had to be incorporated into the definition of the climax community (NRCS, 2003; Briske et al., 2005). Ecological sites are identified and delimited by (1) the dominant plant community at the onset of European immigration and settlement (NRCS, 2003) and (2) soils and climate delineated by major land resource areas (NRCS, 2006).

An ecological state is comprised of group of plant communities which are in a dynamic equilibrium with the historical amounts and types of disturbances at a given ecological site. If disturbances are substantially greater than historical levels, there may be a transition to a different ecological state, with new groups of plant communities (NRCS, 2003; Briske et al., 2005).

Rangelands and Grazing, Figure 1 State-and-transition diagram for an ecological site. The large boxes with solid lines are stable ecological states (A, B, ..., N) within which dynamic changes in plant communities result from natural disturbances. Changes from one state to another (transition) are usually irreversible without large management inputs. Boxes with dashed lines are used to represent a specific plant community that occurs within a stable ecological state. The historical climax plant community is the ideal management goal for sustainable use. Arrows show possible changes and the symbols represent a mechanism for the possible change. Symbols are *NF* no fire, *PF* prescribed fire, *BM* brush management, *HG* heavy grazing, *PG* prescribed grazing, *CHG* continuous heavy grazing, *Seed* reseeding, *Inv* invasion, and *IM* integrated management.

The relationships among plant communities and ecological states for an ecological site are depicted in a state-and-transition model (Figure 1). In Figure 1, State A includes the various plant communities found at an ecological site with historical levels of disturbance, including the historic climax plant community. Within State A, plant community 2 could be the result of woody shrub establishment allowed by reduced fire frequency and plant community 3 could be an earlier stage of succession after disturbance. However, continuous heavy grazing may result in soil erosion, so the site crosses a threshold into a new State B with plant community 4;

changes of grazing intensity alone are unlikely to restore the site to State A without reseeding (Figure 1). Alternatively, the ecological site could be invaded by a nonnative weed species (State N), requiring integrated management (a combination of biological, cultural, and chemical control) for restoration (Figure 1).

Because an ecological site is defined by the potential to have a climax plant community, and because an ecological state may have many different plant communities, rarely will land cover classification from satellite remote sensing have a major role for mapping either ecological sites or states (Hunt et al., 2003; Pickup et al., 1994).

A combination of imagery, geospatial databases of soils and climate, and computer simulation modeling could be used to determine potential vegetation for ecological sites (Jensen et al., 2001). Simple detection of land cover change between two dates is not useful for detecting a state transition because of year-to-year variability; analysis of long-term imagery is important to distinguish a state transition (Washington-Allen et al., 2006).

Rangeland health

Rangeland health is monitored by relative rankings of 17 indicators based on (1) soils and soil structure; (2) hydrological, nutrient, and carbon cycling (including net primary production); and (3) functional plant diversity and presence of invasive species (BLM, 2005). Of all of the indicators, ground cover fractions have been demonstrated as having the greatest utility for economical sampling and objective measurement on a landscape scale (Booth and Tueller, 2003; Pickup et al., 1994). Other aspects of rangeland health could be monitored operationally with the appropriate sensors, such as changes in vegetation productivity, invasion of noxious weeds, and cover of senesced and living plant material (Hunt et al., 2003; Palmer and Fortesque, 2004). If it is accepted that unbiased, economical monitoring rangelands is required, and remote sensing provides these methods, then the framework for rangeland assessment needs to be reformulated based on what remote sensing can accomplish (Pickup et al., 1994, p. 499).

Rangeland productivity

Primary production of rangelands can be estimated using the amount of absorbed photosynthetically active radiation integrated over time, which is the basis of MODIS primary production (MOD17A3) data product (Reeves et al., 2001, 2006; Running et al., 2004). NDVI is approximately equal to the fraction of incident photosynthetically active radiation that is absorbed by the canopy, so NDVI integrated over time is also used to estimate primary production (Paruelo et al., 1997; Piñeiro et al., 2006; Tieszen et al., 1997).

Net primary production provides the upper limit on available forage on a sustainable basis and hence determines the stocking rate or carrying capacity. Determination of standing biomass by remote sensing is possible, but grazing based on standing biomass may not be sustainable. A 455 kg cow (one animal unit) consumes about 9.1 kg of forage per day (Holechek et al., 2004); 273 kg of forage is one animal unit month (AUM). The above-ground net primary production divided by 273 kg/month sets the stocking rate in AUM per area; factors such as slope and distance to water reduce the stocking rate from the maximum (Holechek et al., 2004). Many of these factors can be estimated from geospatial databases allowing determination of recommended stocking rates (Hunt et al., 2003; Hunt and Miyake, 2006). Environmental data records of NDVI from AVHRR, MODIS, SPOT

Vegetation, and VIIRS (Tucker et al., 2005; Brown et al., 2006) are important because the long time series available can assess variability of net primary production due to variability in rainfall.

Detection of invasive weeds

Invasive shrubs and weeds dominate the vegetation of many rangeland plant communities, affecting native biodiversity and reducing the amount of available forage (DiTomaso, 2000). Some invasive plants have spectrally distinctive flowers or leaves that can be detected with imaging spectroscopy (Andrew and Ustin, 2006; Everitt et al., 2002; Hunt et al., 2004; Lass et al., 2002; Parker Williams and Hunt, 2002; Underwood et al., 2003). Imaging spectrometers cover small areas and require extensive expertise for image processing; thus, they may not be useful for operational maps of detectable invasive species (Hunt et al., 2007). However, distribution maps from small areas may be used to test and refine geospatial models for the prediction of sites susceptible to invasion (Bradley and Mustard, 2006; Hunt et al., 2010). Other species such as cheatgrass (Bradley and Mustard, 2006) and salt cedar (Everitt et al., 2002; Groeneveld and Watson, 2008) can be detected using differences in phenology compared to the co-occurring native vegetation.

Ecosystem degradation

The cover fractions of bare soil, senesced plant matter (plant litter or residue), and green vegetation are key indicators of rangeland health (Booth and Tueller, 2003). Bare soil is very susceptible to erosion, and erosion increases the amount of bare soil visible from aircraft and satellites (Vrieling et al., 2007). Green vegetation cover is usually measured by scaling NDVI to account for soil background reflectance (Jiang et al., 2006; Montandon and Small, 2008; Pickup et al., 1998). Senesced plant matter is spectrally similar to bare soil at visible and near-infrared wavelengths; narrowband reflectances in the shortwave infrared may be used to detect senesced plant matter based on the absorption feature of cellulose at a wavelength of 2.1 μm (Daughtry et al., 2004; Nagler et al., 2000).

Spectral unmixing of remotely sensed imagery allows the cover fractions of bare soil, senesced plant matter, and green vegetation to be determined simultaneously (Asner and Heidebrecht, 2002; Roberts et al., 1993). Furthermore, there are a large number of studies that have successfully unmixed multispectral data based on the phenology of vegetation (Arsenault and Bonn, 2005; de Asis and Omasa, 2007; Kuemmerle et al., 2006; Metternicht and Fermont, 1998; Numata et al., 2007).

Very large-scale aerial photography

Very large-scale aerial (VLSA) photographs have very large map scales from 1:50 to 1:500 (pixel sizes of 1–50 mm) and are an important method of rangeland monitoring for either ecological-state or rangeland-health paradigms. Whereas aerial photography has been used

for over 50 years, digital cameras may reduce the cost for image acquisition, processing, and storage. At very large scales, composition of spectrally similar plant species may be identified (Petersen et al., 2005). Individual plants of an invasive species may be detected at the initial stages of establishment (Blumenthal et al., 2007; Naylor et al., 2005; Booth et al., 2010).

Landscape digital photographs may be compared quantitatively with digitized historic landscape photographs for change detection (Clark and Hardegree, 2005). With special robotic camera mount, landscape panoramas may be acquired at full magnification, resulting in a seamless image for analysis (Nichols et al., 2009). Analysis of large numbers of images may be very labor intensive without automation; supervised image classification is usually problematic because only three bands are acquired. "SamplePoint" software (Booth et al., 2006) reduces the time required to estimate cover from VLSA photographs.

Two types of airborne platforms for VLSA photography are being evaluated: unmanned aerial systems (Hardin and Jackson, 2005; Rango et al., 2006) and light manned aircraft (Booth et al., 2006, 2008). Light aircraft and unmanned aerial systems may cover transects or provide wall-to-wall coverage (Laliberte et al., 2010). Ground cover fractions from VLSA photography are highly correlated to ground measurements (Booth et al., 2008). However, because the area covered by each photograph is small, ground cover is not strongly correlated with satellite vegetation indices (Sivanpillai and Booth, 2008).

Management of economic risk with AVHRR NDVI

Crop insurance is used as a risk management tool in which payments are based on actual crop losses. In 2007, USDA Risk Management Agency started a pilot insurance program for pasture, rangeland, and forages (RMA, 2010) in order to manage risks from drought. In nine US states, rangeland managers may choose whether to estimate drought from either a rainfall index or a vegetation index (RMA, 2010). Then, the managers select one or more 3 months time periods when rainfall is important for pasture, rangeland, and forage production in their operations.

Grasses and forbs grow when water is available in the soil, so AVHRR NDVI is an indicator of rainfall in rangelands and low NDVI is an indicator of drought (Davenport and Nicholson, 1993; Di et al., 1994; Ji and Peters, 2003; Wang et al., 2003). Currently, 14 days composites of AVHRR NDVI are made and aggregated to an 8 km by 8 km grid cell by the USGS Earth Resources Observation and Science (EROS) Center (Sioux Falls, South Dakota). Based on the historical averages for a grid cell, a trigger grid index is determined. If the final value of NDVI falls below the trigger grid index, payments to the consumer are made based on area insured. Actual production losses are not used to calculate payments (RMA, 2010).

Conclusion

Primary production and pasture, range, and forage insurance are based on the frequent coverage provided by AVHRR, MODIS, SPOT Vegetation, and VIIRS. In the future, economic losses from drought may be better determined from primary production estimates using these sensors, to better estimate the forage available for livestock and wildlife. Rangeland management is currently based on ecological sites so very large-scale photography is the best remote sensing method; but it is difficult to cover large areas. Rangeland health needs to be better integrated with rangeland management based on ecological sites (Herrick et al., 2006). With the large area of rangelands globally, monitoring rangeland health will be unbiased and cost-effective using remote sensing, but only if the cost of the data is reasonable (Palmer and Fortesque, 2004).

REFLECTED SOLAR RADIATION SENSORS, MULTIANGLE IMAGING

David J. Diner

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA, USA

Synonyms

Multangular imaging; Multidirectional imaging; Multiple view angle imaging

Definitions

Sequential multiangle imaging. The acquisition of images of a scene at different view zenith angles (the angle between the local vertical and the direction to the observer) as a result of observing the scene on different occasions, for example, on different orbits of a satellite. In this case, the time separation between views may be hours, days, or weeks.

Simultaneous multiangle imaging. The acquisition of images of a scene at different view zenith angles during a single overpass, obtained by reorienting the sensor in the along-track direction (the direction parallel to the sensor's flight direction) or by using multiple sensors pointed at different along-track angles to observe the target repeatedly as the view zenith angle changes. Here, the time separation between views is several minutes.

Introduction

Clouds, aerosol layers, vegetation canopies, soils, snow or ice fields, and other natural scenes reflect solar radiation into angular reflectance patterns that depend on the angle at which the scene is illuminated or viewed. The Bidirectional Reflectance Distribution Function (BRDF) (Nicodemus et al., 1977; Schaepman-Strub et al., 2006) is the ratio of the radiance reflected by a target as a function of view direction, divided by the irradiance illuminating the target at a single incidence angle. The magnitude and angular shape of the BRDF is largely governed by the composition, density, and geometric structure of the reflecting medium.

Many satellite instruments having a wide image swath, for example, the multispectral MODerate-resolution Imaging Spectroradiometer (MODIS) on the National Aeronautics and Space Administration (NASA) Terra and Aqua satellites, acquire multiangle data according to the sequential approach defined above. For many applications, the simultaneous multiangle measurement strategy is required, and a number of satellite sensors have been

designed with this objective in mind. Examples of such instruments are described below and provide the focus of this discussion. As noted by Diner et al. (2005), the interpretation of multiangle information can be categorized into two main strategies: geometric and radiometric. The first involves real or apparent differences in the location of observed objects with changing angle of view, resulting from stereoscopic parallax (displacement dependent upon distance from the observer) or actual motion of the target during the time interval between views. The second refers to changes in the brightness, color, contrast, or polarization of the reflected light as a function of view angle.

Satellite sensors

Several Earth-orbiting instruments have been designed to make simultaneous multiangle observations at visible and shortwave infrared wavelengths (see Table 1). Airborne counterparts are associated with some of these instruments. In addition, airborne sensors such as the Cloud Absorption Radiometer (CAR) with 13 bands between 503 and 2,289 nm (King et al., 1986) (later upgraded to 14 bands between 340 and 2,302 nm; Gatebe et al., 2003) and the Advanced Solid-State Array Spectroradiometer (ASAS) with 29 bands from 465 to 871 nm (Irons et al., 1991) have provided a legacy on the information content of multiangle imagery.

- The United Kingdom's Along-Track Scanning Radiometer (ATSR)-1 (Delderfield et al., 1986; Mutlow et al., 1994) was launched on the European Space Agency (ESA) Earth remote sensing satellite (ERS)-1 in 1991. It was primarily designed to retrieve global sea-surface temperatures. The only solar reflective channel in this instrument was a band at 1.6 μm . An enhanced version, ATSR-2, was equipped with additional visible and near-infrared channels and was launched in 1995 aboard ERS-2. In 2002, the Advanced ATSR (AATSR) was launched on ENVISAT. Each of these instruments contains a conical scanning radiometer that provides curved swaths at two measurement angles, one near nadir and the other at an oblique forward-viewing angle (<http://www.atsr.rl.ac.uk/>).
- Contact with the ENVISAT spacecraft was lost in spring 2012, and ESA declared an end to the mission.
- The Polarization and Directionality of the Earth's Reflectances (POLDER) instrument (Deschamps et al., 1994), developed by the French Centre National d'Etudes Spatiales (CNES), was launched aboard the Japanese Advanced Earth Observing Satellite (ADEOS) in 1996 and acquired 8 months of global data. A follow-on instrument, POLDER-2, was launched on ADEOS-2 in 2002 and acquired data for nearly a year. Both missions were cut short by spacecraft failures. A third POLDER instrument was launched in 2004 on the French PARASOL satellite as part of the polar-orbiting "A-train," a constellation of satellites in similar orbits to acquire near-simultaneous observations. In late 2011, PARASOL separated from the A-train orbit, but the instrument is still collecting data. POLDER uses a wide-angle imaging system and an area array detector to acquire measurements at a multitude of along-track and cross-track angles (<http://www.icare.univ-lille1.fr/parasol/>). An airborne version of this instrument, AirPOLDER, also exists (<http://loag5-ct13.univ-lille1.fr/AirPOLDER/data.html>).
- The Multiangle Imaging SpectroRadiometer (MISR) (Diner et al., 1998a), developed in the United States, was launched aboard the NASA Terra spacecraft, part of the Earth Observing System, in late 1999. The MISR instrument uses nine separate cameras to acquire data at nine discrete along-track observation angles. Images are acquired globally in push broom fashion, with four line arrays in each camera filtered to four visible and near-infrared spectral bands (<http://mISR.jpl.nasa.gov>). An airborne instrument making use of a single, gimbaled camera to acquire multiangle imagery – AirMISR – has also been used for aerosol, cloud, and surface investigations (Diner et al., 1998b; <http://mISR.jpl.nasa.gov/Mission/airMISR.html>).
- The US Department of Energy's Multispectral Thermal Imager (MTI) (Szymanski and Weber, 2005) contains 15 spectral bands of which 10 are at solar reflective wavelengths. MTI was launched in 2000. The satellite has an agile-pointing capability and multiangle imagery

Reflected Solar Radiation Sensors, Multiangle Imaging, Table 1 Earth-orbiting multiangle remote sensing imagers

	(A)ATSR	POLDER	MISR	MTI	CHRIS	CIPS
Number of along-track view angles	2	14	9	2	5	7
Maximum view angle (at Earth's surface)	56° (forward only)	60° (forward + backward)	70° (forward + backward)	60° (typically backward)	55° (forward + backward)	71° (forward + backward)
Shortwave spectral bands	555, 659, 865, 1610 nm	443 ^a , 490, 565, 670 ^a , 763, 765, 865 ^a , 910 nm (^a polarized)	446, 558, 672, 866 nm	484, 558, 650, 810, 874, 940, 1,015, 1,376, 1,646, 2,224 nm	Nominally 18 channels from 415 to 1,050 nm	265 nm
Footprint (nadir)	1 × 1 km ²	6 × 7 km ²	275 × 275 m ² , 1.1 × 1.1 km ²	5 × 5 m ² , 20 × 20 m ²	17 × 17 m ²	1 × 2 km ²
Swath width	512 km	2,200 km	400 km	12 km	13 km	950 km

is acquired by reorienting the satellite during a target overpass. Due to this strategy and the sensor's narrow field of view, MTI is a targeting instrument (<http://www.lanl.gov/orgs/isr/isr2/>).

- The Compact High Resolution Imaging Spectrometer (CHRIS) instrument (Barnsley et al., 2004) was developed in the United Kingdom and launched in 2001 on an agile spacecraft known as PROBA (Project for On-Board Autonomy), under the auspices of ESA. Like MTI, CHRIS is a targeting instrument and acquires multiangle imagery by pointing the PROBA spacecraft (<http://earth.esa.int/missions/thirdpartymission/proba.html>).
- The Cloud Imaging and Particle Size Experiment (CIPS) (McClintock et al., 2009), developed in the United States, was launched aboard NASA's Aeronomy of Ice in the Mesosphere (AIM) mission in 2007. CIPS uses an array of four cameras in a "+" configuration, two pointing forward and backward, and two pointing to either side, each with a $44^\circ \times 44^\circ$ field of view. Observations are acquired in a single ultraviolet spectral band to measure the physical characteristics of polar mesospheric clouds (PMCs, also known as noctilucent clouds to ground-based observers) (<http://aim.hamptonu.edu/instrmt/cips.html>).

Example applications

Aerosols (liquid or solid airborne particulates having sizes ranging from less than $0.1 \mu\text{m}$ to more than $10 \mu\text{m}$) and clouds (consisting of larger-sized liquid water or ice particles) play critical roles in our climate system. Whether a particular cloud or aerosol cools or warms the surface depends on the physical properties of the particles, as well as their heights. For aerosols, injection height into the atmosphere also determines how far the particles can be transported away from their source, with ramifications for downwind air quality.

The angular distribution of scattering from particles is different for spherical (liquid) cloud or aerosol droplets and among various irregularly shaped (e.g., dust) or crystal (ice) forms. As a result, multiangle imagery has proven valuable in distinguishing cloud and aerosol types characterized by the particle shape, one of several factors affecting climate impact. Data from ATSR-2, POLDER, and MISR have been used to explore ice crystal habit in cirrus clouds (Baran et al., 1999; Chepfer et al., 2001; McFarlane and Marchand, 2008). Scattering phase functions from CIPS were used to derive particle sizes of polar mesospheric clouds (Bailey et al., 2009). Additional information on cloud particle size as well as shape is contained in multiangular polarization data (Parol et al., 2004). Kalashnikova and Kahn (2006) demonstrated the ability to distinguish among granular, platelike, and spheroidal dust particles using MISR data over ocean. Discriminating between nonspherical and spherical particles is also useful in separating dust from fine particle pollution over land. Liu et al. (2007) showed improved correlations between column aerosol amount and the concentration

of near-surface airborne particulate matter with diameters less than $2.5 \mu\text{m}$ ($\text{PM}_{2.5}$, a regulated air pollutant) by using multiangle data.

Over land, accurate satellite aerosol retrievals are complicated by the large spatial variability in surface reflectance. Bright deserts and urban areas are major aerosol source regions, and separating the surface and atmospheric contributions to the observed top-of-atmosphere radiances is challenging. ATSR-2/AATSR and MISR use multiangle observations to solve this problem, making use of the enhanced atmospheric signal at oblique view angles and differences in the manner in which atmospheric and surface layers scatter radiation (Flowerdew and Haigh, 1996; Martonchik et al., 2002). Enhanced retrieval accuracy is obtained at certain view geometries, a subject explored using MTI (Chylek et al., 2003). Differences in the angular reflectance signature of clouds and snow/ice have proven valuable in improving cloud detection capability in polar regions (Di Girolamo and Wilson, 2003; Shi et al., 2007).

Many satellite stereoscopic imagers designed to retrieve land surface topography have been placed into Earth's orbit. Either the sequential or simultaneous viewing strategy can be used for this purpose. For remote sensing of highly dynamic targets such as clouds, however, the simultaneous multiangle strategy is required. Cloud stereo imagery can be acquired with more than one geostationary satellite viewing the targets at different angles (Seiz et al., 2007), but these equatorial-orbiting satellites do not observe polar latitudes. Alternatively, stereo observations can be obtained from a single instrument in polar orbit by acquiring data at more than one along-track view angle. Stereoscopic imaging from MISR and ATSR has been used to capture global cloud-top heights (CTH) (Moroney et al., 2002; Prata and Turner, 1997; Naud et al., 2006). Unlike thermal infrared-based techniques, which are based on measurements of cloud-top temperature, the stereoscopic approach is purely geometric, thereby making it capable of providing cloud height climatologies independent of confounding factors such as temperature inversions (Garay et al., 2008; Harshvardhan et al., 2009). Efficient, automated computational methods have been developed to "match" the images of clouds seen from different view angles (Muller et al., 2002); knowledge of the spacecraft position and view angles is then used to obtain CTH. Stereo imaging using at least three angles has made possible a novel technique for simultaneously retrieving height-resolved cloud-tracked velocity (Horváth and Davies, 2001; Zong et al., 2002). Imaging at multiple view angles helps quantify the effect of 3D cloud morphology on reflected radiation (Horváth and Davies, 2004; Cornet and Davies, 2008). Stereo imaging is also able to determine aerosol plume heights. Statistical studies of wildfire plumes in North America between 2002 and 2007 using MISR show that (a) a significant fraction of fires inject smoke into the free troposphere, (b) smoke tends to concentrate in stable layers within the atmosphere, and (c) there is a pronounced seasonal cycle of plume

heights over certain vegetation types (Kahn et al., 2008; Val Martin et al., 2010).

Angular reflectances of surface covers contain information about their physical structure (e.g., Widlowski et al., 2004). Ice surface roughness provides an indicator of snow accumulation, surface melt, and wind ablation, and studies using the sensitivity of multiangle observations to surface roughness show great potential for distinguishing glacial zones and identifying different types of sea ice, which are indicators of climate change (Nolin et al., 2002; Nolin and Payne, 2007). For terrestrial vegetation, the canopy and understory density and morphology (e.g., height and width) of the plants and trees impact photosynthetic efficiency, nutrient cycling, suitability as wildlife habitats, fresh water availability, and fire risk. Multiangle data are particularly useful for separating canopy and understory/ground reflectance (Canisius and Chen, 2007; Pinty et al., 2008), which is particularly significant for bright surfaces (i.e., snow or desert). CHRIS/PROBA and MISR have been used for remote sensing of desert shrub cover (Chopping et al., 2003, 2008a), which has been expanding during the last century in the southwestern USA at the expense of grasslands. Geometric-optical methods for using multiangle data to retrieve plant number density, mean radius, crown height, and crown shape in forests are also being developed (e.g., Chopping et al., 2008b). One technique that holds significant promise is the use of active lidar, which provides more direct measurements of tree heights, in conjunction with passive multiangular imagery to retrieve canopy structure (Kimes et al., 2006; Schull et al., 2007).

Conclusions

Multiangle imaging is a rich source of information regarding the micro- and macrophysical structure of different types of aerosols, cloud forms, and surface covers. Combined with stereoscopic techniques, it enables construction of 3D scene models and estimation of the total amount of sunlight reflected by Earth's diverse environments. As with any imaging technology, the range of applications is myriad. Just a few representative examples have been presented here. Many other uses exist, and additional ones likely remain to be discovered.

Stokes measurements

Definitions

Stokes vector. A set of four parameters describing the polarization state of a beam of light, named for the Irish mathematical physicist George Gabriel Stokes (1819–1903). As an electromagnetic wave propagates, the orientation of the tip of the electric field vector traces out an ellipse. Specific manifestations of the polarization ellipse are linear polarization, where the electric field vibrates in a single plane, and circular polarization. The Stokes vector consists of intensity, I ; the excess of horizontally over vertically polarized light, Q ; the excess of light polarized at 45° over 135° , U ; and the excess of right-handed over left-handed circular polarization, V . “Handedness” describes the direction in which the electric field vector rotates.

Degree of polarization. The ratio of polarized to total intensity is equal to $\sqrt{Q^2 + U^2 + V^2}/I$. The degree of linear polarization (DOLP) is equal to $\sqrt{Q^2 + U^2}/I$, and the degree of circular polarization (DOCP) is equal to V/I .

Angle of polarization. The orientation of the major axis of the polarization ellipse. In terms of the Stokes components, the angle of polarization equals to $0.5 \arctan(U/Q)$.

Polarimetry. Measurement of the Stokes vector, typically involving the use of polarization *analyzers*, devices that preferentially transmit certain states of polarization, and *retarders* or *phase plates*, which alter the shape of the polarization ellipse. *Division-of-amplitude* polarimeters optically divide the incoming light and direct the resulting beams toward multiple analyzers and detectors. *Division-of-aperture* polarimeters employ multiple analyzers operating side-by-side. *Snapshot* devices encode the polarization state within a spatially varying signal recorded on an area array detector. *Spectrum* channeling approaches use thick birefringent crystals plus a polarizer and spectrometer to encode the Stokes components in fringes superimposed on the recorded spectrum. A *time-multiplexed* polarimeter uses a rotating analyzer or

retarder, or an electro-optical retardance modulator, and the measurements are acquired sequentially.

Introduction

Sunlight incident on the Earth system is unpolarized, but scattering by clouds, aerosols, and surfaces in general polarizes the light. Polarimeters of myriad designs, operating in various wavelength intervals, have been used in a host of scientific applications. A classic example of the application of polarimetry to planetary astronomy was the identification of sulfuric acid clouds in the upper atmosphere of Venus (Hansen and Hovenier, 1974). This entry presents examples of Earth remote sensing polarimeters that record reflected sunlight photographically or photometrically from suborbital and orbital platforms. With the exception of a brief discussion on rocket-borne observations of mesospheric clouds, the scope is confined to sensors viewing the Earth at angles between the downward (nadir) and horizontal (limb) directions.

Polarimetric remote sensing from balloons

Photopolarimetry of earthlight was obtained from high-altitude balloons over Arizona and New Mexico by researchers at the University of California, Los Angeles (Rao and Sekera, 1967; Rao, 1969). Photomultiplier tube-based instruments with a 3° field of view (FOV) were scanned on either side of nadir. Initial measurements, from 13 km altitude, used a rotating half-wave retarder, a fixed polarizing prism, and spectral filters at 327, 398, 500, and 612 nm. Later observations (from 28 km) used 362, 401, 501, and 599 nm filters and a rotating calcite prism for polarimetric modulation. Balloon-borne (20 km altitude) polarimetry over southwestern France was obtained by Herman et al. (1986) at 850 and 1,650 nm using a rotating Polaroid analyzer and a germanium photodiode. Horizontal scans obtained when the Sun was close to the horizon provided evidence of spherical submicron particles consistent with established stratospheric aerosol models. Downward-looking observations of tropospheric aerosols, clouds, and the ocean surface were later obtained by adding a scan mirror (Deuzé et al., 1989).

The three commonly known neutral points in the polarization of skylight – Arago, Babinet, and Brewster, named after their discoverers – are locations where the degree of polarization vanishes, typically displaced tens of degrees from the solar or antisolar directions. Horváth et al. (2002) confirmed the existence of a suspected fourth neutral polarization point below the antisolar direction (thus invisible from the ground). This was accomplished by flying a Nikon F801 film camera equipped with a fisheye lens and linear polarizers oriented at 0° , 45° , and 90° (Gál et al., 2001) in a low-altitude (0.8–3.5 km) hot air balloon. The data were collected during two flights over central Hungary.

Polarimetric remote sensing from rockets

Noctilucent or polar mesospheric clouds consist of tiny ice particles that reside in the Earth's upper atmosphere at altitudes near 80 km. Remote sensing from suborbital rockets enables determination of their light-scattering properties and vertical distribution. Witt et al. (1976) at the University of Stockholm used a photomultiplier-based instrument operating at 256 and 536 nm to derive a particle size upper bound of ~ 50 nm. A two-color (410 and 540 nm) polarimeter from the Dudley Observatory (New York) implied somewhat larger sizes (Tozer and Beeson, 1974). More recently, the Ultraviolet Imaging Polarimeter (UVIP) built by the University of Colorado (Lawrence et al., 1994) provided rocket-borne limb imaging using a Reticon detector array. Data at polarizer orientations of 0° , 45° , and 90° were acquired at 265 nm.

Polarimetric remote sensing from airplanes

Among the earliest non-imaging aircraft polarimeters was a Grumman instrument deployed on a Piper Tri-Pacer (Egan, 1968). The instrument had a 1° FOV and was equipped with filters at 533 and 1,000 nm and employed a rotating Polaroid analyzer. Initial results over forest discriminated red pine and hardwood trees. Hariharan (1969) described an airborne polarimeter for atmospheric radiation studies consisting of polarizing (Glan-Thompson) prisms, four blue-green spectral filters, and a photomultiplier tube. It flew in the National Aeronautics and Space Administration (NASA) CV-990 aircraft and made observations over a uniform cloud deck. A University of Arizona instrument (Fernald et al., 1969) with a Polaroid analyzer oriented at 0° , 90° , and 120° observed sparsely vegetated desert terrain at 429 nm from 300 to 600 m altitude. DOLP varied from 3 % to 18 %, depending on scattering angle, and the angle of polarization was generally perpendicular to the scattering plane. The University of Arizona's AEROPOL instrument (Coffeen et al., 1975) flew on the NASA CV-990. Observations within a 1.5° FOV were acquired between 1,100 and 3,500 nm using a rotating wire-grid analyzer to study cloud and aerosol polarization. Comparisons with theoretical computations showed sensitivity to cloud phase and particle size distribution (Hansen and Coffeen, 1974).

Early airborne imaging polarimeters included the Grumman Digital Photometric Mapper (DPM) (Halajian and Hallock, 1972) and an instrument developed at the University of Cologne (Prosch et al., 1983). The DPM used an image dissector tube and required multiple passes to obtain different polarization orientations. An inverse relationship between water turbidity and DOLP was demonstrated. The Cologne instrument contained three Plumbicon-based video cameras mounted side-by-side with polarizing filters at 0° , 60° , and 120° , spectrally filtered to a single band at 550 nm. Data collected over the Olefalsperre reservoir indicated a sensitivity to surface wind speed.

The Airborne Polarization and Directionality of Earth's Reflectances (AirPOLDER) instrument, built by the Laboratoire d'Optique Atmosphérique at the Université de Lille became operational in June 1990 (Deuzé et al., 1993). A rotating wheel provides spectral and polarimetric filter selection in discrete bands between 443 and 910 nm. A silicon charge-coupled device (CCD) detector array and a wide-angle lens provide imagery over a $\pm 41^\circ \times \pm 51^\circ$ FOV. Successive images obtained during flight enable each point to be observed at 12 view angles. More recently, the Lille group developed a single-view-angle aerosol polarimeter, MICROPOL, which operates in the visible/near-infrared (VNIR) and shortwave-infrared (SWIR) (Waquet et al., 2005). Three separate optical systems at each wavelength contain polarizers in orientations separated by 60° . A new instrument based on the AirPOLDER design, the Observing System Including polaRization in the solar Infrared Spectrum (OSIRIS), uses separate VNIR and SWIR optical systems to acquire data at 440, 490, 670, 763, 765, 865, 910, 940, 1,020, 1,240, 1,365, 1,600, and 2,200 nm (Auriol et al., 2008). It has been tested aboard a French research aircraft flying at 10 km altitude.

Several of the instruments described in this entry are *incomplete polarimeters* (Chipman, 1994) that measure linear polarization in just two perpendicular orientations, typically providing Q but not U . One such sensor was developed at NASA Ames Research Center to study oil slicks (Millard and Arvesen, 1972). Measurements at 380 nm over controlled spills were acquired with polarizers parallel and perpendicular to the flight direction of a Cessna 401. The difference between the two measurements increased by 25 % over the oil-contaminated water. Another Ames sensor was developed for the high-altitude ER-2 aircraft (Hildum and Spinhirne, 1992). It used a commercial silicon CCD camera to acquire data in support of cloud observation campaigns. Colorado State University's Scanning Spectral Polarimeter (SSP) also included channels for left and right circular polarization (Stephens et al., 2000).

The Research Scanning Polarimeter (RSP), developed by SpecTIR Corporation and operated by the NASA Goddard Institute for Space Studies (Cairns et al., 2003), was designed for high polarimetric accuracy (<0.2 % uncertainty in DOLP). RSP observes in nine spectral bands (410, 470, 555, 670, 865, 960, 1,590, 1,880, and 2,250 nm). Refractive telescopes measure the Stokes parameters I , Q , and U simultaneously. A rotating scan mirror assembly sweeps the telescope FOVs to enable data collection at $\pm 60^\circ$ from nadir. The two mirrors in the scan assembly are oriented such that any polarization introduced by the first mirror is compensated by the second. RSP has flown on different aircraft in a variety of field campaigns and has been used in a cross-track scanning mode to provide imagery as well as in an along-track scanning mode to obtain polarimetric angular signatures of aerosols, clouds, and land surfaces.

The Airborne Multi-Spectral Sunphoto- and Polarimeter (AMSSP) developed at the Freie Universität Berlin is

designed to operate in conjunction with an optical scan head that enables multidirectional observations of both the upwelling and downwelling hemispheres (Ruhtz et al., 2009). AMSSP contains a combination of analyzers and retarders to measure all four components of the Stokes vector in the visible and ultraviolet. An engineering model of the instrument has flown aboard a British research aircraft in field campaigns aimed at cloud and aerosol studies.

The Airborne Optical Spotlight System-Multispectral Polarimeter (AROSS-MSP), built by Areté Associates in Virginia, is a 12-camera system containing one camera for each of four spectral bands (blue, green, red, near-infrared) in each of three polarization orientations (Hooper et al., 2009). It is an upgrade of an earlier 9-camera system that included the three visible bands only. Designed to measure suspended material transport in rivers and near-shore ocean environments, AROSS-MSP has flown on a Twin Otter aircraft and was able to track water current velocities using high spatial resolution time-lapse imaging.

Several aircraft polarimeters use nonconventional approaches. Utah State University's Hyperspectral Imaging Polarimeter (HIP) employed ferroelectric liquid crystal (FLC) retarders to rapidly switch between different polarization orientations (Jensen and Peterson, 1998). HIP was designed for high spatial and spectral resolution polarimetry at 2,700 nm to determine cloud particle phase. The Hyperspectral Polarimeter for Aerosol Retrievals (HySPAR) developed by Aerodyne Research (Jones et al., 2006) is a spectrum channeling imaging spectrometer operating at 480–960 nm. It has participated in field campaigns aboard the NASA King Air B200 aircraft. The Airborne Multiangle SpectroPolarimetric Imager (AirMSPI), built by the Jet Propulsion Laboratory in collaboration with the University of Arizona, uses photoelastic modulators (PEMs) to provide rapid time multiplexing of the Stokes components (Diner et al., 2007, 2010). AirMSPI obtains intensity images between 355 and 935 nm and polarization images at 470, 660, and 865 nm. It is mounted on a gimbal to acquire imagery at multiple along-track view angles and has been flying aboard NASA's ER-2 high-altitude aircraft since 2010 (Diner et al., 2011). Another imaging design for atmospheric remote sensing makes use of a Philips-type prism (Fernandez-Borda et al., 2009). Incoming light is split into three optical channels for simultaneous measurement in three polarizer orientations. The Visible-regime Polarimetric Imager developed at TRW (Barter et al., 2003) uses a prism to split the beam into four optical channels. CCD arrays are used in each channel and a combination of polarizers and a quarter-wave retarder enables imaging all four Stokes components in a single mid-visible spectral band. Airborne images of DOLP and DOCP were acquired over agricultural fields.

The rainbow and cloudbow are scattering phenomena resulting from refraction and reflection of light within spherical droplets. Light in the bow is polarized and its

variation with angle depends on the droplet size distribution (Bréon and Goloub, 1998). The Rainbow Camera is an airborne imaging polarimeter developed at the NASA Goddard Space Flight Center to derive effective radii and widths of cloud droplet size distributions. The instrument has a 60° FOV and observes at 470, 550, 660, 760, 870, and 910 nm. It has flown on a research aircraft over the Amazon Basin (Correia et al., 2007).

Polarimetric remote sensing from space

Polarimetric observations of the Earth from orbit were acquired using a pair of Hasselblad cameras aboard NASA's Space Shuttle (Coulson et al., 1986). The cameras were outfitted with polarizing filters in perpendicular orientations, providing measurements of Q and I . Images were initially recorded on black and white film; color film was added on later flights. Egan et al. (1991) analyzed imagery over the Hawaiian islands and interpreted DOLP patterns as indications of soil texture, sea surface state, the presence of haze, and cloud optical depth.

Several spaceborne sensors designed for atmospheric trace gas measurements – the Global Ozone Mapping Experiment (GOME), the SCanning Imaging Absorption spectroMeter for Atmospheric CHartographY (SCIAMACHY), and GOME-2 – make use of grating spectrometers that impart polarization sensitivity to the observations which, if uncorrected, lead to radiometric errors. To compensate, polarization measuring devices (PMDs) are incorporated to measure Q (SCIAMACHY also has sensitivity to U). The PMDs have been applied to atmospheric and surface remote sensing (e.g., Krijger et al., 2005; Lotz et al., 2009). GOME (Burrows et al., 1999) was launched aboard the European Space Agency (ESA) European Remote Sensing satellite ERS-2 in 1995, SCIAMACHY (Bovensmann et al., 1999) was launched aboard ESA's Envisat in 2002, and GOME-2 (Callies et al., 2003) was launched aboard ESA's MetOp-A in 2006.

The satellite Polarization and Directionality of the Earth's Reflectances (POLDER) instrument (Deschamps et al., 1994), developed by the French Centre National d'Etudes Spatiales (CNES), was specifically designed to obtain quantitative global, multiangle polarization imagery at a spatial resolution of ~ 6 km. POLDER was launched aboard the Japanese Advanced Earth Observing Satellite (ADEOS) in 1996 and acquired 8 months of data. A follow-on instrument, POLDER-2, was launched on ADEOS-2 in 2002 and acquired data for nearly a year. Both missions were cut short by spacecraft failures. A third instrument was launched in 2004 on the French PARASOL satellite. POLDER uses a mechanically stepped rotating filter/polarizer wheel, a fisheye refractive lens, and an area array CCD. Spectral bands are centered at 443, 490, 565, 670, 763, 765, 865, and 910 nm. Data at 443, 670, and 865 nm are acquired in three polarizer orientations to obtain I , Q , and U . DOLP uncertainty is ~ 1 –2% (Hagolle et al., 1999). A successor to POLDER, the

Multi-polarization Multidirectional Multispectral Instrument (3MI), extends the spectral coverage into the short-wave-infrared (Riedi, 2011). Launch of 3MI aboard Europe's EUMETSAT Polar System-Second Generation (EPS-SG) satellite system is planned for the 2020 time frame.

The Aerosol Polarimetry Sensor (APS) instrument, built by Raytheon as a successor to the airborne RSP, was intended to fly aboard NASA's Glory mission (Mishchenko et al., 2007), but due to a launch failure in March 2011, the spacecraft failed to reach orbit. The APS was designed to scan the FOVs of six bore-sighted telescopes in the along-track direction to acquire data at 410, 443, 555, 672, 865, 910, 1,378, 1,610, and 2,250 nm with a spatial resolution at nadir of ~ 6 km. Three of the six telescopes measure polarization at 0° and 90° and the other three measure at 45° and 135° (Peralta et al., 2007). As in RSP, the scan assembly design uses a pair of polarization-compensating mirrors. APS was to have provided the first highly accurate (non-imaging) multiangle polarimetric measurements from Earth orbit, with a DOLP uncertainty of $\sim 0.2\%$.

Conclusions

A variety of polarimeters have been deployed to view the Earth in reflected sunlight from suborbital and orbital vantage points. (Others have also flown on spacecraft missions to other planets). An earlier tabulation has been published by Coffeen (1974). Many investigations have demonstrated the value of polarimetry for characterizing terrestrial aerosols (e.g., Chowdhary et al., 2002; Herman et al., 2005; Waquet et al., 2009), clouds (e.g., Chepfer et al., 2001; Parol et al., 2004), and vegetation (e.g., Perry et al., 1997). Over the past several decades, dramatic improvements in polarimetric accuracy have resulted from increasingly sophisticated optical designs, the use of digital electronic detectors, and careful instrument calibration. Various imaging architectures have been developed (see, e.g., Tyo et al., 2006). The interested reader is referred to the vast body of literature that exists on the diverse scientific applications of polarimetry to the terrestrial environment.

Acknowledgment

The research to prepare this contribution was carried out at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with NASA.

REFLECTOR ANTENNAS

Yahya Rahmat-Samii
 Department of Electrical Engineering, University of
 California at Los Angeles, Los Angeles, CA, USA

Definition

Reflector antenna. An antenna consisting of one or more reflecting surfaces and a feed system for transmitting and/or receiving electromagnetic waves.

Introduction

Modern utilizations of reflector antennas in radars, satellite communications and tracking, remote sensing, radio astronomy, and the like have resulted in the development both of sophisticated reflector antenna configurations and of analytical and experimental design techniques. Reflector antennas typically take various configurations, some of the most popular ones being singly and doubly curved, single and multiple reflectors, and many others. The nature of applications and the resulting radiation patterns, such as pencil beam, contour beam, multifrequency, polarizations, and so on, dictate the actual configuration of reflector antennas.

One may classify reflector antennas in a variety of ways. Reflector antennas may be identified according to the types of radiation pattern, reflector surface, and feed. Pencil-beam reflectors are perhaps the most popular ones and are commonly used in point-to-point microwave communications and telemetry, since their patterns yield the maximum boresight gain and typically their beam directions are fixed at the time of antenna installation. In some applications, such as satellite systems, the uplink beam of these pencil-beam reflectors may be either fully steerable by reflector movements or capable of limited steering. Recent generations of satellite reflectors have produced other popular types of pattern classifications: contour (shaped) beams and multiple beams.

These applications require reflectors with improved off-axis beam characteristics, which result in more sophisticated configurations. There are many microwave communication antennas operating with one sense of polarization at a given frequency and require only reasonable discrimination between orthogonal polarizations. However, the current generation of microwave communication and remote sensing antennas operate with dual polarizations at the same frequency to enhance their frequency reuse capabilities or radar polarimetric properties. These requirements necessitate improved polarization performance and could be used as factors in pattern classification.

The objective of this entry is to briefly introduce reflector antennas by providing a summarized description of the performances of many representative reflector configurations. There are a few recently published handbooks, book chapters, and collections of papers that the reader is strongly advised to study (Silver, 1949; Jasik, 1961; Collin and Zucker, 1969; Skolnik, 1970; Love, 1976, 1978; Clarricoats and Poulton, 1977; Rudge and Adatia, 1978; Rudge et al., 1982; Rahmat-Samii, 1988, 2007).

Diffraction analysis techniques for reflector antennas

Advances in analytical and numerical techniques have allowed reflector antenna engineers to extensively utilize commercial or customized computer programs in the performance evaluation and design of reflector antennas. Accuracy of these techniques has been successfully checked against measured data.

Reflector diffraction analysis techniques may be classified as aperture field (AF) method (Collin and Zucker, 1969), geometrical optics (GO) and physical optics (PO) (Bucci et al., 1980; Rahmat-Samii and Galindo-Israel, 1980; Rahmat-Samii et al., 1981; Rahmat-Samii and Chueng, 1987), geometrical theory of diffraction (GTD) (Keller, 1962; Lee et al., 1979), method of moments (MoM), Gaussian beam method, or any hybridization of these. Clearly, there are advantages and disadvantages when comparing these techniques (Rahmat-Samii et al., 1991). Comparisons can be made based on the particular reflector configuration, far-field pattern domain, polarization, computation time, accuracy, and so on. MoM gives the most accurate result but it is impossible to use it economically for reflectors larger than many wavelengths. The aperture field method is not very accurate for offset configuration with displaced feeds when the edge diffracted rays are not included in the construction of the aperture fields. The GTD method is not easily applied in the caustics regions of pencil-beam reflectors. The PO method can take an excessive amount of computation time for large reflectors, in particular in the dual-reflector configurations, etc. Many advances have been reported to improve both the accuracy and the computation time. One of the most appealing techniques has been the application of GTD for the subreflector and PO for the main

Reflector Antennas, Figure 1 Geometrical parameters of an offset parabolic reflector (For symmetric cases, $H = -D/2$).

reflector, in conjunction with efficient expansions, such as Jacobi-Bessel expansion and sampling theorem.

In many applications the reflector surface may not be simply a solid PEC surface. For example, mesh reflectors are used in large unfurlable antennas, FSS (frequency selective surfaces) are used as subreflectors for frequency separation of feeds, and the reflector surface may be affected by snow. In all these cases, one is able to modify the PO integral and incorporate the effects of these surfaces (Rahmat-Samii and Lee, 1985; Imbriale et al., 1991; Rahmat-Samii and Tulinseff, 1993; Ip and Rahmat-Samii, 1998; Miura and Rahmat-Samii, 2005, 2007).

Offset (symmetric) parabolic reflectors

Parabolic-reflector antennas are still one of the most popular and practical reflector antenna configurations. The radiation characteristics of offset (symmetric) parabolic-reflector antennas illuminated by a single feed element are briefly discussed in this section. As is typical in any reflector design, there are too many almost-independent parameters which may be varied to achieve a particular design goal. To design an offset parabolic reflector, one must study the effects of such parameters as offset angles, illumination tapers, F/D ratios, locations and orientations of the feed, polarizations, etc., on such far-field pattern characteristics as scan loss, beamwidth, sidelobe level, cross-polarization level, and efficiency. Clearly it is not possible to perform an extensive study of all these parameters; rather, attempts are typically made to present the most important reflector characteristics based on a few key parameters. The results presented here can therefore be used

as a guideline for an initial design, which can then be refined by using computer programs and measured data.

Geometrical parameters

The geometry of an offset parabolic reflector with focal length F , diameter D , and offset height H is shown in Figure 1. In designing offset reflectors, any combination of the geometrical parameters may be given and the others may be constructed. Typically parameters D , F/D , and H/D are used as independent parameters and the others are obtained. The reader may want to refer to Rahmat-Samii (2007) for representative design curves.

Edge and feed tapers

The edge taper (ET) is a widely used parameter in characterizing the effects of the feed pattern on the far-field pattern of the reflector. The ratio of the field intensity at the reflector edge to the intensity at its center in decibels defines the edge taper. Although this definition is unambiguous when it is applied to symmetric reflectors, it can become ambiguous for offset reflectors. Customarily the feed taper (FT) is defined to overcome the ambiguity.

As observed in Figure 1, the feed taper FT_U in the upper-tip direction is defined as

$$FT_U = 20 \log \left[\frac{C(\psi_U - \psi_C)}{C(0^\circ)} \right]$$

where 0° defines the central direction (i.e., OC in Figure 1) and C is the feed pattern. Corresponding definitions for FT_L and FT_S can also be made at the lower and side angles

by using $\psi_C - \psi_L$ and ψ_S , respectively. The edge taper ET_U at the upper tip may now be expressed as

$$ET_U = FT_U + 20 \log(R_C/R_U)$$

where R_C and R_U are the path lengths from the feed to the center and the upper tip of the reflector, respectively. The second term $20 \log(R_C/R_U)$ is also called the path loss. Similar definitions can also be made for ET_L and ET_S . Note that for most cases of interest ET_U , ET_L , and ET_S have nearly equal values, and especially for symmetric reflectors, ET and FT only need to be defined at one edge (tip). Since ET directly controls the reflector's aperture amplitude taper, it has a more dominant effect on the far-field pattern than FT does. It is worth mentioning that it is not only the taper level which controls the reflector pattern but also the overall shape of the illumination distribution. In particular, the slopes of the illumination pattern at the reflector's edge can affect the sidelobe levels.

Radiation pattern characteristics

The following discussions on reflector pattern characteristics are based on the beams produced by on-focus feeds. The characteristics of the reflector antennas when the feed is displaced are investigated in Rahmat-Samii (2007). It is also assumed that the path losses are small (less than 0.5 dB) and, therefore, no substantial differences may be observed for path losses at different tips of the reflector. For these cases, $\psi_{UC} \approx \psi_{CL} \approx \psi_{SC} \approx \psi_S$ and $FT \approx ET$. The reader should attempt to properly interpret the results when the path losses are substantial.

In general, an offset parabolic reflector generates different far-field patterns in different cuts even when the on-focus feed has a symmetric pattern. Moreover, the pattern can be slightly asymmetric in the plane of offset depending on the F/D ratio (Rahmat-Samii, 1984). However, for the results presented here, a large F/D ratio is used in order to reduce the path loss effects and asymmetry of the pattern. Figure 2 shows the half-power beamwidth, first-null, second-null positions, and first sidelobe positions as functions of edge tapers. Note that the results shown here are for $\cos^q(\theta)$ -type feed amplitude patterns and the pattern characteristics depend heavily on the actual feed pattern description for edge tapers beyond -20 dB. Also shown in Figure 3 are the first sidelobe level, taper efficiency η_t , spillover efficiency η_s , and overall efficiency η as functions of edge tapers. It is readily observed that the resulting overall efficiency $\eta = \eta_s \eta_t$ is maximized for edge tapers about -11 dB with a value of 81 %. Some representative far-field patterns for different edge tapers are plotted in Figure 4. It can also be observed that for edge tapers in the neighborhood of -20 dB, the first sidelobe starts to merge with the main beam, which results in a widened beam. Again the exact distribution of the feed pattern can have a significant effect on the pattern characteristics for this level of edge taper.

The cross-polarization level of the radiated far-field is another performance parameter of interest. This topic has

been addressed in Love (1978), Chu and Turrin (1973), and Ludwig (1973) for both symmetric and offset reflectors, and some representative cases are presented in this entry. Figure 5 shows some typical patterns of cross-polarized field of a symmetric reflector fed by an unbalanced linearly polarized feed (a feed with different E- and H-plane patterns). The maximum of cross-polarized fields occurs in the plane $\phi = 45^\circ$, and the level of the cross-polarized field decreases substantially as the feed becomes more balanced. Note that these results are dependent on the F/D ratio and the edge taper.

In contrast to symmetric reflectors with balanced and linearly polarized feeds, which produce very low levels of cross-polarized fields, offset parabolic reflectors can generate high level of cross-polarization, depending on the tilt angle of the feed axis with respect to the reflector axis for linearly polarized feeds. For instance, Figure 6 presents the cross-polarized fields for various feed-axis tilt angles for a fixed offset reflector configuration, where the feed pattern is chosen to be isotropic in order to better illustrate the generation of the cross-polarized fields. Clearly, a high level of cross-polarized field should be expected in practice, since the feed axis is always tilted toward the center of the offset reflector in order to reduce spillover. The levels of cross-polarized fields for different values of bisect angle ψ_B and the half-subtended angle ψ_S (see Figure 1) can be found in Chu and Turrin (1973). It is worth mentioning that the cross-polarized field is predominantly observed in the plane $\phi = 90^\circ$ (normal to the plane of the offset) for offset parabolic reflectors.

When illuminated with balanced circularly polarized feeds, both symmetric and offset parabolic reflectors generate very low levels of cross-polarized fields. However, an additional feature, which is referred to as the beam squint, is observed for offset parabolic reflectors with circularly polarized feeds. In the plane normal to the plane of offset, the beam peak is shifted from the boresight by a small amount, which depends on the tilt angle of the feed axis and the reflector geometry. The following expression is a good approximation to estimate the beam squint:

$$\sin \theta_S = \mp \frac{\sin \psi_B}{4\pi(F/\lambda)}$$

where $\mp$ signs are for right and left circularly polarized beams, F is the focal length, and θ_S is the amount of squint. The squint angle obtained from diffraction analysis and experimental data (Chu and Turrin, 1973) agrees well with the approximate formula. A representative example is shown in Figure 7 (Chu and Turrin, 1973), where again ψ_B is used to characterize the reflector. Attempts have also been made to correct the undesired beam squint effect in certain reflector designs (Duan and Rahmat-Samii, 1991).

Other conventional reflector antennas

Different types of reflector antennas have been developed for a variety of applications. The parabolic arc can be used

Reflector Antennas, Figure 2 (a) Half-power beamwidth and (b) first-null, second-null, and first sidelobe positions as functions of the edge taper ET , where D/λ is the diameter of the reflector in terms of wavelengths.

as a generating curve for a number of useful reflector surfaces. When moved so that the focal point travels along a straight line, the curve generates a parabolic cylinder. With a limited motion along this line, the reflector for a pillbox is generated. When the focal point is moved

along a circle enclosing the arc, an hourglass surface is generated, and for a circle which does not enclose the arc, a parabolic torus is generated. This entry only discusses some representative designs due to the limited space.

Parabolic cylinder

A parabolic cylinder is constructed by moving a parabolic arc along a straight line. Being a singly curved surface, problems of construction and maintaining tolerances are somewhat easier than those encountered in doubly curved surfaces such as the paraboloid. A line-source feed is usually employed to illuminate the parabolic cylinder, and its aperture coincides with the focal line of the cylinder. The line source may be formed in a number of ways. When the aperture of the line source contains energy in phase along the length, a cylindrical wave front is generated and further focused by the parabolic cylinder into a plane wave in the direction of the axis of the parabolic arc. If a linear-phase variation exists along the length, a conical wave front is resulted, which then produces a plane wave tilted from the parabolic axis by an angle equal to the half angle of the cone.

The parabolic cylinder can also be used as the reflector in the pillbox, or cheese, antenna. It is constructed by two parallel plates which cut through a parabolic cylinder perpendicular to the cylinder. Typically positioned in the center of the aperture, the feed blocks a significant portion of the open region. Large sidelobes in the pattern of the pillbox are resulted due to the feed blockage, and the feed backlobes can also significantly affect the reflector pattern. Furthermore, a portion of the feed's radiation is reflected back into itself to produce a standing wave. An improvement in performance can be achieved when a half pillbox is used in the same fashion as the offset parabolic cylinder. The arc of the parabola extends from the vertex to the 90° point. The feed horn is directed at the 45° point. Although the illumination is asymmetrical, good sidelobes are obtained. A recent spaceborne concept was designed and tested in Rahmat-Samii et al. (2005).

Parabolic torus

A parabolic torus reflector is formed by rotating the parabolic arc about a vertical axis positioned on the concave side of the arc. It can be generated by a symmetrical arc or by the more widely used offset arc. The entire reflector is illuminated by multiple adjacent feeds, each of which uses portions of the reflector surface. A relatively compact structure can be obtained with multiple usage of the surface. A recent spaceborne application using this concept was suggested in Hoferer and Rahmat-Samii (1998); Njoku et al. (1999).

Spherical reflector antennas

When a point source is positioned at the focus, caustic region, of a spherical reflector, the reflected wave front in the aperture plane is not planar, and the subsequent phase error is known as spherical aberration. Although not a perfect focusing device, spherical reflectors are capable of focusing paraxial rays quite well. The design of the sphere is based upon the phase-error formula. The error curve is used out to the point at which the phase error is zero. An argument can be made that some phase error

beyond this point can be accepted. In practical designs, two points on the phase-error curves, namely, the maximum value and the edge (zero) value which defines the maximum value of the aperture radius r , are used. A specific curve using proper geometrical parameters is selected so that a simple ratio, namely, maximum phase error divided by r , is satisfied. Therefore, a practical sphere is limited in extent in order to keep the phase error acceptable.

If the spherical reflector can have efficiency of the order of 10 %, it will give patterns which do not change with the beam moved off axis (Li, 1959). In this instance, the sphere is fed from a large feed horn which confines its radiation to a small portion of the surface. The reflector edges which were the problem in the normal sphere are then eliminated. In effect, this solution uses a very long-length system in which the paraboloid and the sphere become very much alike.

An auxiliary correcting apparatus is usually required if a spherical reflector with large-aperture size is of interest. The potential of using a large spherical reflector antenna as a hurricanes-monitoring radar from geostationary orbit was investigated in Bahadori and Rahmat-Samii (2005a) and Xu and Rahmat-Samii (2009). A spherical reflector operating at Ka band (35.6 GHz), with a 35.5 m aperture and 28 m effectively illuminated area, was chosen to meet the most challenging demands of producing an unconventionally high gain and large number of beams scanned up to 200 beamwidths. Using a properly designed planar array feed or a sub-reflector array, the spherical aberration can be effectively compensated.

Large-aperture reflector antennas

In the 1970s, reflector antennas with electrically large apertures, typically greater than 60 wavelengths, became relatively common. Dominantly analyzed by geometrical optics and often refined by physical optics (Rusch and Potter, 1970), these designs focus on some parameters of concern: gain, beamwidth, sidelobe level, polarization and cross-polarization, beam efficiency, antenna noise temperature, and, if more than one beam position is needed, the variation of these parameters with scan angle. The design of the feed or, in the case of more complex antenna systems, the feed system and subreflector profoundly affects the parameters through illumination control, feed polarization properties, and spillover past the subreflector or the main reflector. Also the structural design affects electrical performance through the scattering of energy from surface-panel irregularities and interpanel gaps, from subreflector and/or feed-support spars, and from the correlation of this scattering arising from the structural design and alignment procedures.

The gain and complexity of spaceborne antennas have steadily increased since the inception of satellite communications. A need to increase the effective isotropic radiated power (EIRP) in a power-limited environment demands higher gain, while other requirements such as

Reflector Antennas, Figure 8 Geometrical configuration of a front-fed parabolic-reflector antenna.

beam shaping or reconfigurability necessitate more complex antenna configurations. Electrically large reflectors are usually fed by simpler antennas such as horns or array feeds or by folded-optics systems involving subreflectors. In many instances, the antennas are designed to produce two coaxial beams with orthogonal polarizations over near-octave bandwidths. The feed systems may then terminate in complex microwave circuits involving polarizers and orthomode transducers to separate or combine orthogonally polarized beams as well as in microwave multiplexers to separate or combine different frequencies.

Reflector antennas with electrically large apertures have their principal applications in radars and radiometry, where their high gain and narrow beamwidths enhance radar range and angular resolution; in radio astronomy and other deep-space telemetry, where the same parameters enhance sensitivity and resolution of stellar radio

sources; and in microwave communications and remote sensing, where high gain, high beam efficiency, low noise, and sidelobe control enhance EIRP, receive sensitivity, and isolation from interference. For reflector antennas of diameter in the range of 60–1,000 wavelengths, gains range from 45 to 70 dBi, half-power beamwidths from 1.5° to 0.05° , and average wide-angle sidelobe levels down to -20 dBi (almost 90 dB below the peak of the main beam). Clearly, these features depend upon the feed system as well as the reflectors.

Folded optics: Cassegrain and Gregorian reflectors

The simple symmetric front-fed reflector has disadvantages due to the blockages of the aperture by the feed system and by the feed supports. Two views of a front-fed parabolic-reflector antenna with feed supports extending from the reflector edge are presented in Figure 8. It is

Reflector Antennas, Figure 9 Geometrical configuration of a Cassegrain antenna: (a) symmetric and (b) offset.

Reflector Antennas, Figure 10 Geometrical configuration of a Gregorian antenna: (a) symmetric and (b) offset.

observed that the feed and its supports intercept partial radiation energy reflected from the reflector. It is important to note that supports which are not on the edge intercept energy from the feed before it reaches the reflector. In a geometrical-optics sense, they cast a shadow upon the aperture plane, as shown in the third view in Figure 8. This shadow, called aperture blockage, reduces gain and affects near-in sidelobes, raising some and lowering others. Moreover, the blocked radiation is further scattered by the feed and its supports and can significantly increase wide-angle sidelobes. The front-fed reflector typically has an efficiency of 55–60 %. One possible approach to increase efficiency is to employ folded-optics designs.

The radiation energy may be reflected by one or more subreflectors in the path from the feed to pencil-beam reflectors. As illustrated in Figure 9, the Cassegrain reflector system folds the incoming-ray trajectories back in the direction of the vertex of the paraboloid P by reflection from the hyperboloidal subreflector H . The focusing properties of the system derive from the collocation of one focus of the hyperboloid H with that of the paraboloid at F_1 . An incoming plane wave from the direction of the paraboloid axis is reflected from the paraboloid and then from the hyperboloid and focuses at F_2 , the other focus of the hyperboloid H . Therefore, the incident energy can be received by the feed with its phase center at F_2 .

The geometry of the Gregorian reflector system is shown in Figure 10. The subreflector is an ellipsoid E with its near focus collocated at F_1 with the focus of the paraboloid. To create a confocal geometry, the phase center of the feed should then lie at F_2 , the other focus of the ellipsoid E .

For the same focal length, the Cassegrain system is more compact than the Gregorian system. Arguments have been made that Gregorian systems may provide improved wide-angle sidelobes in apertures of the order of 200 wavelengths. However, the sidelobes of these folded antennas are not especially low, because of blockages of the feed system, subreflector, and supports.

A number of sources contribute to the high sidelobes in a folded-optics system, which include (1) radiation-pattern sidelobes from the aperture illumination, (2) spillover and edge diffraction from the subreflector illuminated by the feed system, (3) spillover and edge diffraction from the main reflector illuminated from the subreflector, (4) central blockage (subreflector and feed system), (5) spar (subreflector support) blockage and scattering, (6) deviation of reflector surfaces from the desired contours, and (7) effects of gaps between panels (Williams, 1965; Zucker, 1968; Bao, 1969; Schrank, 1985). Some recent papers (Rahmat-Samii, 1985; Ling et al., 1986; Wu and Rahmat-Samii, 1991; Bahadori and Rahmat-Samii, 2005b) and a review paper (Corkish, 1990) on the effects of reflector surface distortions on sidelobe levels cover the various approaches to this subject in some detail and provide a wealth of references.

The increased interest in large, spaceborne antennas and in sidelobe control has given rise to increased interest

in and use of offset configurations, especially for multibeam and scanning applications (Rudge and Adatia, 1978; Lee and Rahmat-Samii, 1981). The conventional pencil-beam Cassegrain and Gregorian configurations have been studied to provide design techniques for the offset cases (Rusch et al., 1990). A technique for increasing antenna efficiency by extending the subreflector in an offset Cassegrain antenna has been analyzed (Rahmat-Samii, 1986). When offset Cassegrain or Gregorian reflector systems (Figures 9b and 10b) are used in beam-scanning or multibeam applications, feeds must be moved or located in the positions that provide optimal beam performance. This turns out to be a hyperboloid for the offset Cassegrain and an ellipsoid for the offset Gregorian (Rahmat-Samii and Galindo-Israel, 1981).

Advances in real-time control techniques and data processing have become more matured, allowing the possibility of correcting for distortions. Adaptive phased-array feeds can be used to compensate for deterioration of scanning (Rahmat-Samii, 1990). Schell's multiplate antenna (Schell, 1966) provides all the necessary characteristics for adaptive removal of both atmospheric and surface distortions. The advent of modern control electronics and drive mechanisms should make the multiplate antenna a candidate approach for large-aperture reflectors. More recently, a novel electronically reconfigurable subreflectarray using microelectromechanical systems (MEMS) technology was proposed to accomplish real-time reflector surface distortion compensation (Rajagopalan et al., 2008; Xu et al., 2009).

Summary

A reflector antenna consists of one or more reflecting surfaces and a feed system. Due to its excellent radiation performances, versatility, and manufacturing readiness, it has been widely used in radars, satellite communications, deep-space telemetry, remote sensing, and radio astronomy. Reflector antennas have various types and designs, among which parabolic reflectors are the most commonly used in practice. By selecting proper geometrical parameters and feed illumination, the reflector radiation characteristics such as gain, beamwidth, sidelobe level, and cross-polarization can be well tailored for different goals. Some more complex systems such as spherical reflectors and Cassegrain and Gregorian reflectors have also been developed for more advanced applications.

Introduction

Geology is sometimes distinguished from geophysics as being the study of the *outside* – the surface of the Earth and structures expressed at the surface – and geophysics being the study of the *inside* of the Earth. These light-hearted definitions are a convenient introduction to what has become the most pervasive and important direct uses of satellite images for geology and, in particular, structural geology.

The value of satellite images for topographic mapping and military reconnaissance was realized at an early stage, but there was virtually no appreciation of the value of orbital methods for geology until the mid-1960s, after hundreds of satellites had been launched. However, geologic remote sensing was given a sudden and unpredicted jump start by the US Mercury and the Gemini programs.

Project Mercury, the first American manned space effort, began in 1958, with the successful orbital flight by John Glenn in 1962. Beginning with the second flight, by Scott Carpenter, the Mercury pilots carried out terrain photography for geologic purposes. The Mercury terrain photographs generated the beginnings of wide appreciation of the geologic value of orbital photography. By the time the 10 Gemini flights were over, some eleven hundred 70 mm color photographs suitable for geology, geography, or oceanography study had been acquired. Published widely, these spectacular pictures generated worldwide interest among public and scientists alike.

Their most important result for geology was the stimulus to the US Geological Survey's Earth Resources Observation Satellite (EROS) program.

The EROS program eventually became Landsat, the first of which was launched in July 1972 and was taken over by NASA. The great success of Landsat and later missions in the series triggered similar programs in other countries, notably France, India, and Russia. In recent years, commercial programs of orbital remote sensing have been highly successful, and anyone interested can now obtain orbital images from Google Earth or other sources.

Orbital imaging radar began with the Seasat mission of the 1960s, whose results like Landsat stimulated development of successive radar-carrying satellites by the European Space Agency (ERS-1 and ERS-2). Most important was Canada's RADARSAT program, the first operational orbital radar system. RADARSAT has now produced global imagery being used for many applications, including oceanography, sea-ice observations, and geology, in particular structural geology.

"Structural geology" is equivalent to tectonics, when applied to regional or continental areas. Plate tectonics is a widely accepted theory in which the Earth's crust is considered to be a number of "plates," rigid segments of the lithosphere that are in motion relative to the interior of the Earth. Examples of satellite remote sensing applied to structural geology or tectonics are described below.

Digital tectonic activity map of the earth

The NASA Crustal Dynamics Program of the 1970s applied space geodesy techniques (satellite laser ranging and very long baseline interferometry) to the measurement of plate motions and rigidity. To plan baselines and station locations, a global map of present tectonic activity was required. The National Geographic "Physical World" map of 1975 was the base for such a map in 1977, which was used for several years by NASA for space geodesy research. Since then, the map has undergone several revisions and has appeared in 16 different textbooks and many technical papers. The most recent version, published in 2002, is a Robinson projection digital map based on sea surface altimetry for the ocean basins (Figure 1). Spreading rates are those of NUVEL-1. Terrestrial features were drawn from published literature, orbital photographs, and seismic epicenters. The one million-year figure was chosen as a time long enough to be representative but short enough that physiographic features such as fault scarps and volcanoes were still recognizable. The map has been useful in teaching geology courses at all levels. It shows recognized plates but also shows that there are many major features not on distinct plate boundaries. The map is available online as "Digital Tectonic Activity Map of the Earth," <http://denali.gsfc.nasa.gov/dtam/data/ftp/dtam.jpg> (Figure 1), accompanied by complementary seismicity and space geodesy baseline maps, and as a public domain publication. It provides a good background for several examples of satellite remote sensing in structural geology.

G221.001

Remote Sensing and Geologic Structure, Figure 1 Digital tectonic activity map of the earth.

Remote Sensing and Geologic Structure, Figure 2 Landsat image showing active faults within the Los Angeles Basin.

San Andreas Fault, California

The Landsat image in Figure 2 shows the active geologic features of the densely populated Los Angeles Basin and adjacent areas. The main faults are easy to see: the San Andreas and Garlock faults outline the large triangle of the Mojave Desert. The curved south margin of the San Gabriel Mountains is another active fault. The 1971 San Fernando earthquake occurred on a fault in the San Gabriel system. All these faults are active and their location must be accurately known to construct and maintain features such as highways, pipelines, and aqueducts in the region. The fault systems and their seismic behaviors have been studied extensively. More recently ground geodetic and interferometric synthetic aperture radar satellite observations across the southern San Andreas Fault systems were used to study slip rates and the viscosity structure of the lower crust and upper mantle in Southern California.

Sudbury impact structure, Ontario, Canada

The Sudbury area in Canada is a major mineral district since the 1880s, when nickel was discovered near the city

of Sudbury. The Sudbury Basin is one of Canada's richest mining areas, with world-class mineral deposits and the world's oldest, largest, and best-exposed meteorite impact site (Mungall et al., 2004). This elliptical feature, known as the Sudbury Basin, is 300 km in diameter and approximately 2 billion years old. Over the past 100 years, over \$120 billion of nickel and copper ores were mined from more than 90 mines distributed around the rim of the Basin. The Basin has been intensely studied by geologists; it is not clear how big the structure is or how its elliptical shape was formed. Much remains to be learned about the structural evolution of the Sudbury Basin and the mineralized showings around it. The geologic structures are keys to this understanding.

Figure 3 shows some regional geologic rock units and the location of mining properties (red dots), superimposed on a RADARSAT image. The RADARSAT image helps to delineate the surface expression of mapped geologic structures published by Ames et al. (2006). RADARSAT images and image fusion techniques have been used to study the characteristic elliptical shape and the associated geologic structure fractures around the Basin (Lowman, 1994; Singhroy and Molch, 2004).

Remote Sensing, Historical Perspective, Figure 3 Sudbury impact structure in Canada showing faults and geologic units superimposed on a RADARSAT image.

The RADARSAT Standard beam mode at 20–27° incidence angles provides an excellent view of the topography and structural features of the Sudbury structure as expressed by differential erosion controlled by fractures, dykes, and lithology. The radar images have been used by geologists to study the size, shape, and evolution of the Sudbury Basin and show the result of folding from the southeast to the northwest.

Summary

Satellite images are an invaluable tool to study structural geology and regional tectonics as shown for the above examples. The synoptic and global coverage provided by satellites, the wide swath width of different orbital sensors, and the repeated coverage have produced images with different viewing angles to easily map geologic structures in vegetated and non-vegetated areas.

REMOTE SENSING, HISTORICAL PERSPECTIVE

Vincent V. Salomonson
Department of Geography, University of Utah, South Jordan, UT, USA

Definition

Remote sensing, historical perspective. An overview of the history of remote sensing where remote sensing is defined as the technique of obtaining information about objects through the analysis of data collected by special instruments that are not in physical contact with the objects of investigation.

Introduction

The term “remote sensing” began with the evolution of human capability to observe regions of the electromagnetic spectrum outside the range of wavelengths discernable by the human eye and traditional photography. The term “remote sensing” is attributed to Evelyn Pruitt, Office of Naval Research (see Fischer et al. in the 1975 edition of the *Manual of Remote Sensing*). Dr. Nicholas Short, formerly of NASA, provided an extended definition of remote sensing as follows:

- Remote sensing refers to instrument-based techniques used in the acquisition and measurement of spatially organized (distributed) data/information on some property(ies) (spectral, spatial, physical) of an array of target points (pixels) within the sensed scene that correspond to features, objects, and materials, doing this by applying one or more recording devices not in physical, intimate contact with the item(s) under surveillance (thus at a finite distance from the observed target, in which the spatial arrangement is preserved); techniques involve amassing knowledge pertinent to the sensed scene (target) by utilizing electromagnetic radiation, force fields, or acoustic energy through employing cameras, radiometers and scanners, lasers, radio frequency receivers, radar systems, sonar, thermal devices, seismographs, magnetometers, gravimeters, scintillometers, and other sensing instruments.

After a quick review of the beginnings of remote sensing, this overview of the history of remote sensing will be focused principally on its evolution and development for studies of the Earth-atmosphere system with emphasis on spaceborne remote-sensing systems.

Selected histories of remote sensing

Several historical perspectives can be found on the Internet and elsewhere. An excellent overview history of remote sensing by C.J. Cohen (2000) is a recommended reading. An in-depth history up through the early 1970s is provided in the *Manual of Remote Sensing*, Volume 1, pp. 27–50 (Fischer et al., 1975). Several other helpful references in the historical evolution of remote sensing include a history of NASA “Space Applications” given in Ezell (1988) or <http://history.nasa.gov/SP-4012/vol3/ch4.htm>. This resource lists key missions and also the people and documents that were important in the evolution of NASA projects designed to improve knowledge of Earth-atmosphere systems as well as providing useful information for managing the resources of the Earth. Kramer (2002) provides probably the most comprehensive listing of national and international missions and sensors along with descriptions of the background and characteristics of the missions and sensors focusing on observing the Earth and its environment. Additional insights for active and passive microwave remote sensing can be found in Njoku (1982),

Elachi (1987), and Atlas (1990). Hecht (1991) provides background history for lidar/laser remote sensing.

Historical background for Earth remote sensing

A historical background of remote sensing can be linked back to the understanding of light and its characteristics and the development and application of photography. The history can be traced back to circa 336–323 BC when Aristotle philosophized at length about the nature of light. During the intervening years, some selected events include the development of photography along with the explanation of the “camera obscura” (Latin for “dark box”) – the simplest camera by Al Hazen of Basra in 1038 AD. The principles of the camera obscura were later explained by Leonardo da Vinci in 1490. Sir Isaac Newton who was experimenting with a prism in 1666 described the dispersion of light into a spectrum of colors that could be recombined into white light. In 1839, Daguerre invented the Daguerrotype – a forerunner of pictures we know today.

Aerial photography can be traced to 1858, when Gaspar Felix Tournachon took the first aerial photograph from a captive balloon at 1,200 ft over Paris. Another noteworthy achievement was the attachment of a camera to carrier pigeons, called The Bavarian Pigeon Corps, in 1903. In 1909 at the Dresden International Photographic Exhibition, picture postcards of the fair taken by pigeons were very popular. In 1909, Wilbur Wright took an aerial photograph of Centocelli, Italy, from an airplane while trying to sell planes to the Italian government for their campaigns in Northern Africa. Photoreconnaissance began in World War I with the mounting of cameras on airplanes by the German and US armies to observe troop positions. By 1918, in the war, French aerial units were developing and printing as many as 10,000 photographs each night, during periods of intense activity. During the Meuse-Argonne offensive, 56,000 aerial prints were made and delivered to American Expeditionary Forces in 4 days. The first photograph of the actual curvature of the Earth was taken from a free balloon at an altitude of 72,000 ft by Captain Albert W. Stevens in 1936. In 1942, Kodak patented the first false color infrared-sensitive film. These events set the stage in great measures for the implementation of remote sensing from space that will be described in later paragraphs.

Some key events in development of nonphotographic remote-sensing systems should be mentioned. Notable development and discoveries include the use of the infrared portion of the electromagnetic spectrum by Sir William Frederick Herschel, a German astronomer, in 1800 (Reference: Wikipedia encyclopedia); the use of bolometers by Samuel P. Langley to make measurements of incident electromagnetic radiation or temperature in 1879; and Heinrich Hertz’s demonstration of the reflection of radio waves from solid objects in 1889 which subsequently led to the concept of radar remote sensing. In 1940, incoherent radar systems were developed in

Britain and the USA to detect and track aircraft and ships during World War II. In the 1950s, extensive research and development was carried out on infrared systems, coherent radar systems, and the synthetic aperture radar (SAR) at the University of Michigan. Major corporations such as Westinghouse, Motorola, Philco, Goodyear, Raytheon, and others developed side-looking airborne radar (SLAR) and SAR systems in the mid-1950s.

The development of laser and lidar actually was influenced significantly by the use of searchlights for remote sensing of aerosols. Hulbert (1937) pioneered the aerosol measurements using the searchlight technique and photographs of the searchlight beam to obtain aerosol observations up to a distance of 10 km. Elterman's research (1951, 1953, 1966) focused on the study of atmospheric phenomena using searchlights and made significant progress in building practical devices. The first laser – a ruby laser – was invented in 1960 by Schawlow and Townes (1958) and Maiman (1960). The first giant-pulse technique (Q-Switch) was invented by McClung and Hellwarth (1962). The first laser studies of the atmosphere were undertaken by Fiocco and Smullin (1963) and by Ligda (1963). These technologies and their applications have advanced to where lasers are now being flown in space for studies of the Earth's atmosphere, polar regions, oceans, and terrestrial ecosystems.

An overview of the evolution of Earth remote sensing from space

The beginning of Earth-system science using remote sensing from space can be traced to the launches of the early V-2 rockets (Herring and King, 2001). Following World War II, the US Naval Research Laboratory experimented with V-2 rockets and smaller ones called "sounding rockets." During a flight on March 7, 1947, what is believed to be the first space-based picture of the Earth was taken 100 miles (123 km) above the Earth over New Mexico, USA. These images and others demonstrated the potential for spaceborne cameras to help in developing a better understanding of the dynamic processes taking place in the atmosphere and on the Earth surface. The launch of Explorer 7 in 1959 included an experiment to study the Earth's radiation balance using a simple, bolometer-based sensor. Professor Verner Suomi, an eventual US Medal of Science winner, from the University of Wisconsin-Madison, was the Principal Investigator.

A major milestone for entry into the present era of sustained Earth observations from space was the launch of TIROS-1 in 1960. An excellent description of events leading to the launch of TIROS-1 is provided by Vaughan and Johnson (1994). Following the launch of the TIROS-1 satellite, the ensuing two decades (1960–1980) saw a virtual armada of satellites and accompanying sensors launched into low Earth orbit by the USA and other countries to better understand Earth-atmosphere, oceans, polar

regions, and land surface processes and trends (see Kramer, 2002). Similarly, progress was made with the launch and operation of satellites in geosynchronous orbit that provide hemispheric views of the Earth at several times during the day. These started with the NASA Advanced Technology Satellite (ATS) series beginning in 1966 and Synchronous Meteorological Satellites (SMS) starting in 1974 and evolving into the Geostationary Operational Environmental Satellite (GOES) series starting in 1975 that were operated by NOAA all using essentially a Visible and Infrared Spin Scan Radiometer (VISSR). Similar and complementary geosynchronous systems were put into place by Russia, Japan, the European Space Agency (ESA), and India, thereby providing effectively complete geosynchronous coverage of the Earth with emphasis on observing rapidly varying phenomena such as severe storms, for example, thunderstorms and hurricanes.

As time progressed, the sensors became more capable and the lifetime of the spacecraft and sensors increased (see <http://centaur.sstl.co.uk/sshp/mini/mini60s.html>). By the late 1970s and early 1980s, Earth-observing satellites and accompanying sensors often lasted for several years. As the dependability of the sensors and spacecraft improved, several nations established what were generally described as "operational" systems put in place to provide systematic, reliable, global observations of the Earth's environment with particular emphasis on meteorological variables such as cloud properties (e.g., cover and cloud-top temperature). These operational systems include now, for example, the NOAA Polar Orbiting Environmental Satellites (POES) and the Geostationary Operational Environmental Satellite (GOES) series operated by the National Oceanic and Atmospheric Administration (NOAA), the US Defense Meteorological Satellite Program (DMSP) block satellite series, the Union of Soviet Socialist Republics (USSR) Meteor series, the EUMETSAT Meteosat satellite series, the Japan Geostationary Meteorological Satellites (GMS), and India's Insat satellites (see Office of Technology Assessment, 1993).

Nimbus-7, TIROS-N, and NOAA-6. Nimbus-7 carrying the Coastal Zone Color Scanner (CZCS), the Total Ozone Mapping Spectrometer (TOMS), and the Scanning Multichannel Microwave Radiometer (SMMR) serves as an example of the progress and impact of observations from satellites. The CZCS demonstrated that biological activity in the surface waters of oceans can be monitored from space. The TOMS observations provided excellent information documenting the extent of the "ozone hole" over Antarctica. The SMMR extended microwave observations of atmosphere, oceans, and land surfaces that began with the Nimbus-5 Electrically Scanned Microwave Radiometer (ESMR). NOAA-6 was the first operational satellite (as opposed to research and development satellites such as TIROS-N) to carry the Advanced Very High Resolution Radiometers (AVHRR) that has provided since the late 1970s systematic, global observations of

a wide variety of parameters including cloud properties, [sea surface temperature](#), snow and ice cover, and vegetation dynamics and processes. Also NOAA-6 carried the TIROS Operational Vertical Sounder (TOVS) package containing the High Resolution Infrared Sounder (HIRS), the Stratospheric Sounding Unit (SSU), and the Microwave Sounding Unit (MSU) produced vertical profiles of atmospheric temperature and water vapor that could be used to complement the global radiosonde network of observations.

The Landsat satellites must be noted as having provided a major stimulus to remote sensing of the Earth's surface starting in 1972 with the launch of Landsat-1 which was then called the Earth Resources Technology Satellite (ERTS-1). Prior to the launch of the Landsat sensor systems, the photographs taken from the manned, Earth-orbiting Gemini and Apollo missions showed considerable evidence of the utility of relatively high spatial resolution images for studying land, as well as atmospheric and ocean, phenomena with some distinct advantages over airborne systems and sensors. The Landsat series of satellites demonstrated that consistent in space and time, relatively high (as compared to the spatial resolutions provided by meteorological satellite sensors) observations of the Earth's surface (i.e., less than 100 m spatial resolution) could be routinely obtained over several years for studying and documenting changes occurring on the land areas of the globe in particular (see Lauer et al., 1997; Morain, 1998; <http://erg.usgs.gov/isb/pubs/factsheets/fs02303.html>; http://landsat.usgs.gov/about_mission_history.php; http://www.centennial-offlight.gov/essay/SPACEFLIGHT/remote_sensing/SP36.htm). The Landsat series also stimulated many other relatively high-resolution systems, both by governments and the private sector around the world (presently there are several with spatial resolutions less than 1 m being provided) that have resulted in a host of applications of spaceborne remote sensing for resource monitoring, science studies of terrestrial processes and trends, and a host of commercial applications. These satellite systems include not only nationally sponsored systems by France, India, and other countries but also commercial satellite systems (see: Stoney, 1998; http://www.asprs.org/news/satellites/asprs_database_110804.pdf; http://www.eijournal.com/Markets_Opportunities.asp). At present, there are nearly 30 satellite systems in orbit according to this report and more are planned for the future by various countries.

Lastly, great progress has been achieved since the launch of TIROS-1 in the general area of satellite geodesy wherein observations of crustal movements and changes in the length-of-day of the Earth are obtained using satellite laser ranging (SLR), very long baseline interferometry (VLBI) observations, and global positioning systems (GPS) technologies. In addition highly scientifically useful observations of the Earth's gravity field and magnetic field are also obtained from space (Salomonson, 1995). Satellite geodesy is the measurement of the form and

dimensions of the Earth, the location of objects on its surface, and the figure of the Earth's gravity field by means of satellite techniques (reference: Wikipedia). Scientific papers advocating the use of satellites for geodetic purposes were published as early as 1956. Geodetic applications were outlined by the Smithsonian Astrophysical Observatory for data obtained from Project Vanguard during the 1958–1959 International Geophysical Year (IGY). With this information, the constant growth of space technology, the development of electronic distance measuring devices, and the perfection of electronic data processing equipment, satellites specifically equipped for geodetic purposes have been developed and launched, to provide both scientific and practical information for use in surveying, navigation, air/sea/land transportation, etc. Early satellite tracking involved the use of special cameras and included the tracking of Sputnik 1 and 2 in 1957 and the Vanguard satellite orbit in 1959. With the invention of the laser, the capability grew to track with greater precision through the use of laser ranging. Satellite systems with corner-cube reflectors were launched in the 1960s including the first Laser Geodynamics Satellite (LAGEOS-1) and the French Starlette satellite. The combination of satellite laser ranging (SLR) and very long baseline interferometry (VLBI) demonstrated that plate tectonic measurements could be done with accuracies in the centimeter range. The launches of Skylab in 1973 and the Geodetic and Earth-Orbiting Satellite (GEOS-3) with radar altimeters aboard yielded significant, early advances in the use of altimetry over the oceans and the mapping of the gravity field, particularly the marine geoid. Observations of the Earth's magnetic field started with the launch of Sputnik 3 and Vanguard 3 in 1958. These were followed by two Cosmos satellites in 1964 and three US Orbiting Geophysical Observatories (OGO 2, 4, and 6) between October 1967 and July 1971. Magsat launched in 1979 carried both scalar and vector magnetometers. Present space-based geodetic measurement techniques include, for example, the geodetic use of global positioning satellite systems such as the US Navstar GPS and the Russian Global Navigation Satellite System (GLONASS), laser ranging to satellites (SLR) such as the Laser Geodynamic Satellites (LAGEOS) satellites, satellite radar altimetry (mostly over oceans) using the NASA/French TOPEX/Poseidon and Jason series of satellites, orbital tracking of satellites for determining the Earth's gravitational field using the CHALLENGING Minisatellite Payload (CHAMP) operated by Germany, satellite-to-satellite tracking such as done by the NASA Gravity Recovery And Climate Experiment (GRACE), and satellite gradiometry (measuring the gravity gradient from orbit) employing the Gravity Field and Steady-State Ocean Circulation Explorer (GOCE) that is in development by the European Space Agency to be launched in 2008. In the case of the Earth's magnetic field, the Ørsted and CHAMP satellites which were launched in 1999 and 2000, respectively, have provided useful data.

The NASA Earth-observing system (EOS), international systems, and beyond

The satellites described above and associated sensors, along with those developed and operated by other countries, produced data and information that demonstrated Earth-observing satellites can and do provide long-time series of observations that, in combination with in situ observations, result in improved insights into Earth-system processes and help decipher changes/trends (Earth System Sciences Committee, 1988). Furthermore, progress was being made by showing that these observations can be used in numerical models, for example, coupled general circulation models (GCMs), so as to improve their performance for both understanding and predicting/projecting future changes in Earth's atmosphere, oceans, land, and climate system (see National Research Council, 1991).

In addition, in the 1970s and into the 1980s, a widely held concern emerged that humankind was more than just a passenger and observer on "Spaceship Earth." There was increasing evidence that humankind was not only making greater demands on Earth's resources due to population increases and the desire for a better quality of life but also human activities could be affecting processes occurring in the land/ocean/atmosphere systems in ways that could change the composition of Earth's atmosphere, chemistry of its oceans, and composition of its land surfaces with subsequent impacts on Earth's climate and environment.

Eventually, NASA proceeded to join their Earth science efforts with the human spaceflight program by

defining very large, comprehensive, observational missions that would make use of the considerable cargo launch capabilities of the Space Shuttle and unique inclined orbit of the Space Station. These efforts were initially designated "System Z." However, these efforts evolved further to become largely independent of the NASA human space flight program and became part of NASA's "Mission to Planet Earth" in 1987 (Taubes, 1993; Pielke, 2000). The space segment of this effort was called the NASA Earth-Observing System (EOS). The early versions of the EOS envisioned a large effort composed of approximately 15 missions building and based upon the demonstrated success of previous satellite observations for studying the Earth. This set of instruments within the EOS would allow comprehensive observational efforts ranging from observing the electric and magnetic fields of the Earth to improved instruments for acquiring observations of atmosphere, oceans, and land processes and trends that would extend and improve upon data sets acquired by sensors on the Nimbus series and other operational satellite systems. In addition, new, but highly desirable instruments, such as a synthetic aperture radar (SAR) and a high spectral resolution, hyperspectral instrument (later called High Resolution Imaging Spectroradiometer [HIRIS]), could be developed and launched into space. However, over time budgetary constraints eventually reduced the original concepts to the series of missions depicted in Figure 1. The original EOS-A mission evolved to being designated "EOS-AM-1" because it had a descending

Remote Sensing, Historical Perspective, Figure 1 NASA Earth-Observing Systems flown since 1997 through 2003.

(north to south) polar orbit with an equator-crossing time near 10:30 a.m. The EOS-AM terminology was later changed to “EOS-Terra” indicating the principal emphasis of the mission was related to studies of land processes. Similarly the EOS-B mission was changed to “EOS-PM-1” indicating an equator-crossing time near 1:30 p.m. and an ascending (south to north) polar orbit. This designation was later changed to “EOS-Aqua” because the principal theme of the mission was related to the hydrological cycle, the water budget, and dynamics of the Earth-atmosphere system. The Terra mission was eventually launched in December 1999 and the Aqua mission in May of 2002. The missions depicted in Figure 1 extending from 1997 to 2003 had other missions added as time went on. The EOS Aura (focused on chemistry of atmosphere), for example, was launched in 2004. Cloudsat (cloud profiling radar observations) and CALIPSO (cloud aerosol lidar and infrared pathfinder satellite observation) missions were launched in 2006. The extent and scope of the Earth-Observing System (EOS) along with established international Earth-observing capabilities summarized above truly became a total system that is ongoing and demonstrating the power of remote sensing for gaining better understanding of Earth-system trends and processes.

Figure 1 dramatically illustrates the breadth and depth of the contributions that remote sensing is making across Earth-system science as represented by the NASA Earth-Observing Systems. There are a wide array of passive optical, multispectral observations of the land, oceans, and atmosphere features being acquired: for example, TOMS-EP, UARS, SAGE, and Aura (atmospheric chemistry); ACRIMSAT, ERBS, and SORCE (radiation balance); Landsat-7 and EO-1 (high-resolution observations land features primarily); Terra and Aqua (several optical sensors and microwave sensors/AMSU and AMSR-E observing land, ocean, and atmosphere parameters); and SeaWiFS (ocean color and land vegetation). Beyond those missions and sensors, there are active microwave/radar observations being obtained regarding precipitation and cloud water (TRMM and Cloudsat – not shown in Fig. 1); ocean surface winds (SeaWinds and QuikScat); ocean topography (TOPEX/Poseidon); lidar observations of ice sheets, clouds, and land features (ICESat and CALIPSO – not shown in Fig. 1); plus the dynamic Earth’s gravity field (GRACE). More extensive descriptions of these missions and accompanying sensors can be found in the EOS Reference Handbook at http://eospsoc.gsfc.nasa.gov/ftp_docs/2006ReferenceHandbook.pdf; Parkinson et al. (2006).

In early 2000, a new debate begun in the USA about the future of US Space Exploration beyond the completion of Space Station in 2010 and the retirement of the Space Shuttle. Based on the initial goal of a 15 year climate data record by EOS and the experience NASA gained by completing successfully the first phase of this program, a study was conducted by the US National

Academy of Sciences (NAS) to identify the second generation Earth-observing satellites that NASA and its sister agencies in the USA must build, with potential cooperation with its international partners (Space Studies Board, 2007).

There are several satellites beyond those noted above that have been put into operation and to be developed by NASA and its partners to fulfill the priorities identified by the NASA (http://eospsoc.gsfc.nasa.gov/eos_homepage/mission_profiles/index.php). For example, the Ocean Surface Topography from Space Missions (OSTM) is a continuation of the TOPEX/Poseidon and Jason missions and is to be accomplished jointly with France, NOAA, and EUMETSAT. This mission was launched in 2008. The Aquarius mission developed and launched jointly with Argentina has as the primary objective to measure the surface salinity in the oceans of the world. It was launched in 2011. The Suomi National Polar-orbiting Partnership (NPP) project was launched in 2011 and carries several improved instruments as a prototype for the next generation US National Polar Orbiting Environmental Satellite System (NPOESS). The Landsat Data Continuity Mission (LDCM) has the objective of extending the very successful Landsat series beyond Landsat-7 in cooperation with the US Geological Survey. It is to be launched in 2013.

There are also significant efforts underway globally in processing and fusing measurements from different sensors and satellites plus assimilating these data into GCMs (Le Marshall et al., 2007). For example, efforts are being made to utilize the combined power of satellites and sensors comprising what is termed the EOS “A-Train.” The “A-Train” constellation of satellite consists of GCOM-W1, Aqua, CALIPSO, Cloudsat, the French PAROSOL, and Aura. The Global Change Observation Mission-Water (GCOM-W1) “SHIZUKU” satellite was launched by the Japan Aerospace Exploration Agency (JAXA) on May 18, 2012. The Orbiting Carbon Observatory-2 satellite is scheduled to enter the A-Train in 2013. These satellites cross the equator within a few minutes of one another at around 1:30 PM local time. By combining the different sets of observations, scientists will be able to gain a better understanding of very complex Earth-system processes and parameters related to climate change.

Throughout the entire planning and execution phase of EOS program and to the present, there has been and is considerable international consultation and deliberation on potential partnerships with Europe, Japan, Russia, and other nations around the world to (1) share the costs of the EOS satellites by providing instruments, spacecraft, launching rockets, and/or contributing to the data and information management aspects of EOS program; (2) avoid duplication or gaps in critical measurements between/among the nations pursuing Earth observations from space; and (3) establish common formats, standards, and protocol for collection, archive, distribution, and sharing of the observations and information resulting from Earth-observation satellites.

Several ad hoc and formal committees/groups have been established to facilitate international dialogue and cooperation. Notable among them is the Committee on Earth Observation Satellites (CEOS) which consists primarily of the space agencies from around the world and later on its companion International Global Observing System Partnership (IGOSP) to promote the use of space-based observations by both traditional and nontraditional users of such observations. The membership of these groups/committees included primarily scientific, technical, and international officers of space agencies, international organizations, and public and private sector users of observations and information resulting from the satellites. The leadership of these groups has identified a need for high-level political support to sustain these space-based capabilities and to incorporate them into the operational networks of member organizations. To achieve this objective, the Group on Earth Observations (or GEO) was established to coordinate international efforts to build a Global Earth Observation System of Systems (GEOSS; <http://earthobservations.org/>). This emerging global coordination effort has the objectives of interconnecting a diverse and growing array of instruments and systems for monitoring and forecasting changes in the Earth's global environment. These efforts reflect that remote-sensing observations and particularly those from space have matured greatly and represent a capability that is crucial and essential to understand changes occurring on the Earth associated with natural and anthropogenic effects and to use the resulting information in early hazards warnings, managing Earth's natural resources, understanding and predicting Earth's environment, assessing the conditions of Earth's atmosphere, oceans, and continents to just name a few benefits.

Certainly remote-sensing observations now are being used for a wide variety of scientific and resource management activities, and this evolution will continue to grow and evolve into the future. It is believed that a combination of technological innovations in remote sensing and information and communication technologies together with an increasing demand for better understanding of how the Earth system and its climate is evolving to inform both policy and practical decision making in mitigating and/or managing the risks associated with changes will result in unprecedented use of these capabilities by the present generation and those who will follow for the rest of this century and beyond.

Summary

Since the beginning in understanding the power and potential of remote sensing, its use for studies of the Earth-atmosphere system has grown to the point where it is now a truly essential tool in scientific studies of the Earth and applications involved in monitoring and assessing the Earth's natural resources and its environment. The scope and extent of spaceborne systems is

worldwide including both operational and research systems operated by many nations as well as commercial systems. There has been considerable progress in the coordination among countries and organizations to achieve better, more efficient utilization of space assets for earth science and applications. Such efforts are now represented by the international efforts to build a Global Earth Observation System of Systems (GEOSS) having the objectives of interconnecting a diverse and growing array of instruments and systems for monitoring and forecasting changes in the Earth's global environment.

Definition

Remote Sensing. The study of objects at a distance, without direct physical contact.

Introduction to remote sensing platforms

Before delving into physics and techniques, it is appropriate to briefly discuss the types of remote sensing platforms that are used to host remote sensing instruments, so that the various remote sensing techniques can be put into context. Remote sensing of the Earth can be carried out from many types of platforms, including towers, balloons, unmanned airborne vehicles (UAVs), manned aircraft, satellites, and space stations, using techniques principally in the ultraviolet (UV), visible, infrared (IR), and microwave portions of the spectrum (see [Observational Systems, Satellite](#)). Because it is impractical to instrument the entire globe with ocean buoys, land-based sensors, weather balloons, etc., the emphasis to date has been on remote sensing from aircraft and unmanned satellites.

Satellite orbits

Most Earth remote sensing satellites are placed into circular, near-polar, sun-synchronous orbits at altitudes of approximately 600–900 km above the Earth's surface. A satellite in a sun-synchronous orbit passes over a given region on the ground at approximately the same local time every day. This means that the solar illumination angle changes relatively slowly for that area from day to day, which simplifies data interpretation. Some sun-synchronous satellites are in exact repeat orbits, meaning that they fly over the same region at exactly the same local time every day. Instruments on sun-synchronous LEO satellites can cover the globe in a synoptic manner, which means they can provide coverage of large areas within a short period of time.

If an instrument onboard a satellite can gather data over a geographically wide swath (approximately 3,000 km in the direction perpendicular to the direction of satellite motion), then that instrument can cover the entire globe in 12 h, if it is designed to collect data both day and night. The visible and infrared instruments currently flying on LEO satellites typically have spatial resolutions (a measure of the size of discernible features) of approximately 1 m–1 km on the ground. Higher spatial resolution generally means less geographical coverage, owing to practical considerations of focal-plane size, onboard data storage,

David L. Glackin: deceased.

Remote Sensing, Physics and Techniques, Figure 1 Electromagnetic spectrum from the ultraviolet to the microwave.

and downlink data rates (see [Mission Operations, Science Applications/Requirements](#)).

Other remote sensing satellites, all weather satellites, occupy geosynchronous orbits. Positioned at 36,000 km above the equator, their orbital periods of 24 h make them appear to hang over one spot on Earth. With broad-area imagers on five “GEO birds,” it is possible to cover the globe up to approximately 60° latitude, with spatial resolutions as good as approximately 1 km.

The L1 libration point, a gravitationally stable point between the Earth and the sun, has been discussed as a possible location for a satellite to study the Earth as a planet for climate research. Other, less used, orbits include Medium Earth Orbit (MEO) and Molniya orbits (see [Observational Systems, Satellite](#)).

Aircraft

Despite the growth in satellite observations, aircraft are still used to gather much remote sensing data and dominate the field for some applications. Because they can fly specific paths at selected times, aircraft offer more flexibility than spacecraft, and the higher spatial resolution that is possible provides the finer detail necessary for applications such as urban planning, disaster assessment, and mapping (see [Observational Platforms, Aircraft, and UAVs](#)). Bridging the gap between conventional aircraft and orbiting spacecraft are the UAVs. These aircraft, capable of long-duration, high-altitude flight, have undergone successful tests and have the potential to provide a valuable supplement to satellites (see [Observational Platforms, Aircraft, and UAVs](#)).

The remote sensing spectrum

The portions of the electromagnetic spectrum (see [Radiation, Electromagnetic](#)) that are most useful for remote sensing can be defined as follows: The ultraviolet (UV) extends from approximately 0.1 to 0.4 μm, the visible (VIS) from 0.4 to 0.7 μm, the near infrared (NIR) from 0.7 to 1.0 μm, the short-wave infrared (SWIR) from 1 to 3 μm, the mid-wave infrared (MWIR) from 3 to 5 μm, the long-wave infrared (LWIR) from 5 to 15 μm, and the far infrared (FIR) from 15 to 100 μm. These ranges are typically defined in terms of wavelength, but other ranges can be defined in terms of frequency as well. Thus, the submillimeter-wave (sub-mm or sub-mm-wave) range

encompasses wavelengths from approximately 100 to 1,000 μm or frequencies from approximately 3 THz (THz) to 300 GHz (GHz). The millimeter-wave (mm or mm-wave) range extends from 300 to 30 GHz or 1 mm to 1 cm (cm) and the microwave region from 30 to 1 GHz or 1 to 30 cm ([Figure 1](#)).

The special case of the gamma-ray spectrum is not discussed here (see [Gamma and X-Radiation](#)).

Within these spectral regimes, there are “window bands” of low atmospheric absorption, in which imaging instruments typically operate and “absorption bands” of relatively high atmospheric absorption in which atmospheric profiling or sounding instruments operate. From the UV through the SWIR, the spectrum is dominated by reflected sunlight. In the MWIR during the daytime, the spectrum is a mix of reflected solar and emitted thermal radiation ([Figure 2](#)); the fraction of each depends on the exact circumstances of observation. From the LWIR to the FIR, the spectrum is dominated by the natural thermal emission of the environment. The sub-mm or terahertz regime (between the electro-optical and mm/microwave regimes) is in its relative infancy with regard to remote sensing techniques, showing particular potential for measuring ice in the atmosphere. The mm-wave and microwave regimes are especially useful for measuring environmental phenomena that are water related. These include atmospheric water vapor, cloud liquid water, and rainfall (see [Atmospheric General Circulation Models](#)); sea-surface temperature, wind vector, and salinity (see [Ocean, Measurements and Applications](#)); sea ice extent and concentration, snow extent, and water equivalent (see [Cryosphere, Measurements and Applications](#)); and soil moisture, land surface temperature, land freeze/thaw state, and vegetation (see [Land-Atmosphere Interactions, Evapotranspiration](#)).

The portion of the spectrum from the UV through the FIR is generally called the electro-optical (E-O) portion of the spectrum, while the portion of the spectrum from the mm-wave through microwave is generally loosely called the microwave (sometimes abbreviated as μW) portion of the spectrum.

Instruments operating in the E-O spectrum are adversely affected by clouds (see [Optical/Infrared, Scattering by Aerosols and Hydrometeors](#)) unless they are designed to be meteorological imagers or other specialized instruments. E-O imagery in the VIS-SWIR spectrum has low utility at night, although moonlight is sufficient

Remote Sensing, Physics and Techniques, Figure 2 Example of solar/thermal crossover characteristics in the mid-wave infrared. During the day, the region from 3 to 5 μm is a mix of reflected solar and emitted thermal radiation.

for high-sensitivity low-light-visible systems and hot fires are visible at night, particularly in the SWIR. E-O imagery in the LWIR-FIR is effective day or night, since it relies on natural thermal emission, not sunlight (see *Thermal Radiation Sensors (Emitted)*). Microwave instruments, on the other hand, can operate day or night and can penetrate nearly all types of weather, including most clouds. They thus offer views of areas that are frequently cloud covered, such as tropical countries, or that are in darkness for extended periods, such as the wintertime polar caps.

With the above background, an overview of remote sensing techniques and the physics upon which they rely will now be presented. The list of instruments below is not exhaustive, but it includes the major ones in use today.

Types of instruments

Remote sensing instruments fall into the general classes of passive and active electro-optical and passive and active microwave instruments. Passive instruments collect and detect natural radiation from the environment. They receive upwelling radiation from the Earth-atmosphere system, collect it, focus it, detect it, and convert it into electrical signals. These signals are then processed, stored, compressed, formatted, and transmitted to ground stations. Active instruments emit radiation and measure the returning signals. They emit a pulse of radiation that interacts with the environment and then backscatters or reflects off of it. Some of the radiation travels back to the instrument for detection and processing.

Passive electro-optical instruments include multispectral imagers, hyperspectral imagers, atmospheric profilers or sounders, spectrometers, radiometers, and polarimeters (as well as digital CCD (charge-coupled device) cameras, analog vidicon (tube-type) cameras, and film cameras). Active electro-optical instruments include backscatter lidars, differential absorption lidars, Doppler wind lidars, fluorescence lidars, and Raman lidars (“lidar” is an acronym for “light detection and ranging”). Passive microwave instruments include imaging radiometers, atmospheric sounders, spectrometers, synthetic-aperture radiometers, and submillimeter-wave radiometers (assuming for now that the sub-mm spectrum is organized under the microwave spectrum). Active microwave instruments include real-aperture radars, synthetic-aperture radars (SARs), altimeters, and scatterometers. Instruments that observe signals from GPS satellites as they propagate through the Earth’s atmosphere or scatter off the Earth’s surface, namely, GPS occultation instruments and GPS reflectometers, are organized under active microwave instruments, because the GPS signals are actively transmitted. (“Aperture,” for microwave instruments, refers to the effective size of the antenna. “Synthetic aperture” refers to the process of making the instrument function as if it has a larger or more continuous antenna than it does. For SAR, this is done by exploiting the motion of the satellite to make the antenna effectively larger. For radiometers, this is done by exploiting the properties of an array of thin antennas that only partially populate the desired aperture (“sparse aperture”), to make the aperture effectively filled in.)

The special case of using accurate measurements of the Earth’s gravitational field to infer measurements of underground water resources is not treated here. For more information, see *Water Resources*.

Passive electro-optical

There are three basic classes of passive E-O imagery: panchromatic, multispectral, and hyperspectral. Panchromatic imagery in a single broad spectral band (“black-and-white”) is useful for maximum spatial resolution, because more light is available over the wide spectral range. Multispectral imagery in several to tens of moderately wide spectral bands (“color”) adds information for discrimination, classification, and analysis of objects based on their spectral properties. Hyperspectral imagery in hundreds of narrow contiguous spectral bands further improves discrimination, classification, and analysis.

Passive electro-optical multispectral imagers observe Earth’s natural thermal radiation in the MWIR-FIR and solar radiation that has been reflected and scattered back toward space in the UV-MWIR (see *Calibration, Optical/Infrared Passive Sensors*). In the case of panchromatic or multispectral imagers looking down at the Earth from LEO, scanning optics moving in a cross-track “whiskbroom” motion, perpendicular to the direction of satellite travel, can be used to collect a swath of data.

Remote Sensing, Physics and Techniques, Figure 3 Examples of whiskbroom (left) and pushbroom (right) scan geometries. The whiskbroom scan may either be a sinusoidal scan (oscillating back and forth) or a barrel roll scan (constant direction of spin) perpendicular to the direction of flight.

Alternatively, the motion of the spacecraft can simply carry the imager's field of view along track in a "pushbroom" fashion, parallel to the direction of satellite motion (Figure 3). The radiation captured by the front-end telescope optics is transferred through a set of back-end optics and band-pass filters to one or more focal-plane arrays, where it is converted to electrical signals by a number of detectors in the focal plane. These signals are then digitized and may be compressed to reduce down-link bandwidth requirements. Whiskbroom imagers can scan a wide swath of the planet with relatively few detectors in the focal-plane array, while pushbroom imagers can be built with no moving parts; each approach involves trade-offs (Slater, 1980). Whiskbroom scanners result in a "bow tie" effect in the data, because the projection of the focal-plane array on the Earth grows progressively larger as the instrument scans progressively farther toward the edge of the swath. The resultant data swath grows larger in both directions perpendicular to the direction of satellite motion and in outline looks like a bow tie. This effect is often removed in onboard processing.

If the multispectral imagers are calibrated to quantitatively measure the incoming radiation (as indeed most are), they are termed imaging radiometers. Such instruments detect radiation in a number of (typically less than 20) spectral bands. Multiple wavelengths are almost always required to retrieve the desired environmental

phenomena. Multispectral imagers have applications in the study of clouds, aerosols, volcanic plumes, sea-surface temperature, ocean color, vegetation, precision agriculture, forestry and deforestation, land cover and land use, urban planning, snow, ice, pollution and fire monitoring, disaster assessment, emergency response, news reporting, etc. Multispectral imagers typically fly in LEO orbits, although they are also hosted on GEO weather satellites.

Some of these applications make use of the technological advances in spatial resolution offered by the high-resolution (1 m panchromatic or less) commercial remote sensing satellites that began flying in LEO orbits in 1999. The emphasis on higher-spatial-resolution systems for mapping and other applications is sparking an increasingly close tie between remote sensing and the geographic information system (GIS) and geoprocessing technologies. GIS allows the combination of remote sensing imagery with infrastructure information such as roads, bridges, waterways, power lines, and pipelines. The ongoing increases in spatial and spectral resolution, data rate, and data volume emphasize the need for improved image compression techniques, data fusion, image archiving and browsing techniques, and advanced computer hardware (Glackin and Peltzer, 1999).

In contrast to multispectral imagers, hyperspectral imagers (HSI) typically cover 100–200 spectral bands,

Remote Sensing, Physics and Techniques,

Figure 4 Conceptual example of a hyperspectral imager, showing the implementation that uses an area array detector, in which one direction along the array is the spatial dimension and the other direction along the array is the spectral dimension. Spectra of each ground footprint along a line are collected simultaneously, and then the instrument pushbrooms along the direction of satellite motion to collect spectra of the next line on the ground. The result is a two-dimensional “image cube” of data, with two spatial axes and one spectral axis.

producing simultaneous imagery in all of them (Figure 4). Moreover, these narrow bands are usually contiguous, typically extending from the visible through SWIR regions. This makes it easier to discriminate surface types by exploiting fine details in their spectral characteristics. Exploitation of imagery from HSI systems is done with spectroscopy, whereas exploitation of imagery from multispectral systems is often done with multivariate classification. Hyperspectral imagery is used for mineral and soil-type mapping, precision agriculture, forestry, and other applications. Because the desired spatial resolution is usually on the order of 30 m, HSI instruments typically fly in LEO orbits. A few airborne hyperspectral imagers operate in the thermal (MWIR-LWIR) infrared, but this technique has yet to advance to space.

Profilers or sounders exploit the properties of a spectral band characteristic of a particular species of gas (e.g., the 15 μm band of carbon dioxide). Typically operating in the thermal infrared, they are most often used to measure the vertical profile of atmospheric temperature, moisture, ozone, and trace gases. Sounding while looking down at the Earth exploits absorption bands in the spectrum, in which the gaseous species of interest absorbs the radiation that is upwelling from the Earth. The vertical profile of the atmospheric property or species of interest can be inferred by observing in spectral regions that are narrow compared to the absorption bandwidth. When the spectral region observed is in the center of the absorption band, the instrument can see only so far down into the atmosphere, because of the high absorption. As the wavelength being observed is increasingly shifted from the absorption band

center out into the “wings” of the absorption band, absorption steadily decreases, allowing the instrument to see increasingly deeper into the atmosphere. By observing in relatively narrow portions of the spectrum, one can infer the properties of different layers of the atmosphere, because different amounts of absorption allow us to examine different depths in the atmosphere. The raw observations in the different narrow regions of the absorption band, when combined with the physics of spectroscopy and radiative transfer (see *Radiative Transfer, Theory*), and a model of the structure of the atmosphere, can yield the desired vertical profile. This process is known as “inversion”.

Sounding while looking above the edge of the Earth at the atmosphere is known as “limb sounding” (see *Limb Sounding, Atmospheric*). Limb sounding can be done by observing an atmospheric absorption band against the bright background of the solar disk (“solar occultation”). Limb sounding can also be done by observing the spectral band of a gaseous species against the black background of space, in which case the spectral band is seen in emission (i.e., a bright spectral feature against a dark background, as opposed to a dark spectral feature against a bright background) (Figure 5). Sounding may also be done with active E-O or passive microwave techniques (see below).

Spectrometers exploit the spectral “fingerprints” of environmental species and surfaces, providing much higher spectral resolution than multispectral imagers. They use a grating, prism, or more complicated method [such as a Fourier transform spectrometer (FTS) or FabryPerot spectrometer (FPS)] to spread the incoming radiation into a spectrum that can be detected and digitized. Spectrometers are typically used for measuring trace species in the atmosphere or the composition of the land surface. Various types of vegetation, soil, and minerals have unique spectral signatures.

A special class of spectrometer is the gas correlation spectroradiometer (GCS), which is similar to the pressure-modulated radiometer (PMR). The GCS is a simple, compact, and robust method for spectral detection. It uses an optical cell filled with a sample of the gas to be detected, and it compares the spectral signature of that gas with the spectral signature being observed in the Earth’s environment. Very high discrimination is possible in the presence of interference from other species. Another special class of spectrometer is the acousto-optical tunable filter (AOTF). The AOTF is an electrically tunable band-pass filter. The observed radiation from the Earth is passed through a crystal. An oscillating radio-frequency signal is applied to piezoelectric transducers (PZTs) attached to the crystal. The PZTs vibrate and generate sound waves in the crystal that turn it into an optical diffraction grating by locally perturbing the refractive index of the material. This is a compact and effective technique for spectral discrimination.

The distinction between the various classes of instruments is often blurred. For example, a sounder might use band-pass filters to observe discrete spectral bands or it

Remote Sensing, Physics and Techniques,

Figure 5 Conceptual example of (a) vertical sounding and limb (both (b) solar occultation and (c) emission) sounding.

might employ a spectrometer to observe a spectrum from which the appropriate sounding frequencies can be extracted. Similarly, a hyperspectral imager will typically use a spectrometer for spectral discrimination (in which case, it is known as an imaging spectrometer).

Nonimaging radiometers are typically used to study the Earth's energy balance. They measure radiation levels across the spectrum from the ultraviolet to the far infrared, with low spatial resolution. They can measure such quantities as the incoming solar irradiance at the top of the atmosphere and the outgoing thermal radiation caused by the sun's heating of the planet (see *Thermal Radiation Sensors (Emitted)*). These are two of the principal quantities that determine the net heating and cooling of the Earth. Such instruments typically fly in LEO, although they have application to GEO and L1 orbits.

A special technique for the study of the Earth's energy balance makes use of earthshine from the Moon.

Earthshine is most easily visible to the eye when the Moon is a crescent, and it can be seen that the "dark" portion of the moon is actually faintly illuminated. This illumination is due to sunlight reflected from the Earth, off the dark portion of the Moon, and back to the Earth. Measurement of earthshine provides a measurement of the Earth's global albedo, a measure of the fraction of incident sunlight that is directly reflected back into space. Changes in the global albedo infer changes in the Earth's energy balance, which relate to climate change. This measurement is currently made from Big Bear Solar Observatory in California. This is an example in which ground-based observations looking up at the Moon have an advantage over satellite-based observations looking down at the Earth and attempting to measure the same quantity. The ground-based lunar observation measures global albedo, while the satellite-based Earth-observing instruments measure the albedo over a fraction of the globe at any given time (Goode, 1998).

Polarimeters, which can be imaging or nonimaging devices, exploit the polarization signature of the environment (see *Reflected Solar Radiation Sensors, Polarimetric*). As anyone who has experimented with polarized sunglasses knows, the sky on a clear day is polarized, particularly at a 90° angle from the sun. Sunlight reflected from metal or glass structures can also be polarized, as drivers with polarized sunglasses know. Electromagnetic radiation can be characterized as a wave, having both electric and magnetic fields, each of which can be expressed as a vector that is perpendicular to the direction of the motion of the wave (Figure 6). If the direction of the electric vector varies randomly with time, the radiation is said to be unpolarized. If the vector has a preferred orientation as a function of time, the radiation is polarized. Radiation from Earth-atmosphere system can be unpolarized, linearly polarized, circularly polarized, or elliptically polarized, depending on the physics of reflection and scattering. Polarization is fully characterized by the Stokes parameters (see *Reflected Solar Radiation Sensors, Polarimetric*). The resulting information can be used to study phenomena such as cloud-droplet size distribution and optical thickness, aerosol properties, vegetation, and other land surface properties.

Stereo imagers are a special case of E-O instruments and fly in LEO orbits. Stereo imagers that afford both fore and aft looks as the satellite passes over the Earth can provide "3-D" data useful for topographic mapping. A nadir (straight down) look is often added for accuracy in mountainous terrain (see *Land Surface Topography*). Multi-angle imagers are also a special case, often having many more view angles than three. When implemented as a polarimeter, multi-angle instruments are particularly useful for measuring the properties of clouds and aerosols (see *Reflected Solar Radiation Sensors, Multiangle Imaging*).

UV instruments are also something of a special case (see *Ultraviolet Sensors*). Their observations are limited to the Earth's upper atmosphere and near-Earth space

Remote Sensing, Physics and Techniques, Figure 6 Diagram showing the electric (E) and magnetic (H) vector in an electromagnetic wave (top). For linear polarization (left), the direction of the E -vector is fixed. For circular polarization (center), the direction of the E -vector, when viewed along the direction of propagation of the electromagnetic wave, continually moves in a circle (right- or left-hand). For the general case of elliptical polarization (right), the E -vector moves in an elliptical manner.

environment (Huffman, 1992). UV instruments are used for ozone monitoring (see *Stratospheric Ozone*) and for imaging of the Earth's aurora, airglow, polar mesospheric clouds ("noctilucent" clouds), and ionosphere.

Calibration of passive electro-optical instruments is a very important issue, if their raw observations are to be turned into scientifically and operationally useful data (National Research Council, 2007). The four types of calibration are radiometric, spectral, geometric, and polarimetric. Radiometric calibration is important both in absolute terms (conversion of raw counts to absolute radiance or irradiance units, e.g., for temperature measurement) and in relative terms (for combining observations in different spectral bands). Spectral calibration, the determination of the exact positions in the spectrum at which the data were taken, must be performed for spectrometers and imaging spectrometers. Geometric calibration is performed to determine the position on the ground at which data is taken and to remove instrumentally induced distortions. Polarimetric calibration, the determination of the type and percent polarization that is observed, must be performed for polarimeters (see *Calibration, Optical/Infrared Passive Sensors*).

Active electro-optical

A lidar sends a laser beam into Earth's environment and measures what is returned (Figure 7) via reflection and scattering. This typically requires a large receiving telescope to capture the returning photons. The returning signal can be measured either by direct detection or by heterodyne detection (NASA ESTO, 2006). With direct detection, the receiving telescope acts as a simple light

bucket to collect photons, which means that the phase information in the electromagnetic wave is lost. With heterodyne ("coherent") detection, the returning photons are combined with the signal from a laser onboard the satellite (a "local oscillator"), whose frequency is close to that of the lidar's frequency. The act of combining these two signals generates an "intermediate frequency" that is much lower in frequency than either the lidar or the local oscillator (like a heterodyne circuit in a radio), making it easier to detect while maintaining the frequency and phase information.

Only a handful of lidars have flown in space, owing to limitations involving high power, high cost, and the availability of robust laser sources. With a few notable exceptions, lidar remote sensing is typically carried out with an aircraft.

Lidars can potentially generate high-resolution vertical profiles of atmospheric temperature and moisture because the returns can be sliced up or "range gated" in time (and thus space) if they are strong enough. Lidar also has potential for profiling winds, determining cloud physics, measuring trace-species concentration, etc.

Backscatter lidar is the simplest in concept: A laser beam scatters off of aerosols, clouds, dust, and plumes in the atmosphere. The data can be used to generate vertical profiles of these phenomena, except where the beam is absorbed by clouds. A related device is the laser altimeter, which records the backscatter from the Earth's surface to measure features such as ice topography and the vegetative canopy (e.g., the tops of trees for biomass studies).

Differential absorption lidar (DIAL) transmits at two wavelengths, one near the center of a spectral absorption band of interest, the other just outside of it. The difference in the returned signal can be used to derive species concentration, temperature, moisture, or other phenomena, depending on the spectral band selected (akin to passive E-O sounding). The differential technique requires no absolute calibration, so it is relatively easy to achieve high accuracy (e.g., parts-per-million to parts-per-billion for species concentration).

Doppler lidar measures the Doppler shift of aerosols or molecules that are carried along with the wind. Thus, wind speed and direction can be determined if two separate views of each atmospheric parcel are acquired to measure velocity in the horizontal plane. In concept, this can be done with a conically scanning lidar and a large receiving telescope. The available aerosol backscatter is too low to measure the complete wind profile as desired (from the surface to 20 km in altitude), but molecular scattering can be used to cover the aerosol-sparse regions. Strong competition has existed between two schools of thought that propose using direct or heterodyne detection. Although wind lidar has been studied since 1978, according to current plans, approximately 30 years would have passed before the first Doppler lidar is launched into space (Kramer, 2002). Of all of the environmental parameters that can only be crudely measured today, improved wind measurements would have the

Remote Sensing, Physics and Techniques, Figure 7 Example of a lidar pulse that is emitted from the instrument and is backscattered from the atmosphere, clouds, and the Earth's surface.

greatest impact on the accuracy of numerical weather prediction (see [Tropospheric Winds](#)).

Fluorescence lidar transmits a spectral frequency that is absorbed by the species of interest and then reradiated at a different frequency, which is then detected on orbit by a radiometer. A related technology, Raman lidar, exploits the Raman scattering from molecules in the air, a process in which energy is typically lost and the scattered light is reduced in frequency.

Calibration of lidars is a very important issue, if their raw observations are to be turned into scientifically and operationally useful data.

Passive microwave

Passive microwave imaging radiometers (usually called microwave imagers; see [Microwave Radiometers, Conventional](#)) collect the Earth's natural radiation (see [Microwave Radiometers](#)) with an antenna and typically focus it onto one or more feed horns that are sensitive to particular frequencies and polarizations. From there, it is detected as an electrical signal, amplified, digitized, and recorded for the various frequencies and polarizations (linear or circular; see [Microwave Radiometers, Polarimeters](#)). The antenna usually rotates such that it scans the Earth in a conical fashion ([Figure 8](#)), and these instruments have all flown in LEO. The amount of radiation measured at different frequencies and polarizations can be analyzed to produce environmental parameters such as soil moisture content, precipitation, sea-surface wind speed, sea-surface temperature, ocean salinity, snow cover and water content, sea ice cover, atmospheric water content, and cloud water content (NASA ESTO, 2004). Unlike visible imagers, microwave imagers can operate day or night through most types of weather, including most clouds,

affording views of portions of the globe that are usually cloud covered, including the polar ice caps and many tropical countries (Janssen, 1993). Microwave instruments are ideal for imaging sea ice during the polar winter when the polar region is not illuminated by the sun and they can see through the persistent cloud cover that often plagues these regions (see Ulaby et al., 1981).

A special class of microwave radiometer is a passive polarimetric radiometer that measures not only sea-surface wind speed but also sea-surface wind direction. By measuring various combinations of linear and circular polarization from the sea surface at different frequencies (e.g., 10, 18, and 36 GHz), a signal can be derived that varies with the conically scanning look angle as a function of wind direction. This provides a potential alternative to scatterometers (see section "[Active Microwave](#)" below).

Microwave profilers or sounders, like electro-optical sounders, operate in several frequencies around a spectral band characteristic of a target gas and may be either vertical sounders or limb sounders. They are often used to measure the vertical profiles of temperature and moisture in the atmosphere. The oxygen band near the frequency 60 GHz, which becomes more or less opaque as a function of atmospheric temperature, is usually used for temperature sounding, while the water vapor band at 183 GHz is typically used for moisture sounding. The advantage of microwave over electro-optical sounding is that it can be done through most types of weather and cloud cover.

Passive microwave imagers and sounders generally operate at frequencies ranging from 6 to 183 GHz. Higher frequencies have recently been used in submillimeter-wave radiometers for measuring cloud ice content. Lower frequencies, around 1 GHz, can be used to measure soil moisture and ocean salinity; however, such low frequencies are not always practical. For a given antenna size,

Remote Sensing, Physics and Techniques, Figure 8 A conventional conically scanning microwave imager, which maps out a data swath as a result of the motion of the satellite.

spatial resolution decreases as the frequency decreases. Most microwave imagers are limited to a lower frequency of about 6 GHz because a large antenna would be required at 1 GHz to achieve acceptable resolution.

This difficulty can be overcome through a technique known as aperture synthesis (see *Microwave Radiometers, Interferometers*). In this concept, which has long been used in radio astronomy, the operation of a large solid dish antenna is simulated by using only a sparsely populated aperture or “thinned array” antenna. In such an antenna, only part of the aperture physically exists and the remainder is synthesized by correlating the individual antenna elements (see *Microwave Radiometers, Correlation*). This technique has been proven in aircraft flight demonstrations, but has not yet been flown in space. This type of instrument is often referred to as a STAR (Synthetic Thinned Array Radiometer – [Figure 9](#)).

A significant problem in the field of microwave radiometry is the existence of man-made sources of radio-frequency interference (RFI) on the Earth, especially in advanced and highly populated regions. Research on various techniques for addressing this problem is ongoing.

Calibration of microwave radiometers is a very important issue, if their raw observations are to be turned into scientifically and operationally useful data (Skou, 1989). Radiometric calibration is important both in absolute terms for conversion of observed radiation to temperature (“brightness temperature”) of the Earth’s environment and

in relative terms (one frequency relative to another). It is usually done in spaceborne instruments using a regulated “warm load” and a view to cold deep space, each of which is viewed periodically as the antenna and feedhorn assembly rotates past the warm load and the space view (see *Calibration, Microwave Radiometers*).

Active microwave

Active microwave instruments can be broadly divided into real-aperture and synthetic-aperture radars and operate from LEO. They all transmit microwaves toward Earth and measure what is reflected and scattered back. “Real aperture” typically means that the instrument has a solid, dish-shaped antenna that defines its performance properties, such as spatial resolution on the ground. “Synthetic aperture” usually means that the performance of a hypothetically very large real aperture is achieved by letting the satellite’s motion along its orbit sweep the field of view of the radar along with it for a period of time while data is collected, such that the length of the effective aperture equals the amount of space swept out by the satellite during that period of time (Ulaby et al., 1982; Cantafio, 1989; NASA ESTO, 2004).

Real-aperture radars can be further categorized as atmospheric radars, altimeters, and scatterometers. Atmospheric radars are useful for studying precipitation and the three-dimensional structure of clouds. The use of more

Remote Sensing, Physics and Techniques, Figure 9 Conceptual example of a Synthetic Thinned Array Radiometer (STAR) passive microwave interferometer, in which the full aperture is synthesized by correlating the signals from a small number of stick antennas.

than one frequency is beneficial for separating the effects of cloud and rain attenuation from those of backscatter. The first spaceborne atmospheric radar to fly was the precipitation radar on the US/Japan Tropical Rainfall Measuring Mission. The second was on NASA's CloudSat mission, which performed the first 3-D profiling of clouds. This mission is especially important because clouds and aerosols are the primary unknowns in the global climate-change equation.

Altimeters measure surface topography, and radar altimeters are typically used to measure the surface topography of the ocean (which is not as uniform as one might think). They operate using time-of-flight measurements and typically use two or more frequencies to compensate for ionospheric and atmospheric delays (see [Radar; Altimeters](#)). Altimeters have been flying since the days of Skylab in 1973. Aperture synthesis and interferometric techniques can also be employed in altimeters, depending on the application.

Scatterometers are a form of instrument that uses radar backscattering from the Earth's surface (see [Radar; Scatterometers](#)). The most prevalent application is for the measurement of sea-surface wind speed and direction.

This type of instrument first flew on Seasat in 1978. A special class of scatterometer called delta-k radar can measure ocean surface currents and the ocean wave spectrum using two or more closely spaced frequencies.

Synthetic-aperture radars (SARs) also flew for the first time on Seasat. These radars sometimes transmit in one polarization (horizontal or vertical) and receive in one or the other (Campbell, 2007). A fully polarimetric synthetic-aperture radar employs all four possible send/receive combinations (see [Radar; Synthetic Aperture](#)). Synthetic-aperture radars are powerful and flexible instruments that have a wide range of applications, such as monitoring sea ice, oil spills, soil moisture, snow, vegetation, and forest cover.

Some active microwave instruments (predominantly SARs) are interferometric (InSAR), meaning that they exploit the signals that are seen from two somewhat different locations but are sufficiently close in time. This is a powerful means of elevation/topographic measurement. Interferometry can be done by using two antennas separated by a rigid boom, or by using a single antenna on a moving spacecraft that acquires data at two different times or by using similar antennas on two separate

spacecraft. InSAR can be used to monitor surface motion due to earthquakes and volcanoes and to create Digital Elevation Models that represent the three-dimensional topography of the Earth's surface, information that has a wealth of applications.

GPS occultation instruments exploit a technique that was first used for remote sensing of planetary atmospheres. They observe the GPS satellites as they rise and set over the Earth's limb (NASA ESTO, 2004). They detect the signals emitted from the GPS satellites and track the phase of those signals as a function of altitude above the limb (see *GPS, Occultation Systems*). Those phase changes can be converted to atmospheric density changes, which in turn can be used to compute the temperature profile in the lower atmosphere, as well as the electron density profile in the ionosphere (the moisture profile in the lower atmosphere can also be derived, but with more difficulty). Temperature profiles derived using this technique are more accurate and structured than those using weather balloons. The other type of GPS-based instrument, the GPS reflectometer, measures the difference between direct and ocean-reflected GPS signals, to measure ocean surface height (topography). This is a newer technique that has flown on three satellites through 2008.

Calibration of active microwave instruments is a very important issue, if their raw observations are to be turned into scientifically and operationally useful data (see *Calibration, Scatterometers* and *Calibration, Synthetic Aperture Radars*).

Conclusion

Remote sensing is a field that involves a wide variety of instruments that exploit the physics of the Earth's environment (atmosphere, oceans, land, solid Earth, ice cover, and near-Earth space environment) to measure a large number of environmental phenomena. The field has blossomed tremendously since the launches of Landsat-1 in 1972, Skylab in 1973, and Seasat and Nimbus-7 in 1978. New and more sophisticated techniques are being applied, resulting in the ability to measure a wider range of environmental phenomena and an increase in the accuracy with which those measurements are made. Technologies for access to and manipulation of the data have increased dramatically. The field has benefited from international proliferation, as the number of countries owning remote sensing satellites increased by a factor of 6 from 1980 to 2008. As the field evolves, there will be a continued need for trained scientists and engineers with a broad and interdisciplinary perspective to work in the remote sensing field.

Synonyms

Mineral exploration Nonrenewable resource exploration; Oil and gas exploration

Definition

Use of remote sensing technology to directly or indirectly explore for occurrences of specific nonrenewable resources.

Remote sensing resource exploration

Introduction

Nonrenewable resources are a key part of daily life. Materials as varied as salt, silicon, clays, and diamonds are used in many products. Metals including lead, silver, copper, molybdenum, gold, and many others are used daily for both basic needs and in modern conveniences. Oil and gas provide power for automobiles and other transportation, lighting and heating, and manufacturing.

Classical resource exploration typically utilizes field geologic mapping of the physical characteristics of rocks and soils such as outcrop exposure, mineralogy, weathering characteristics, and geochemical and/or geophysical signatures to determine the nature and distribution of geologic units and associated resources. Structural/geomorphic interpretation, including estimation of rock orientation, mapping key unit contacts, identifying folds and faults, and interpreting drainage patterns and linear/circular features, also provides clues to help locate specific resources. Unfortunately, many of the factors important for making distinctions for resource discovery and mapping are often difficult to map in the field. Several geologists mapping the same area often produce very different geologic maps. In addition, many areas of the world have no geologic maps or incomplete geologic maps. Remote sensing technology provides a unique means of quickly mapping Earth-surface properties that can potentially improve and enhance the resource exploration process.

Direct versus indirect methods

Ideally remote sensing technology would directly detect the resources of interest. While this is possible for some resources (e.g., spectral mapping of a specific materials like carbonate rocks or sources of silica), most resources do not have direct indicators and use of indirect remote sensing indicators is required. Some of these indirect indicators include lithology, alteration minerals, vegetation distribution and vegetation-stress mapping, and mapping geologic structures.

In mineral exploration, direct spectral detection of ore minerals such as pyrite using remote sensing data would be an ideal method of locating, mapping, and monitoring metallic mineral deposits. Pyrite and other ore minerals cannot, however, generally be mapped using VNIR/SWIR spectral techniques (Swayze et al., 2000) (Figure 1, left). Fortunately, secondary Fe-bearing minerals resulting from the alteration or weathering of pyrite have distinctive spectral signatures in the VNIR (Taranik and Kruse, 1989; Clark et al., 1993a; Farrand, 1997; Rowan et al., 1996; Rowan, 1998) (Figure 1, left). Spectral data can be used to directly map this indirect evidence – allowing identification of even individual iron mineral species (Swayze et al., 2000). In addition, given the proper instrument (spectral and spatial resolution) and signal-to-noise (SNR) performance, spectroscopy can be used to unambiguously identify, quantify, and map other ubiquitous alteration and weathering minerals often associated with ore (minerals such as kaolinite, alunite, sericite (muscovite), montmorillonite) based on their molecular absorptions in the Short-Wave-Infrared (SWIR) (Goetz et al., 1985; Kruse, 1996; Swayze et al., 2000; Kruse et al., 2003, 2006; Mars and Rowan, 2006) (Figure 1, right). LWIR emissivity spectra also provide the ability to discriminate between important rock-forming minerals based on fundamental molecular absorptions (Lyon, 1964; Salisbury et al., 1988, 1992; Salisbury and D'Aria, 1992) (Figure 2).

Oil and gas accumulations occur primarily in sedimentary rocks. Requirements for formation of this resource include source rocks, a heat source, and a suitable trap (usually structural) (Lang and Nadeau, 1984). Oil and gas exploration typically requires extensive geologic mapping and assessment of large areas using geophysical techniques such as gravity, magnetics, and seismic surveys to detect suitable targets. While direct remote sensing detection of hydrocarbons at the surface has been demonstrated using radar data for offshore occurrences (slicks) (MacDonald et al., 1993, 1996; De Beukelaer, 2003) and hyperspectral data for onshore environments (seeps) using hydrocarbon absorption features near 2.3 μm (Ellis et al., 2001), exploration more typically relies on detection and mapping of indirect indicators such as geologic structure, lithology, and detection of specific indirect spectral indicators such as formation of clays, bleaching of iron-rich rocks, and vegetation anomalies (Lang et al., 1984, 1987; van der Meer et al., 2002; Sabins, 1997; Prost, 2001; Khan and Jacobson, 2008). Remote sensing technology is also used to map specific lithologies, to detect geologic structures exposed at the surface, and to help with the siting of geophysical surveys.

Two remote sensing approaches are used for oil and gas exploration (Lang and Nadeau, 1984; Sabins, 1997; Prost, 2001). The first approach, photogeologic interpretation, has been used since the 1930s with data sources as diverse as (initially) black-and-white photography, (more recently) true-color, and color-infrared aerial photographs, synthetic aperture radar (SAR), and panchromatic

Resource Exploration, Figure 1 Left: Reflectance spectra of Fe-bearing secondary minerals and pyrite showing Fe absorptions (Spectra are offset vertically for clarity). Spectra are from the USGS Digital Spectral Library (Clark et al., 1993a) and from Swayze et al. (2000). Right: SWIR (Airborne Visible/Infrared Imaging Spectrometer, AVIRIS) reflectance spectra for selected minerals.

and multispectral satellite imagery (Sabins, 1997). This approach uses the topographic expression of lithology and geologic structure to infer subsurface conditions favorable for oil and gas accumulations (Prost, 2001). The second approach, spectral remote sensing, uses multispectral and/or hyperspectral data to measure spectral properties of materials, thus extracting compositional information about surface materials. Visible and Near-Infrared (VNIR) data (approximately 0.4–1.2 μm) are used to map iron oxide-bearing minerals (hematite, goethite, jarosite) and vegetation distributions (Figure 1, left). Short-Wave-Infrared (SWIR) data (2.0–2.5 μm) can directly map minerals such as clays and carbonates (Figure 1, right). Long-Wave-Infrared (LWIR) data (8.0–14.0 μm) allow detection and quantification of silica (Lyon, 1964; Rowan, 1998) (Figure 2).

Airborne and satellite remote sensing can provide information to assist with resource exploration, assessment, management, and production. Imagery from multispectral satellite sensors such as Landsat and the Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) gives project managers a synoptic view of producing fields and potential exploration targets/areas. New high-resolution panchromatic and multispectral satellite systems provide spatial resolution better than 1 m, often acting as de facto base maps for

the layout of 2D and 3D seismic surveys, geochemical surveys, and drill sites, as well as logistics planning. Hyperspectral sensors allow detailed mapping of surface mineralogy and vegetation distributions.

Multispectral versus hyperspectral technology

Multispectral imaging (MSI) sensors usually have only a few spectral bands (<20), cover broad spectral regions, and provide synoptic coverage. They do not generally allow direct identification of specific materials, but rather broad groups of materials (e.g., vegetation, clays or carbonates, iron oxides). Examples include Landsat, SPOT, IRS, and ASTER. MSI sensors with high spatial resolution have recently become available (e.g., IKONOS, QuickBird, WorldView). The Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) is a NASA facility instrument on the Earth Observing System (EOS) TERRA platform that provides Visible/Near-Infrared/Short-Wave-Infrared/Long-Wave-Infrared (VNIR/SWIR/LWIR) Earth observation capabilities in a total of 14 total spectral bands (+one backward-looking band) (Kahle et al., 1991; Fujisada et al., 1998; Yamaguchi et al., 1998; JPL ASTER Website, 2012). ASTER and/or ASTER-simulated data (MODIS/ASTER Airborne Simulator) have been successfully used for

Resource Exploration, Figure 2 Left: Selected LWIR emissivity spectra for the mineral calcite and quartz. Right: Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) LWIR emissivity for pixels containing these materials (QSP Alteration Quartz-Sercite-Pyrite alteration – a predominantly quartz-bearing mineralogy) (From Kruse, 2002).

geologic applications, providing basic mapping capabilities using both the VNIR/SWIR and LWIR spectral ranges (Hook, 1990; Hook et al., 2001; Rowan, 1998; Kruse, 2000, 2002; Rowan and Mars, 2003; Rowan et al., 2003, 2005). The four VNIR bands provide information about iron mineralogy and some rare earth minerals (Rowan and Mars, 2003). The six SWIR bands (Figure 1) allow mapping of molecular vibration absorption features commonly seen in minerals such as carbonates and clays (Hook et al., 2001; Kruse, 2000, 2002). ASTER has collected global multispectral coverage of the Earth between approximately 83° N and 83° S latitudes.

Imaging Spectrometers or “Hyperspectral Imaging (HSI)” sensors, measuring up to hundreds of spectral bands, provide a unique combination of both spatially contiguous spectra and spectrally contiguous images of the Earth’s surface unavailable from other sources (Goetz et al., 1985). HSI data have been used in the geologic community since the early 1980s and represent a mature technology (Goetz et al., 1985; Lang et al., 1987; Pieters and Mustard, 1988; Kruse, 1988, 2012; Crowley, 1993; Boardman and Kruse, 1994; Clark et al., 1996, 1993b; Boardman and Huntington, 1996; Crowley and Zimbelman, 1996; Rowan et al., 1996, 2003, 2004; Cudahy et al., 2001; Kruse et al., 1993, 1999, 2003, 2006). Current airborne HSI sensors provide high

spatial resolution (<1–20 m), high spectral resolution (2–20 nm), and high SNR (>500:1) data for a variety of scientific disciplines.

The Airborne Visible/Infrared Imaging Spectrometer (AVIRIS) represents the current state of the art. AVIRIS, flown by NASA/Jet Propulsion Laboratory (JPL), is a 224-channel imaging spectrometer with approximately 10 nm spectral resolution covering the 0.4–2.5 μm spectral range (Green et al., 1998). The sensor is a whiskbroom system utilizing scanning foreoptics to acquire cross-track data. The IFOV is 1 mrad. Four off-axis double-pass Schmidt spectrometers receive incoming illumination from the foreoptics using optical fibers. Four linear arrays, one for each spectrometer, provide high sensitivity in the 0.4–0.7 μm , 0.7–1.2 μm , 1.2–1.8 μm , and 1.8–2.5 μm regions, respectively. AVIRIS is flown as a research instrument on the NASA ER-2 aircraft at an altitude of approximately 20 km, resulting in approximately 20 m pixels and a 10.5 km swath width. Since 1998, it has also been flown on a Twin Otter aircraft at low altitude, yielding 2–4 m spatial resolution.

The launch of NASA’s EO-1 Hyperion sensor in November 2000 marked the establishment of spaceborne VNIR/SWIR hyperspectral mapping capabilities. Hyperion is a satellite hyperspectral sensor covering the

0.4–2.5 μm spectral range with 242 spectral bands at approximately 10 nm spectral resolution and 30 m spatial resolution from a 705 km orbit (Pearlman et al., 2003). Hyperion is a pushbroom instrument, capturing 256 spectra each with 242 spectral bands over a 7.5 km-wide swath perpendicular to the satellite motion along an up to 160 km path length. The system has two grating spectrometers, one Visible/Near-Infrared (VNIR) spectrometer (approximately 0.4–1.0 μm) and one Short-Wave-Infrared (SWIR) spectrometer (approximately 0.9–2.5 μm). Key Hyperion characteristics are discussed further in Green et al., 2003. Hyperion data are available for purchase from the US Geological Survey (USGS EO-1 Website, 2012). Thousands of Hyperion scenes have been acquired for a variety of disciplines. The EO-1 Science Validation Team has evaluated and validated the instrument. Selected results have been presented at team meetings (NASA Goddard EO-1 Website, 2012) and also published at various venues (Asner and Green, 2001; Hubbard and Crowley, 2001; Kruse et al., 2003). Also see Ungar et al. (2003) for a summary along with associated papers.

Mineral exploration examples

Case history: mineral mapping using hyperspectral remote sensing at Mt. Fitton, Australia

HyMap (Integrated Spectronics, Sydney, Australia) is a commercially available hyperspectral sensor that provides combined high spatial resolution (2–10 m), high spectral resolution (12–16 nm), and high signal-to-noise (>500:1) performance. Figure 3 shows images and spectra of the Mt. Fitton area, South Australia, acquired by the HyMap scanner. The local geology in this area is comprised of a series of folded unconformable Adelaidean (Proterozoic) sediments syn- and post-intruded by Proterozoic diapirs, and Palaeozoic granitic and granodioritic intrusives (Reston and Cocks, 1998). Sedimentary facies show a full range of argillaceous, arenaceous, and carbonaceous compositions and textures. Palaeozoic tectonism is characterized by E/ENE trending asymmetric folds with steeply dipping axial traces. Synform features are strongly developed within the area. The HyMap data shown in Figure 3 cover an approximately 2.6×4 km area at 5 m spatial resolution in 128 narrow (10–20 nm-wide) spectral bands. Analysis of these HyMap data without a priori information and using only the 2.0–2.5 μm range indicates the presence of over 15 distinct minerals associated with primary lithology and alteration. Figure 3 shows a selection of spectra for these minerals and the mapping results.

Case history: mapping silica, alunite, kaolinite at an active hot springs system

Study of the nature and spatial distribution of specific hydrothermal alteration minerals at hot springs using hyperspectral remote sensing provides insight into system geochemistry, and to the occurrence and characteristics of hot springs systems in the fossil record, potentially leading to new and/or improved exploration methods for ore

deposits. The Steamboat Springs hydrothermal system is described as a present-day equivalent of epithermal gold–silver deposits (White, 1955, 1967). This hydrothermal system, located just south of Reno, Nevada (Figure 4), is associated with four rhyolite domes, and thermal activity has probably been continuous for at least the past 0.1 m.y (Silberman et al., 1979). Numerous wells have been drilled at Steamboat for geothermal energy and to obtain hot water for local resort facilities. Early exploration wells ranged from 218 to 558 m with a maximum measured temperature of 186 °C (White, 1968, 1981). Geothermal resource exploitation for power production commenced in the early 1980s, with the first production facility producing 14.4 MW starting in 1988. A new well brought into production in July 2000 had a high temperature of 248°C (Nevada Bureau of Mines, 2008). The principal surface mineralogy reported at Steamboat consists of chalcedonic sinter deposits (Figures 4 and 5). Prior to 1988, dark siliceous muds were also being deposited in the active springs; however, this activity ceased after start of power production. Acid-leached opaline residues, kaolinite, and alunite occur in solfatarically altered granodiorite and basaltic andesite in the western part of the area (Figures 4 and 5) (Sigvaldason and White, 1962; White et al., 1964; Schoen and White, 1967; Schoen et al., 1974). Significant concentrations of precious metals and related pathfinder elements occur in the Steamboat Springs sinter deposits, as chemical sediments in spring vents and as veins at depth (White, 1981; Nevada Bureau of Mines, 2008). Gold was detected at the 1–2 ppm level along with anomalous Ag and As concentrations in analysis of samples from several drill holes, and small amounts of Hg has been mined from the Mercury mine at Steamboat (White et al., 1992). Deep drilling at Steamboat shows vein and alteration patterns that are indistinguishable from those of many epithermal ore deposits, containing adularia, illite, montmorillonite, and chlorite-group minerals as well as kaolinite, chalcedony, calcite, and quartz. Both stibnite and cinnabar are present near the surface; however, ore-grade concentrations of metals appear to be absent both in the near-surface deposits and in the veins at depth.

AVIRIS data were acquired during July 1995 for the Steamboat Springs area and during October 1998 as part of the JPL AVIRIS low-altitude test program. AVIRIS data from both flights were calibrated to apparent reflectance using the ATREM method (Gao and Goetz, 1990; Kruse, 2004; Gao et al., 2009). Data were then analyzed using standardized procedures (Boardman et al., 1995; Kruse et al., 2003; Boardman and Kruse, 2011). Figure 6 shows an image, endmember spectra, and mineral map for the 1998 data (~2.2 m pixels).

Case history: gold exploration using hyperspectral remote sensing

Numerous gold deposits occur in Eureka County, North Central Nevada, along a regional mineral zone known as the Cortez or Battle Mountain-Eureka Trend (Figure 7).

Resource Exploration, Figure 3 HyMap data of the Mt. Fitton area, South Australia (Data courtesy of Integrated Spectronics Pty Ltd, acquired March 1998). The *left* image is a Color-Infrared Composite (CIR) Image of HyMap bands 30, 17, and 10 (0.863, 0.665, 0.557 μm) (RGB). The *center* image shows bands 1, 2, and 3 (RGB) of a Minimum Noise Fraction Transform (MNF) of selected VNIR bands. The *left* plot shows laboratory reflectance spectra from the US Geological Survey spectral library for selected minerals. The *right* plot shows average apparent reflectance spectra for selected minerals extracted from the HyMap hyperspectral data identified using visual comparison to the USGS spectral library. The *right* image shows color overlays of these selected mineral occurrences on a grayscale image of HyMap Band 17 (0.665 μm). Colors in the *right* image correspond to those used in the spectral plots. Additional information about HyMap is available at <http://www.intspec.com>.

Resource Exploration, Figure 6 *Left*: AVIRIS endmember mineral spectra. *Right*: AVIRIS mineral map of selected minerals overlain on topographic map (red kaolinite, green silica, black alunite).

Resource Exploration, Figure 7 Battle Mountain trend location map.

Disseminated, sedimentary-hosted gold deposits occur along this trend associated with Palaeozoic regressive-transgressive, continental shelf facies (Broili et al., 1988). This style of gold mineralization is also known as the Carlin-style deposit model, where host rocks include siltstone, limestone, marls, and other Palaeozoic nearshore units. Generally, gold deposits are associated with fluid movement along feeder structures. Hydrothermal fluids flowing upsection and updip decalcify and alter (or “sand”) host units, which typically are silty or shaley carbonate units. This initial hydrothermal phase prepares the host rock by increasing porosity and permeability, and gold is deposited during a second alteration stage as microscopic particles within the altered silty calcareous units. Silica and iron mixtures can solidify near or adjacent

to gold deposits forming jasperoids, often manifested as resistant red-color ridges within carbonates at the surface. Generally, associated alteration minerals are limited to silica, skarn minerals, pyrite, iron oxides (jasperoids), and limited argillic alteration minerals.

Recent exploration in this area by Perry Remote Sensing (PRS)/Horizon GeoImaging LLC using remote sensing data consisted of analysis of ASTER data to predict mineral components expected for the area and detailed mineral analysis using AVIRIS. The entire Battle Mountain-Eureka mineral trend was the focus of initial mineral mapping using ASTER without ground truth information. Fieldwork during April 2006, including spectral measurements using a field-portable spectrometer, demonstrated the accuracy of the ASTER mapping

Resource Exploration, Figure 8 Left: AVIRIS SWIR mineral endmembers. Plotted from top to bottom: Mizzonite/Scapolite, Green Vegetation, Illite/Muscovite, Calcite_2, Dry Vegetation, Dolomite_2, Muscovite_2, Kaolinite, Dolomite_2, Montmorillonite_1, Muscovite_1, Calcite_1. Right: AVIRIS mineral mapping results. Red triangles represent areas where field investigation and spectrometer measurements verify AVIRIS mapping. AVIRIS image width is approximately 10 km.

for muscovite/sericite and carbonates. Low-altitude AVIRIS imagery (3.5 m resolution) was acquired along the entire Battle Mountain-Eureka Trend as two overlapping flight lines collected on September 27, 2006. Each AVIRIS flight line was processed and analyzed separately using VNIR and SWIR spectral ranges and standardized procedures (Boardman et al., 1995; Kruse et al., 2003; Boardman and Kruse, 2011). AVIRIS SWIR processing and analysis revealed 15 mineral endmembers including several varieties of carbonates and muscovite (Figure 8). Together, the muscovite and muscovite/illite endmember classes cover the greatest extent of the AVIRIS survey. Illite/muscovite appears to be the primary mineral component of the pediment gravels and broad alluvial basins. Of particular interest, muscovite

#1 spatially coincides with a Jurassic intrusion near a known gold district as well as a large molybdenum deposit near Eureka called Mount Hope. This same muscovite class is mapped in other areas and may reflect unmapped alteration associated with intrusive activity. Comparison to geochemical results shows a strong correspondence between AVIRIS-mapped muscovite #1 and gold concentrations (Figure 9).

Oil and gas exploration example

Case history: Patrick Draw, Wyoming

The following information is mostly extracted and modified from the section describing the Patrick Draw test site in the Joint NASA/GeoSat Test Case Final Report

Resource Exploration, Figure 9 Left: AVIRIS muscovite #1 image map for a subarea, Right: Gold concentration in soils for the same area color coded from dark blue, to cyan, to green, to yellow, to red from low to high concentration. Note correspondence of high gold values (red) with muscovite #1 mineral mapping.

(Lang et al., 1984). Patrick Draw is a well-known hydrocarbon occurrence (Cox, 1962; McCubbin and Brady, 1963; Weimer, 1966), and the test site has been used for a variety of remote sensing tests for hydrocarbon exploration (Richers et al., 1982, 1986; Lang et al., 1984; Scott et al., 1989; Khan and Jacobson, 2008 and others). The site is located in South Central Wyoming approximately 55 km east of the city of Rock Springs, Wyoming (Figure 10).

The Patrick Draw field consists of oil and gas in stratigraphic traps located on the eastern flank of the Rock Springs Uplift (Figure 11). It was first discovered in 1959 based on observation of the “pinch out” of known gas-producing sandstones against the Rock Springs Uplift. The principal productive interval consists of permeable and porous sandstone bodies at the top of the Upper Cretaceous Almond Formation that grade up dip on the west into impermeable shale and sandstones (Weimer, 1966). Extensive work in support of the NASA/GeoSat Test Case Project demonstrated suggestive correlations between remote sensing data and suspected gas microseepage (Richers et al., 1982, 1986; Lang et al., 1984). While designed as a “direct detection” experiment, this case history demonstrates remote sensing

approaches and methods that could be applied to exploration for typical oil and gas occurrences without direct indicators. Multispectral remote sensing (Landsat MSS and NS-001 Thematic Mapper Simulator) was used to map evidence of structural traps. NS-001 photointerpretation at a scale of 1:48,000 showed broad folds that were not detected in previously available subsurface structure maps of the site. Lineament analysis of Landsat MSS, topography, NS-001, and radar images identified stress orientations associated with jointing, faulting, and folding that when compared with known structures helped assess the timing and orientation of structural disturbance. NS-001 Thematic Mapper Simulator imagery provided the ability to recognize and trace stratigraphic units at the surface, essential for the preparation of isopach, facies, and other stratigraphic maps and to help locate potential stratigraphic traps and to develop basin evolution models. The NS-001 data also allowed recognition of a previously unmapped lithostratigraphic unit and tracing of individual discontinuous beds that were difficult (or impossible) to trace using standard field techniques. Soils and vegetation mapping using the NS-001 discriminated between soil units, providing detail similar to existing BLM soil maps, which required years of

Resource Exploration, Figure 10 Map showing the location of the Patrick Draw test site (From Lang et al., 1984).

fieldwork to prepare. Vegetation mapping using the multispectral data showed detail not available using other means (including standard aerial photography) and correlated well with geochemical investigations, including soil–gas surveys (Figure 12). A previously unknown area of abnormal, stunted sage corresponding approximately to the center of the gas cap of the underlying Patrick Draw reservoir was discovered using the NS-001 data. The area of stunted sage occurrence also shows anomalously high soil

hydrocarbons, the highest soil helium concentration, and anomalously high concentrations of titanium, vanadium, copper, and zinc, along with low concentrations of calcium and magnesium.

Subsequent studies comparing Landsat Thematic Mapper data to the soil–gas anomalies at Patrick Draw included a more detailed soil–gas survey on and around the area’s producing fields (Richers et al., 1982, 1986). The results of this study agree with the NASA/GeoSat

Resource Exploration, Figure 11 Regional subsurface structural contour map showing Patrick Draw and adjacent fields. Contours (in feet) on the top of the Almond Formation; datum, sea level (From Lang et al., 1984).

assessment that the faults and fractures visible as linear features on satellite and aircraft imagery provide paths for active microseepage. Additional soil–gas measurements over the known vegetation anomaly revealed a much wider area of anomalously high free soil–gas values and fluorescence than was previously reported.

Scott et al. (1989) point out that the stunted sage anomaly at Patrick Draw may in fact be related to increased soil exposure rather than sage morphological changes. While they also indicate that they do not see a definitive link between the tonal anomaly and gas seepage, the GeoSat Test Case and Richers's evidence seem clear.

More recently, hyperspectral remote sensing data supported by spectral and geochemical measurements of surface soils have been used to locate and characterize alteration mineralogy at Patrick Draw (Khan and Jacobson, 2008). Mineralogical, geochemical, and carbon isotope data support the presence of hydrocarbon microseepage. Specific surface changes associated with

the seepage include decreased feldspar content (determined by XRD), increased clay concentrations (from spectral reflectance measurements), and carbon-13 values consistent with hydrocarbon occurrences. Hyperion data (Ungar et al., 2003) were used to map alteration associated with hydrocarbon microseepages in the Patrick Draw area. A northeast–southwest trending anomalous zone following a defined stratigraphic boundary appeared to be one migrational pathway for hydrocarbon seepage (Figure 13). Alteration mineralogy was also associated with the known vegetation anomaly.

Conclusions

Remote sensing technology provides a unique means of exploring for nonrenewable resources at the Earth's surface and monitoring their development and exploitation. Multispectral satellite imagery provides synoptic, repetitive coverage of most locations and allows both

Resource Exploration, Figure 12 Left: Soil-gas anomaly significance map showing combined results of adsorbed, absorbed, and free soil-gas (Lang et al., 1984, Figure 11–22). Right: NS-001 principle components image (Lang et al., 1984, Figure 11–75). PCs 1, 2, 3 are displayed as RGB. Location “A” shows the total anomaly (a yellow-toned area in a region of green) coinciding with the areal distribution of anomalously stunted sage.

geomorphic and spectral analysis. Radar (SAR) data are also used for mapping geologic structure and for direct detection of seeps in oil exploration. Airborne hyperspectral data (and currently limited satellite data) allow detailed mineralogical mapping important to detection and characterization of indirect indicators of

both minerals and oil and gas occurrences. Case histories described here highlight a few of the methods and applications of remote sensing data to resource exploration. The bibliography provided acts to direct readers to further details, extended case histories, and additional resources.

Retrieval of underwater bottom topography by using synthetic aperture radar (SAR)

Definition

Synthetic aperture radar (SAR) is an active instrument which yields high-resolution images in the microwave frequency band. When applied to image the ocean, it detects small variations in the small-scale sea surface roughness. These roughness variations can result, for example, from variations in surface current speed caused by a tidal flow over shallow sandbanks. Although the microwaves cannot penetrate into the water body, SAR can retrieve information on underwater bottom topography (or bathymetry) indirectly by measuring variations in the small-scale sea surface roughness.

Introduction

Underwater bottom topographic features, such as sandbanks and ridges, become visible on radar images of the sea surface only when there is a current present (usually a tidal current) which flows over them. This causes local perturbations to the current which in turn modulates the sea surface roughness. Locating underwater sandbanks by roughness variations of the sea surface has been used for several hundred years by mariners to avoid running aground. Since SAR is a very sensitive roughness sensor,

it is an ideal instrument for mapping the roughness pattern induced by (tidal) flow over underwater bottom topography.

However, it is not straightforward to invert SAR images of the sea surface into maps of underwater bottom topography. Although theories describing the radar imaging of underwater bottom topography have been developed (Alpers and Hennings, 1984; Shuchman et al., 1985; Romeiser and Alpers, 1997; Vogelzang, 1997), they are at present not capable of generating depth charts (maps of underwater bottom topography) from SAR data alone. But if they are combined with acoustic sounding (sonar) data, they are of great use in generating depth charts. This is achieved by using SAR images to interpolate between depth profiles measured by acoustic sounders operated from ships. Thus, radar measurements can serve to reduce greatly the number of ship tracks required for generating bathymetric maps of a given accuracy and thus reduce greatly the costs of bathymetric surveying.

Principle of radar imaging of underwater bottom topography

Imaging radars such as real aperture radar (RAR) or synthetic aperture radar (SAR) sense underwater topographic features indirectly by variations of the small-scale sea surface roughness induced by a variable surface current. The radar imaging mechanism of underwater bottom topography consists of three parts: (1) the modulation of the current by the structure of the underwater bottom topography, (2) the modulation of the sea surface waves by the variable surface current, and (3) the interaction of the microwaves with the surface waves. This is depicted schematically in [Figure 1](#).

SAR-Based Bathymetry, Figure 1 Schematic plot showing the relationship between radar image intensity, sea surface roughness, tidal flow, and underwater bottom topography (bathymetry). In this case, the bathymetry consists of an asymmetrically shaped sand wave. The steep slopes of the sand wave face the flow direction and are associated with a strongly reduced image intensity. (Plot reproduced from Alpers and Hennings, 1984).

The tidal current is modified by the variable water depth as indicated by the arrows. The current velocity at the sea surface is higher over shallow areas than over deep areas giving rise to convergent flow regimes, where the sea surface roughness is increased, and to divergent flow regimes, where roughness is decreased. In the convergent areas, the waves are “squeezed,” while in the divergent areas they are “stretched.” This leads, in the convergent areas, to an increase of the amplitude of the Bragg waves (which are responsible for the radar backscattering through a process of resonance between the wavelengths of short waves on the ocean surface and the obliquely incident radar beam) and thus to an increase of the backscattered radar power, and in the divergent areas it leads to a decrease. Therefore, on radar images, the convergent areas appear as areas of enhanced image intensity and the divergent areas as areas of reduced image

SAR-Based Bathymetry, Figure 2 SEASAT SAR image of the north eastern approach to the English Channel acquired August 19, 1978. Visible is on the right-hand side the French/Belgian coast. (Because this image is not corrected for the variation of brightness with incident angle, the image intensity is high along the bottom of the image corresponding to near range (steep incident angles)). The imaged area is 100 x 100 km.

intensity. In most cases, the surface current is a tidal current. The strongest modulation of the sea surface roughness, and thus of the backscattered power, is obtained when the tidal velocity is at its peak.

Examples of SAR images showing underwater topographic features

In this section, we present three examples of SAR images showing underwater topographic features acquired by the L-band (1.275 GHz) SAR aboard the American SEASAT satellite (launched 1978) and the C-band (5.3 GHz) SAR aboard the European ERS-1 satellite (launched 1991).

Figure 2 shows a SEASAT SAR image of the northeastern approach to the English Channel. On the right-hand side of the image, the French-Belgian coast is visible with the French town of Calais at the bottom. The V-shaped feature in the lower left-hand section of the image is a pair of two underwater ridges called South Falls (the thin line to the left) and Sandettie (the broader line to the right). South Falls is about 30 km long and 600–800 m wide and rises to within 7 m of the sea surface. The seafloor between the two ridges has a depth between 30 and 40 m. At the time of the SAR data acquisition, the tidal flow was directed toward the southwest with a speed between 1.7

SAR-Based Bathymetry, Figure 3 ERS-1 SAR image acquired July 8, 1995, showing the Xinchuan Gang (Subei) Shoal off the coast of China (north of Shanghai). The dark areas off the coast are sand banks which have fallen dry during ebb tide. The imaged area is 100×100 km. ©ESA 1995.

and 2.4 ms^{-1} . The wind speed was 4 ms^{-1} . Thus, optimum SAR imaging conditions were encountered: the tidal current velocity was close to its peak value during the tidal cycle, and the wind speed was well above threshold for small-scale wave generation (above $2\text{--}3 \text{ ms}^{-1}$), but not too high (above 8 ms^{-1}) such that the sea surface roughness modulation caused by the variable current over the sandbanks would be masked by wind effects.

Figure 3 shows an ERS-1 SAR image of the nearshore section of the Xinchuan Gang Shoal off the coast of China (north of Shanghai). The light gray area on the left-hand side and on the bottom of the image is land. The irregular dark band adjacent to the coast and the dark areas farther off the coast are tidal flats that have fallen dry. The light gray patterns in the right-hand section of the image are submerged sand ridges, which are quite similar to the underwater sand ridges visible in Figure 2.

Figure 4 shows an ERS-1 SAR image of the Waddenze in the North Sea off the Dutch coast. At the time of the SAR data acquisition, the tidal current was close to its peak and the wind was blowing from north with a speed of about 5 ms^{-1} .

Visible are (from left to right) the Dutch islands Terschelling, Ameland, and Schiermonnikoog. The Plaatgat

SAR-Based Bathymetry, Figure 4 ERS-1 SAR image of the Waddenze acquired August 3, 1995, at 1035 UTC. Between the land (lower section of the image) and the open sea (upper section) several islands are located: The Plaatgat area is located approximately in the center of the image. The imaged area is 100×100 km. ©ESA 1995.

area, located north of the tidal inlet between the islands of Ameland and Schiermonnikoog, is a shallow sea area which requires frequent updates of bathymetric maps because here the bottom topography is highly variable. In this area SAR images have been used for generating of bathymetric maps.

Generation of bathymetric maps using SAR images

In certain areas (e.g., the Dutch and the German coasts) the location, shape, and depth of underwater banks or shoals are highly variable due to the presence of strong currents and to the presence of sand or gravel at the seafloor. Under these conditions, regular monitoring and dredging are required in coastal areas. Conventionally, depth charts are obtained by sonar measurements carried out from dedicated vessels (survey vessels). Since depth measurements carried out from ships are quite expensive, it is a challenge to find a way to reduce the number of ship tracks without reducing the accuracy of the depth measurements. Here, SAR imagery comes into play, as it can be used to interpolate depth values between tracks sailed by the survey vessel.

A method to incorporate SAR images in conventional bathymetric surveying has been developed by ARGOS in the Netherlands called the Bathymetry Assessment System (BAS; Calkoen et al., 2001). It constructs depth maps from radar images and a limited number of echo soundings by numerical inversion of a two-dimensional model of the imaging mechanism (Vogelzang et al., 1997; Wensink and Campbell, 1997). For inverting SAR

images into bathymetric maps, the following additional data are needed: (1) sonar sounding data along calibration tracks to allow tuning, (2) tidal data relating to the acquisition time of the SAR image, (3) wind speed and direction relating to the acquisition time of the SAR image, and (4) the SAR image. In the inversion scheme, the depth profiles are retrieved from the SAR data in an iterative process such that the closest possible correspondence between modeled and measured depth profiles is obtained. In several validation experiments, it has been shown that this inversion scheme yields fine-grid bathymetric maps with depth accuracy better than 30 cm.

Summary

Although microwaves cannot penetrate into the water body, SAR can yield information on shallow-water bathymetry or underwater bottom topography. This is achieved indirectly by means of sensing variations in the sea surface roughness over bathymetry when a strong current (usually tidal current) is present. SAR is a very sensitive instrument to sense small variations in the (small-scale) sea surface roughness image. At present, it is not possible to invert reliably SAR images, which are related to sea surface roughness maps, into bathymetric maps by using theoretical models. However, if SAR images are combined with acoustic sounding data acquired from ships, they are of great value for generating bathymetric maps and thus can help to reduce greatly the cost of updating depth charts in tidal areas.

SEA ICE ALBEDO

Donald Perovich
USACE Cold Regions Research and Engineering Laboratory, Hanover, NH, USA

Synonyms

Frozen oceans; Sunlight reflection

Definition

Albedo – the fraction of sunlight reflected by a surface.
Bidirectional reflectance distribution function – the angular distribution of light reflected by a surface as a function of sun angle.

Irradiance – sunlight integrated over a hemisphere with units of watts per meter squared.

Leads – areas of open ocean in a sea ice cover.

First year ice – ice that has not yet endured an entire summer melt season.

Multiyear ice – ice that is one or more years old.

Introduction

The reflection of sunlight from sea ice is of considerable importance for the interpretation of remote sensing imagery and for the large-scale surface heat budget of the ice cover. Light reflection can be characterized by two terms: the albedo and the bidirectional reflectance distribution function (BRDF). These quantities can either be spectral or integrated over the solar spectrum (wavelengths from 280 to 2,500 nm).

The albedo is simply the fraction of the incident solar irradiance that is reflected by the surface. It is dimensionless. The irradiance is integrated over a hemisphere (downwelling for incident and upwelling for reflected) and has units of watts per meter squared. A surface that is a perfect absorber has an albedo of 0, while a perfect reflector has an albedo of 1. The albedo is a key parameter in the surface heat budget of sea ice and has climate implications (Curry et al., 1993). [Figure 1a](#) illustrates using a field portable spectroradiometer to measure spectral albedo. When measuring albedo, it is important to select a shadow-free, undisturbed surface and to keep the detector level while recording the incident and reflected irradiance.

The BRDF is the angular distribution of radiance reflected from a surface as a function of solar incident angle. It is often used for interpreting remote sensing imagery. Satellite sensors measure reflectance at

Sea Ice Albedo, Figure 1 (a) Measuring albedo using a field portable spectroradiometer. As oriented, the instrument is measuring the incident irradiance. The surface is a recently formed melt pond; (b) Apparatus for measuring BRDF consisting of two rings that can be rotated to any combination of zenith and azimuth angle. The surface is bare white ice.

a particular angle for a particular solar incident angle. The reflectances are then interpreted to generate geophysical quantities such as albedo and the type of ice present. An apparatus for measuring BRDF is presented in Figure 1b. It consists of horizontal and vertical rings that can be oriented to any azimuth and zenith angle. A probe is mounted in the ring as illustrated. Surface reflectances are measured at many angles and normalized to a white reference standard.

Impact of surface conditions

Light reflection from sea ice is governed largely by surface conditions (Perovich, 1996). As Figure 2 demonstrates, sea ice surface conditions vary spatially and temporally. Before the summer melt season begins, there are two primary surface types present: snow-covered ice and leads (areas of open ocean). As summer progresses, the surface becomes a variegated mixture of melting snow, bare ice, melt ponds, and leads. The blue areas in the photographs are melt ponds, where melt water collects in a surface layer a few centimeters to half a meter deep. The melt ponds evolve throughout the summer growing deeper and developing a complex, interconnected drainage system. In August or September, fall freeze-up begins and the surface consists of snow-covered ice, young, thin ice, and leads.

Because of the importance of albedo to the surface heat budget, albedo measurements have long been a routine part of sea ice field experiments. Photographs of eight distinct surface types, along with their wavelength-integrated and spectral albedos are presented in Figure 3 (Allison et al., 1993; Grenfell and Maykut, 1977). The varied surface conditions result in albedos that range from a minimum of 0.07 for leads to a maximum of 0.85 for

cold snow-covered ice. Sea ice albedos cover almost the entire possible range of 0–1. The differences in albedo are due to scattering. For example, snow, with an abundance of air-ice interfaces, is a highly scattering medium, while clear melt water scatters little light. For most of the year, the predominant surface type is cold snow-covered ice. In late spring, the snow begins to melt and its albedo decreases to about 0.70–0.75. Once the snow has melted, bare ice is exposed. This bare ice typically has a few centimeter-thick surface layer consisting of small fragments of deteriorated ice. Ice that has been through a full annual cycle (multiyear ice) typically has more air bubbles and more scattering than ice that has not (first year ice). Bare multiyear ice has an albedo of $0.65 (\pm 0.05)$ compared to a value of $0.55 (\pm 0.05)$ for first year ice. Melt pond albedos range from 0.1 to 0.4.

Spectral albedos for eight surface types are presented in Figure 3b (Perovich et al., 2002; Winther et al., 2004). The spectral differences in albedo are due to absorption. Light absorption in ice and water increases rapidly with wavelength, so there is a general tendency for albedo to decrease as wavelength increases. The albedos of snow and bare ice are large and vary little with wavelength across the visible spectrum (400–750 nm) and these ice types appear white. Leads have a small albedo across the visible spectrum and look black. Most melt ponds have a sharp spectral peak and are shades of blue, azure, and cobalt. The brightness and color of the melt ponds are largely determined by the properties of the underlying ice. Dark ponds typically have a thinner layer of underlying ice, while whitish ponds have thicker ice with more air bubbles. Blue ponds have relatively thick ice (more than 1 m), with few air bubbles. The color is a result of minimal absorption of light in ice at blue wavelengths.

Sea Ice Albedo, Figure 2 Aerial and surface-based photographs of sea conditions from May through September.

Ice albedo feedback

The importance of sea ice albedo transcends the polar regions and has implications for the global climate system through the ice albedo feedback. There is an extreme contrast in albedo between snow-covered ice and leads. Also, as the photographs in [Figure 2](#) demonstrate, there is a general decrease in albedo as the sea ice melts. These phenomena combine to form the ice albedo feedback. In spring, the surface is primarily snow-covered ice, with a small area of leads. The albedo is large and roughly 80 % of the sunlight is reflected. However, the remainder is absorbed and, with warming air temperatures, eventually results in surface melting. This melting lowers the albedo, which causes more melting and a further lowering

of albedo. This positive ice albedo feedback mechanism can amplify changes to the sea ice cover and consequently is important to climate change.

Conclusion

A marked decline in the amount of Arctic sea ice in summer has been observed in recent years at a rate faster than predicted by models (Stroeve et al., [2007](#), [2008](#)). There is evidence that there is enhanced solar heating of the upper ocean and consequently an increase in ice melting (Perovich et al., [2008](#); Steele et al., [2008](#)). The ice albedo feedback is contributing to the Arctic sea ice loss and may be accelerating it.

Sea Ice Albedo, Figure 3 Photographs of eight common sea ice surface types (top). Dots on the line represent the wavelength integrated albedo for these surface types, with the dot color matching the photograph border color. Spectral albedos for the eight surface types are shown below.

SEA ICE CONCENTRATION AND EXTENT

Josefino C. Comiso

Cryospheric Sciences Laboratory, Code 615, Earth Sciences Division, NASA Goddard Space Flight Center, Greenbelt, MD, USA

Synonyms

Frozen sea water; Ice floe; Ice pack

Definitions

Sea ice. Sea ice is any form of ice which originated from the freezing of seawater and is found in the sea.

Sea ice concentration. Sea ice concentration is the fraction of an observational area covered completely by sea ice.

Sea ice extent. Sea ice extent represents the total area covered partially or totally by sea ice. For remote sensing applications, a lower threshold of 15 % in the fraction of sea ice cover is usually applied.

Sea ice

Among the most seasonal and most dynamic parameters on the surface of the Earth is sea ice which at any one time covers about 3–6 % of the planet. In the Northern Hemisphere, sea ice grows in extent from about $6 \times 10^6 \text{ km}^2$ to $16 \times 10^6 \text{ km}^2$, while in the Southern Hemisphere, it grows from about $3 \times 10^6 \text{ km}^2$ to about $19 \times 10^6 \text{ km}^2$ (Comiso, 2010; Gloersen et al., 1992). Sea ice is up to about 2–3 m thick in the Northern Hemisphere and about 1 m thick in the Southern Hemisphere (Wadhams, 2002), and compared to the average ocean depth of about 3 km, it is a relatively thin, fragile sheet that can break due to waves and winds or melt due to upwelling of warm water. Being constantly advected by winds, waves, and currents, sea ice is very dynamic and usually follows the directions of the many gyres in the polar regions. Despite its vast expanse, the sea ice cover was previously left largely unstudied and it was only in recent years that we have understood its true impact and significance as related to the Earth's climate, the oceans, and marine life.

We now know that sea ice is part of the polar heat sink and an important component of the climate system. It is a good insulator and serves to keep the ocean warm during winter and at the same time is a good reflector of solar radiation, thereby keeping the ocean relatively cold in the summer. Sea ice also redistributes salt in the ocean since salinity is enhanced where it forms and is reduced where it melts. Among the key sources of cold and high salinity water are regions where ice is formed at a relatively high rate, as in coastal polynyas. These polynyas are known to be ice factories and are the key sources of bottom water that helps maintain the global thermohaline circulation (Gordon and Comiso, 1988; Martin et al., 2007). In the deep ocean regions, the formation of sea ice can initiate deep ocean convection that enables vertical exchanges of chemicals and the resupply of surface water with nutrients and oxygen. Sea ice is also an integral part of the ecology of the polar environment. It is a habitat and a source of food for many marine organisms, and during the melt season, it causes the formation of low-density surface water layer that is stable and exposed to abundant sunlight. Such layers are ideal platforms for photosynthesis and have been regarded as potential sites of phytoplankton blooms (Smith and Comiso, 2008).

Modeling studies have shown that global warming signals can be amplified by as much as 3–5 times in the Arctic region (Holland and Bitz, 2003). This is mainly because of ice-albedo feedback effects associated with the high albedo of ice compared to that of open water. The process may already be occurring in a significant manner since the total Arctic sea ice cover has been declining at about 3–4 % per decade (Parkinson et al., 1999; Bjorgo et al., 1997), while the perennial ice (which is ice that survives the summer melt) has been declining at a much higher rate of about 9–13 % per decade (Comiso, 2002; Stroeve et al., 2004; Comiso et al., 2008), with

sudden declines in the summers of 2007 and 2012. On the other hand, the total extent of sea ice in the Antarctic is going the opposite way with the ice cover increasing at about 1 % per decade (Cavalieri et al., 1997; Zwally et al., 2002). The phenomenon in the Antarctic is still poorly understood and has been associated with a freshening of the Ross Sea that causes enhanced vertical stratification that in turn reduces heat fluxes originating from warmer water in the deeper layers (Zhang, 2007). More recent studies suggest that the depletion of stratospheric ozone in the Antarctic resulted in the deepening of lows in the West Antarctic region, causing strong southerly winds and, therefore, enhanced sea ice production off the Ross Sea ice shelf region (Turner et al., 2009).

Physical and radiative characteristics of sea ice

Geographical maps of the polar regions and the general location of the sea ice cover during minimum and maximum extents as derived from satellite data are shown in Figure 1 for both hemispheres. It is apparent that the

distributions of the sea ice cover in the two regions are different and are affected by the location of continental land masses and other environmental factors. In the Northern Hemisphere, land surrounds the Arctic Ocean which is covered almost completely by sea ice in winter. Sea ice is also found in peripheral seas and bays like the Okhotsk Sea, Bering Sea, Hudson Bay, Labrador Sea, and Baffin Bay during winter but is confined as an almost continuous sheet in the Arctic Basin in the summer. In the Southern Hemisphere, on the other hand, sea ice surrounds the continental land mass, called Antarctica, and has no northern boundary. The ice cover is also almost a continuous ice sheet in winter and gets fragmented at the end of the summer.

Supercooling of ocean water leads to the formation of tiny crystals of ice, called frazil ice, that accumulates at the surface. These tiny particles coagulate to form a soupy layer at the surface that looks like oil slick and has been referred to as grease ice. In the inner pack where the ocean surface is relatively stable, the ice layer gets thicker through the growth of congelation ice at the underside and forms an ice sheet, called nilas, which initially

Sea Ice Concentration and Extent, Figure 1 Location maps of the polar regions in (a) Northern and (b) Southern Hemispheres. Also shown are averages of ice concentrations during ice minimum (white) and ice maximum (light blue) for the period November 1978 to December 2009.

appears dark and then gets lighter gray with time as it gets thicker. Near the ice edge, where the surface is constantly perturbed by winds and waves, the grease ice gets transformed into loosely aggregated disks called pancake ice that have raised edges because of constant collisions with each other. The ice grows in thickness usually through thermodynamic growth, through rafting, which is a process in which one piece of ice goes on top of the other or through ridging which is when two thick ice floes collide and the thinner ice in between is broken up. When ice sheets become about 15–30 cm thick, they are called young ice and beyond that, they become first year ice which is the most dominant sea ice type during the winter period. The sea ice cover that survives one summer melt period is referred to as second year ice, and if it survives more than one summer, it is called multiyear ice.

The key parameter associated with the radiative characteristics of a material is its emissivity which for sea ice depends on many factors such as its thickness, salinity, snow cover, temperature, and liquid content. At microwave frequencies and according to the Rayleigh-Jeans approximation, the radiance from a surface is directly proportional to the temperature of the emitting material, with the emissivity being the proportionality constant. The high contrast in the microwave between the high emissivity of sea ice and low emissivity liquid water makes passive microwave sensors an effective tool for monitoring the sea ice cover. The contrast is most pronounced when the surface of the sea ice cover is dry and is dominated by young ice and thicker ice types. The emissivity of the new ice types changes depending on thickness and varies from that slightly higher than liquid water (as with grease ice) through intermediate values (as with gray ice) before it becomes young ice or thicker ice types. The emissivity of melting snow cover and meltponded areas is also unpredictable and causes ambiguities in interpretation. There is also a difference in the emissivity of seasonal and the older ice types. Young and first year sea ice types, which are the main components of seasonal ice, have relatively high salinity at up to about 12 psu (Weeks and Ackley, 1986). The salinity depends on the amount of brine that is entrapped within the ice during the process of ice-crystallization. Gradual desalinization follows mainly through a process called brine drainage that is usually accelerated during the summer (Martin, 2004; Tucker et al., 1992). Thus, the multiyear ice that survives two or more summers would have much lower salinities and hence different dielectric properties than those of seasonal ice. This phenomenon and volume scattering within the ice makes the multiyear ice emissivity distinctly lower than that of seasonal ice (Vant et al., 1974; Grenfell, 1992) and an opportunity to also monitor separately the multiyear ice cover. The dry snow cover is mainly transparent, but at some microwave frequencies, it also serves as a scatterer of radiation and can affect the emissivity, especially when the grain size becomes comparable to the wavelength of the radiation. The variations in emissivity for different ice or surface types can be a problem but

are mainly accounted for in the estimates of ice concentration as discussed in the following section.

Sea ice concentration: algorithms and validation

The advent of satellite imaging passive microwave sensors enabled for the first time quantitative assessments of the large-scale distribution and estimates of the true extent and area of the global sea ice cover (Zwally et al., 1983). This capability started with the Nimbus-5 Electrically Scanning Microwave Radiometer (ESMR), cross-scanning and horizontally polarized sensor, which operated at 19 GHz and was launched in December 1972. This was followed by the Scanning Multichannel Microwave Radiometer (SMMR), launched onboard the Nimbus-7 satellite in 1978 and subsequently by the series of DMSP Special Scanning Microwave Imager (SSM/I), the first of which was launched in July 1987. The most recent and likely the most versatile is the Advanced Microwave Scanning Radiometer which was launched on board EOS Aqua on May 4, 2002, (AMSR-E) and on May 18, 2012, (AMSR-2) on board JAXA GCOM-W. A comparison of the resolution and other technical characteristics of these sensors is provided by Lubin and Massom (2006).

Passive microwave sensors have the advantage over other types of sensors of providing day/night, almost all weather data globally at a good temporal resolution. Spatial resolution has been cited as a limitation of the system with historical data being archived at a resolution of 25 km. However, this limitation is minimized with the use of a mixing algorithm that estimates the fraction of sea ice within each measurement. The resolution has improved considerably with AMSR-E which provides standard ice data at a resolution of about 12 km, but data with a resolution of 6 km can be obtained from the dual-polarized 89 GHz channels. Other types of sensors have also been used for the study of sea ice such as Landsat, which provides visible imagery at 15 m resolution, and the Synthetic Aperture Radar (SAR) which provides active microwave images at a resolution of about 30 m. Data from these sensors have been useful for mesoscale studies and for validation of passive microwave data (Comiso et al., 2001). Global coverage from these high-resolution sensors, however, has been limited spatially and temporally and cannot be used effectively for large-scale variability studies of global sea ice cover. Several algorithms have been developed for SMMR and SSM/I data (Svendsen et al., 1983; Swift et al., 1985; Cavalieri et al., 1984; Comiso, 1986; Steffen et al., 1992). The standard algorithms used for estimating ice concentrations using AMSR-E data are the Bootstrap and NT2 Algorithms as described by Comiso et al. (2003). Despite differences in the techniques and channels utilized, the Bootstrap and NT2 Algorithms provide very similar values in ice concentration, ice extent, and ice area (Parkinson and Comiso, 2008; Comiso and Parkinson, 2008; Comiso and Nishio, 2008). In this section, we will

briefly describe how ice concentration is derived from passive microwave data.

The brightness temperature (T_B), recorded by a satellite sensor at a given wavelength, can be estimated using the basic radiative transfer equation given by

$$T_B = \varepsilon T_S e^{-\tau} + \int_0^{\tau} T(z) \zeta(z) e^{-\tau+\tau'(z)} d\tau'(z) + (1 - \varepsilon) \kappa e^{-\tau} - \int_0^{\tau} T(z) \zeta(z) e^{-\tau'(z)} d\tau'(z) \quad (1)$$

where ε is the emissivity of the surface, T_S is the physical temperature of the surface, $\tau'(z)$ and τ are the atmospheric opacities from the surface to a height z and from the surface to the satellite height (usually about 800 km), respectively, $T(z)$ is atmospheric temperature at a height z , κ is an estimate of the diffusiveness of the surface reflection, and $\zeta(z)$ is the emittance at z . In Equation 1, the first term in the right hand side of the equation represents radiation directly from the earth's surface, which is the dominant contribution for measurements at microwave frequencies. The second term represents satellite-observed radiation that emanates directly from the atmosphere, while the third term represents downwelling radiation from the atmosphere that has been reflected toward the satellite from the earth's surface. A fourth term that takes into account the reflected contribution of radiation from free space (i.e., the cosmological 2 K contribution from the Big Bang), which is an additive contribution, is negligible and not included in Equation 1.

The estimation of surface parameters from satellite data usually requires the effective implementation of a radiative transfer model that makes use of Equation 1. The goal is to correct for atmospheric effects and to obtain a good estimate of the brightness temperature (T_{BS}) of the surface of interest which in our case is the first term in Equation 1 without the exponential term. Getting an estimate of atmospheric contribution using this equation is usually not trivial because of the need of, as input, many atmospheric parameters that change in space and time. In particular, one has to know not only the dependence with height of atmospheric temperature, pressure, particle size and type, and humidity, but also how they change spatially and temporally. Some of this information is provided by ground-based measurements and radiosonde ascents, but generally, these measurements are not available in good enough spatial resolution to accurately account for the regional and temporal variability of the atmosphere.

In the polar regions, atmospheric effects are usually not as big a factor as those in the tropics and mid-latitudes because of much lower humidity. The net effect on the retrieval is further minimized through the use of multichannel data and the way the algorithm is structured. Ice concentration, C_I , has been defined as the percentage fraction of sea ice within the field of view of the sensor

and is usually derived using the mixing algorithm $T_{BS} = C_I T_{IS} - (1 - C_I) T_{OS}$, where T_{IS} is the brightness temperature of 100 % ice while T_{OS} is the brightness temperature of 100 % open water. The subscript S is meant to indicate that the parameters represent surface measurements. The sea ice concentration can thus be expressed as the ratio of the difference of brightness temperatures as follows:

$$C_I = \frac{T_{BS} - T_{OS}}{T_{IS} - T_{OS}} \quad (2)$$

According to Equation 1, the brightness temperature of the surface ($T_{BS} = \varepsilon T_S$) is the brightness temperature observed by the satellite (T_B) minus the atmospheric contributions and divided by $e^{-\tau}$. The contributions directly from the atmosphere (second term in Equation 1) within the satellite footprint are approximately the same for the ice-covered and ice-free area, while the downwelling component is significantly smaller and the difference may be negligible. Thus, to a first approximation, the atmospheric effects are either small or may cancel out in Equation 2. Also, the atmospheric opacity, $e^{-\tau}$, which appears in the numerator and denominator in Equation 2, is likely similar over ice-covered, partially ice-covered, and ice-free areas within the ice pack and approximately cancels out as well.

The Bootstrap Algorithm for ice concentration as discussed in Comiso et al. (2003) makes use of an equation similar to that of Equation 2 but with satellite values being substituted for surface values. In particular, a modified Equation 2 is used in which T_{BS} , T_{OS} , and T_{IS} are replaced by T_B , T_O , and T_I , which are variables provided or can be inferred from the satellite multichannel data. In Figure 2, we show two sets of scatter plots using brightness temperature data from AMSR-E: One is the set we call VH36 which makes use of 36 GHz data at both horizontal and vertical polarizations (Figure 2a) and the other is the set V1836 which uses 18 and 37 GHz data at vertical polarization (Figure 2b). The two scatter plots show that the data points from the ice-covered regions are generally confined inside a triangle defined approximately by OAD in the scatter plots. Two main clusters of data points, one along AD and the other along OW, are apparent, and with the aid of high-resolution Landsat and SAR data, we are able to establish that the data points along AD represent consolidated ice while those along OW (gray data points) represent ice-free water surfaces with the relatively calm water near the point O while those in the rough seas near W. The data points between the line AD and O represent ice-covered regions with different concentrations, but data along OA can also represent new ice types of different thicknesses. In Figure 2a, the cluster of points along OW and OA overlaps and is difficult to discriminate, but in Figure 2b, the cluster OW for open water is clearly easier to separate from ice-covered regions within the triangle OAD. Data points in OAD but close to O or the cluster OW are data points near the

Sea Ice Concentration and Extent, Figure 2 Scatter plots of brightness temperatures from AMSR-E of (a) 36 GHz at horizontal polarization versus 36 GHz at vertical polarization; (b) 18 GHz versus 36 GHz both at vertical polarization; (c) frequency histogram of data points perpendicular to the AD line in (a); (d) frequency histogram of data points perpendicular to the AD line in (b).

ice edge, and at some ice concentration values, they are virtually impossible to discriminate from ice-free oceans. The threshold at which such discrimination can be done is usually used to define the ice edge and is about 10 % for AMSR-E and 15 % for SSM/I. We use the 18 and 23 GHz channels as discussed in Comiso et al. (2003) for optimal discrimination and to establish the cutoff threshold for ice-covered regions.

The primary cluster of interest is that along AD, because it is the cluster that is used to determine the tie point (T_I) for consolidated ice. Since the data points in Figure 2a are from the same frequency, the slope of the cluster along AD is approximately equal to 1. This is basically because a unit change in brightness temperature in one channel is reflected as a change of approximately the same magnitude in the other channel. The data points for consolidated ice are confined within a tight linear cluster along AD because incremental changes in temperature or emissivity cause the data points to slide along the same line. The distribution of data points along AD in Figure 2b is not as compact as in Figure 2a because the set of data is from different frequencies and the slope is not equal to 1. The cluster shows a larger range of variability along the 37 GHz data than the 18 GHz data, reflecting the stronger impact of scattering on emissivity for radiation at the shorter wavelength (i.e., 37 GHz). The variability across the AD cluster in Figure 2b is in part associated with ice surface temperature effects since the slope is not unity while changes in temperature cause the data points to shift along a diagonal line.

The scheme behind the algorithms, and in particular the Bootstrap Algorithm, is to determine the tie-points (T_O and T_I) needed to estimate ice concentration from the modified Equation 2 by using the scatter plots in Figure 2a and b. For any given pair of satellite data (T_B) represented by the data point B in the scatter plot in Figure 2a, the corresponding brightness temperature for 100 % ice (T_I) is inferred by extending the line OB such that it intersects the line AD at I. The location of the point of intersection is determined by solving for the common point of the two linear equations representing the lines AD and OB. The brightness temperature, T_I , at the point of intersection corresponds to 100 % ice for the type of sea ice that is represented by the data point at B. We can estimate the ice concentration from the ratio OB/OI which yields the same result as the modified version of Equation 2 (Comiso et al., 2003).

Choosing the right sets of channels to be used in the algorithm is an important consideration and was based on the ability to discriminate ice and liquid water and at the same time meet some resolution requirements. The resolution of a passive microwave sensor is dependent on the size of the antenna and the wavelength of the radiation and since one antenna is used for all the radiometers, the resolution is frequency (or wavelength) dependent. The 6 GHz channels provide the best contrast in the emissivity of ice and water and at the same time the least sensitivity to surface effects, including the snow cover. Unfortunately, this channel has the poorest resolution at about 40 by 60 km for AMSR-E and a lot worse (about 70 by 150 km) for SMMR data. Another consideration was the sensitivity to surface temperature variations which affects the compactness of the cluster of data points along the line AD. After evaluating the different possibilities, it was determined that the VH36 and V1836 sets of channels provide a consistent and reliable ice concentration at a reasonable resolution. It is fortuitous that SMMR, SSM/I, and AMSR-E sensors have these sets of channels, making it possible to have a continuous and consistent data set of sea ice from November 1978 to the present to be generated.

The two sets of channels are utilized as follows. The VH36 set appears to be an important set because of the tight linear clustering of ice data points and the good accuracy provided by this set in estimating sea ice concentration. A histogram of data along an axis perpendicular to the line AD in Figure 2a is shown in Figure 2c, and the peak of the AD line is quite narrow with a standard deviation of about 2.5 °C. The narrow peak means that T_I can be derived at a relatively high accuracy and since T_O is expected to be relatively constant; ice concentration can be estimated at an optimum accuracy of about 3 %. The use solely of the VH36 set, however, is not adequate because some data points that represent 100 % ice, as observed from Landsat or SAR data, are not within the AD cluster in Figure 2a. One reason is that horizontally polarized radiation is much more sensitive to some types of sea ice-covered surfaces (e.g., those with layering) than

the vertically polarized radiation (Matzler et al., 1984). This problem is not a factor with the V1836 set since in this case, a horizontal polarization channel is not utilized and these same problem data points are found within the AD cluster in the V1836 set. The strategy is thus to use the VH36 set for the data points in the AD cluster for this set and the V1836 set for the rest of the data points. The technique thus takes advantage of the strength of the different channels and provides accurate estimates of ice concentration within the ice pack. To generate ice concentration maps, there needs to be a way to detect land areas since sea ice is an ocean parameter and the algorithm is not able to discriminate land from ocean areas. A fixed land mask, based on published land boundaries, has been used for this purpose, but adjustments are made during big calving events. An ocean mask is also used, based on the set of data presented in Figure 2b and as discussed in Comiso et al. (2003) to remove bad ice concentration data in the middle of the open ocean. Erroneous retrievals at the land/ocean boundaries away from the pack are also apparent and are removed by using an enhanced version of the algorithm developed by Cho et al., 1996.

Generally, the cluster along the line AD, especially for the VH36 set, does not change much during the ice season. However, unusual weather and surface conditions could cause the ice cluster to shift in slope and offset. Results from regression fits to the cluster of points along the line AD are used on a daily basis to constantly update the line parameters for AD and account for changes in weather and surface conditions. The impact of spatial changes in surface temperature on the accuracy of the retrieval has also been studied, and in snow-covered regions (which is the dominant type of ice cover), the standard deviation of surface ice temperatures has been observed to be about 2.5 °C. The associated error in the retrieval accuracy when using the V1836 set is significant due to temperature variations but is relatively small (about 3 %). The technique is thus basically robust because much of the temporal and spatial changes in emissivity and temperature in ice-covered regions are taken into account. From comparative studies with high-resolution satellite data, the accuracy has been estimated to be about 5–10 % for most types of thick ice cover during the dry (cold) period. During the melt period, the emissivity becomes more unpredictable especially during onset of melt and when melt ponds start to form. Depending on the fraction of melt pond in each pixel, the error is estimated at 15 % or greater during the period. Also, since new ice data are represented by data points between AD and O, data points with close to 100 % of new ice are retrieved with relatively lower percentage of ice cover, depending on thickness.

Validation studies have been done using high-resolution data and other techniques (Steffen et al., 1992; Comiso and Steffen, 2001). A sample-comparative analysis, presented in Figure 3, shows a Landsat image during winter (February 11, 2003) in the Sea of Okhotsk and corresponding ice concentration maps at 6.25 km,

12.5 km, and 25 km resolution from AMSR-E data. It is apparent that the 6.25 km data using solely the 89 GHz channels reproduces many of the small-scale features in the Landsat data. The 12.5 km data provide an accurate depiction of the contours along the ice edge, while the 25 km data show a slight smearing of the ice cover and an ice edge that is not as well defined as the 12.5 km data. Quantitative analysis shows very good agreement of Landsat with the passive microwave data, but the 25 km data provided the best correlation with Landsat data, while the 6.25 km data provided the worst correlation. This is in part because of a few hours difference in observation time and a few km ice drift can cause significant mismatch on a pixel-by-pixel basis when the high-resolution AMSR-E data are used.

Sea ice extent and area

The ability to estimate sea ice concentration from satellite data has provided the means to quantify the large-scale characteristics of the global sea ice cover (Gloersen et al., 1992; Bjorgo et al., 1997; Cavalieri et al., 1997; Parkinson et al., 1999; Zwally et al., 2002). To illustrate the seasonality of the sea ice cover, multiyear monthly averages of sea ice concentration from AMSR-E data using data from June 2002 to December 2009 are presented in Figures 4 and 5 for the Northern and Southern Hemispheres, respectively. We use the AMSR-E data because of the relatively high resolution, and they represent the typical ice cover during the contemporary era. The changes in the ice cover with season are shown to be quite different in the two hemispheres with the ice advance and retreat occurring in close proximity to land in the Northern Hemisphere but basically toward the open oceans in the Southern Hemisphere.

In the Northern Hemisphere, the advance of sea ice from September to November occurs at a relatively fast pace in the Arctic basin, Canadian Archipelago, and Baffin Bay. From December to March, the ice advances farther to the south to the Bering Sea and the Okhotsk Sea in the Pacific region and to Hudson Bay, Labrador Sea, and the Gulf of St. Lawrence in the Atlantic region. The sea ice cover reaches its maximum extent in late February or early March and starts retreating after that, with the peripheral seas becoming ice-free in July. The ice cover usually reaches its minimum extent in early to mid-September with the ice that survives the summer being just the relatively thick ice in the Arctic Basin. The Beaufort gyre tends to keep a significant fraction of ice confined in the basin for as long as 7 years, enabling the ice to be relatively thick. The presence of land surrounding the Arctic basin also makes it more likely for ridging and, therefore, thicker ice to occur in the region. Sea ice is also found at relatively low latitudes (about 44 °N) in the Northern Hemisphere in winter mainly because of the influence of extremely cold surface temperatures in the region and adjacent land areas during the period.

Sea Ice Concentration and Extent, Figure 3 Comparison of (a) Landsat visible channel data with AMSR-E data at (b) 6.25 km, using solely the dual-polarized 89 GHz data; (c) 12.5 km using 18 and 36 GHz data; and SSM/I data at (d) 25 km resolution using 19 and 37 GHz data. The image was taken on February 11, 2003, data at the Sea of Okhotsk.

In the Southern Hemisphere, the sea ice cover in the Weddell and Ross Seas advances quickly to the north from March to June (Figure 5), while the entire ice cover becomes almost symmetrical in July, when other regions have caught up advancing to the north, and reaches maximum extent in September or October. The rate of advance is influenced primarily by sea-surface temperature, southerly winds, and ice production in the coastal regions. The multiyear averaging causes some smearing near the ice edges in May and June on account of large interannual changes of ice edge location. In particular, the gradients in ice concentration at the marginal ice zones are less abrupt than those from monthly averages in a single year. The ice cover subsequently declines in November through January reaching minimum extent in late February or March. The abrupt decline in November and December is caused primarily by big waves and intrusion of warm

water from lower latitudes. In the winter, the ice cover is contiguous and appears like a single circumpolar unit that is more extensive than the Antarctic continent. The seas with the most ice cover during the period are the Weddell and Ross Seas which are also sites of large coastal polynyas that are regarded as ice factories. Also, the sea ice cover does not advance much to the north in areas where the location of the Antarctic coastline is at relatively low latitudes (e.g., Western Pacific region between 100°E and 150°E). In the summer, the ice cover is more fragmented and is basically confined to regions from 140°E to 330°E, with the Western Weddell Sea having the most summer ice.

An area of special interest is the marginal ice zone (MIZ) which is usually a region of very intense air-sea-ice interaction and high primary productivity. Sea ice cover images in the Weddell Sea as depicted by MODIS,

Sea Ice Concentration and Extent, Figure 4 Color-coded multiyear averages (2002–2009) of monthly ice concentration from January to December from AMSR-E data in the Northern Hemisphere.

Sea Ice Concentration and Extent, Figure 5 Color-coded multiyear averages (2002–2009) of monthly ice concentration from January to December from AMSR-E data in the Southern Hemisphere.

AMSR-E, and SSM/I data on September 9, 2002, and mapped to a common projection at a grid size of 250 m, 12.5 km, and 25.0 km, respectively, are presented in [Figure 6a, b, and c](#). The narrow-band albedo data from MODIS have been arbitrarily normalized to obtain a better match with the other images and for convenience in comparative analysis. The MODIS data provide the most detailed characterization of the sea ice cover, while the AMSR-E and SSM/I data show basically similar information but at a lower resolution. It is apparent that resolution can make a significant difference since AMSR-E data

provide a better representation of the mesoscale features of the ice cover than SSM/I data when compared with MODIS data. For example, some of the relatively low concentrations and open water features within the pack that are apparent in the MODIS data are also captured by AMSR-E but not by SSM/I. For a better quantification of the difference in the information provided by the three data sets, plots along a transect defined by a line from A to B, using data from the three data sets, are presented in [Figure 6d](#). The MODIS albedo (in gold) is shown to be relatively low in the open water area (at A) and actually

Sea Ice Concentration and Extent, Figure 6 Sea ice cover in the Weddell Sea on September 9, 2002, as depicted by (a) MODIS albedo data at 250 m resolution; (b) AMSR-E ice concentration data at 12.5 km resolution; and (c) SSM/I ice concentration data at 25 km resolution. (d) Plot of data points across the ice edge and along the line A to B using MODIS (in gold), AMSR-E (in red), and SSM/I (in green) data.

goes down as it approaches the ice edge and then increased to significantly higher values within the pack. Large fluctuations of albedo within the pack are apparent. This is largely due to the spatial variations in ice characteristics and associated changes in the albedo (Allison et al., 1993; Warren, 1984). Plots along the same transect but using ice concentration values from AMSR-E and SSM/I are shown by the red and green lines, respectively. It is apparent that the ice edge locations (i.e., where the ice concentrations increase rapidly), as detected by MODIS, AMSR-E, and the SSM/I data, are consistent. The black line along the ice edge in the AMSR-E image (Figure 6b) is superimposed on the MODIS and SSM/I images for comparative analysis. Generally, the SSM/I image shows an ice edge farther away from the pack than AMSR-E because of coarser resolution. Beyond the ice edge and into the pack, the MODIS data show much more variability in the ice cover than either the AMSR-E or SSM/I data. This is in part associated with the higher resolution that enables the detection of some of the distinct but small ice features within the pack. Some of these features represent different sea ice surfaces which are

represented in the passive microwave data as close to 100 % sea ice. The passive microwave values may indeed be the correct values since many of the features are likely leads that may have intermediate albedo but are completely frozen. The AMSR-E and SSM/I data show a well-defined ice edges and consistent ice cover while MODIS shows large variability that may or may not reflect actual changes in ice concentration.

The two parameters that are usually used in the quantitative assessment of the sea ice cover are sea ice extent and ice area. Ice extent refers to the area covered partially or completely by sea ice and is quantified by taking the integrated sum of the areas of data elements (pixels) with at least 15 % ice concentration. The lower limit of 15 % is based on the ability of the sensor to discriminate sea ice from ice-free regions at low concentrations. This can be set lower especially with the more accurate AMSR-E data, but for consistency with historical data and previous studies, we use the same 15 % lower limit. Ice area corresponds to the integrated sum of the products of the area of each pixel and the corresponding ice concentration. In general, ice extent provides information about how far

south (or north) the ice advances during the winter period and how far north (or south) it retreats toward the poles in the summer, while ice area provides the means to estimate the total volume assuming that the average ice thickness is known. Ice area is thus useful in ice variability and mass balance studies.

The ability to estimate the ice extent and ice area makes it possible to quantitatively study the seasonal and interannual variability as well as trends in the global sea ice cover. For consistency, the data that have been used for sea ice time series studies are those from SMMR which provided good data from November 1978 to August 1987 and a few SSM/I sensors which have been providing good data from mid-July 1987 to the present. Although the best data set available is the AMSR-E data, the record length is less than 10 years and do not provide a long enough record to document meaningful trends in the ice cover. The AMSR-E data benefits from a higher resolution, wider spectral range, and wider swath than previously available data. The higher resolution enables improved ability to do

comparative studies with other data sets, especially MODIS data that are coincident in time and coverage. The tie-points for AMSR-E were therefore optimized with the help of cloud-free MODIS data. With AMSR-E data as the baseline, SSM/I brightness temperatures were normalized to be consistent with AMSR-E brightness temperatures using normalization parameters derived during the period of overlap. Using basically an identical algorithm and matching tie-points, SSM/I ice concentrations were generated to be consistent with AMSR-E data. A similar process was in turn used to make SMMR data consistent with SSM/I data using normalization parameters derived from analysis of SMMR and SSM/I data during overlap period. Results from detailed analysis of ice concentrations, ice extent, and ice area from this time series have been reported by Comiso and Nishio (2008).

Continuous and consistently derived monthly ice extent, ice area, and ice concentrations from SMMR and SSM/I data for the period from November 1978 to June 2013 are presented in Figures 7 and 8 for the Northern

Sea Ice Concentration and Extent, Figure 7 Monthly ice extents, ice area, and ice concentration in the Northern Hemisphere using SMMR and SSM/I data from November 1978 to June 2013.

Sea Ice Concentration and Extent, Figure 8 Monthly ice extents, ice area, and ice concentration in the Southern Hemisphere using SMMR and SSM/I data from November 1978 to June 2013.

and Southern Hemispheres. The temporal variations in the monthly averages are dominated by the large seasonality of the ice cover that fluctuates from minimum values in September to maximum values in February in the Northern Hemisphere and minimum values in February to maximum values in September in the Southern Hemisphere. In the Northern Hemisphere, the ice extent fluctuates from about $7.2 \times 10^6 \text{ km}^2$ in the summer to $15.5 \times 10^6 \text{ km}^2$ in the winter in the 1980s, while in the 1990s and 2000s, the range slightly increased as the trend in winter maximum is not able to keep up with the larger downward trend in summer minimum (Figure 7a). Similar changes from the 1980s to 2000s are also shown in Figure 7b for sea ice area. It is intriguing that high values of ice extents in winter are sometimes followed by low values in the summer (and vice versa) as in 1979 and 1990. Such phenomenon suggests that a cold winter that causes the ice extent to reach abnormally high values does not necessarily lead to more ice surviving the summer, although the ice

cover would be expected to be relatively thick. It also means that other parameters (e.g., wind circulation and percentage of ice exported to the Atlantic Ocean through Fram Strait) have to be considered when making projections about the ice cover for a subsequent season. It is also interesting that while the minimum ice extent and area remain reasonably constant from 1979 to 1990, larger variability occurred thereafter and appears to be significantly lower than previous values starting with 1997. Some recoveries are apparent in the summers of 1992, 1994, and 1996, but since 2002, such recovery has been relatively minor and the five lowest extents during the satellite era occurred in 2007 to 2011. Not shown is the new record minimum ice extent in September 2012.

Monthly extents and ice areas in the Southern Hemisphere, as derived from SMMR and SSM/I data (Figure 8), show an even more seasonal ice cover than that of the Northern Hemisphere. Minimum ice extents and ice areas usually occur in February, while maximum ice extents

Sea Ice Concentration and Extent, Figure 9 Monthly anomalies of (a) ice extents; (b) ice area; and (c) ice concentration in Northern Hemisphere from November 1978 to June 2013. The bold black lines through the data points are the results of linear regression.

and ice areas occur in September. This means that the growth period takes a longer time than the melt period in the Southern Hemisphere. The maximum and minimum extents and areas go through interannual fluctuations, but they appear relatively stable. It is interesting to note that the maximum values increased from 2003 to 2006 while the minimum values decreased during the same period. In the following 2 years, the reverse happened, but the pattern started to go in the opposite direction in 2009. Such phenomenon suggests that the influence of conditioning from the ocean or previous ice patterns is not strong and that the influence of atmospheric circulation on the interannual variability of the ice cover is likely more important.

Monthly anomalies and trends in ice extent, area, and ice concentration

To assess interannual trends in the ice cover, we use monthly anomalies as has been done previously (Parkinson et al., 1999; Zwally et al., 2002) in order

to minimize the uncertainties associated with the large seasonal variations. The monthly anomalies were estimated by subtracting from each monthly average the corresponding monthly climatological average which in our case is the average of all data for the months from November 1978 to June 2013. The monthly anomalies for the ice extent, ice area, and ice concentration in the Northern Hemisphere are presented in Figure 9 using the enhanced data from SMMR and SSM/I. Interannual fluctuations in extent and area are apparent but are usually less than one million square kilometers except for a few occasions as in 1996, 2007, 2008, 2011 and 2012. The latter correspond to a significant increase in the September ice cover in 1996 and a considerable drop in the September ice cover in 2007, 2008, 2011 and 2012. There was also a significant drop in the ice cover in September of 2009 and 2010 but not as much as the other two. The time series shows that the trends in ice extent and ice area in the Northern Hemisphere are -3.8 ± 0.2 and $-4.4 \pm 0.2 \text{ \%/dec}$ per decade, respectively, the difference associated with

Sea Ice Concentration and Extent, Figure 10 Monthly anomalies of (a) ice extents; (b) ice area; and (c) ice concentration in Southern Hemisphere from November 1978 to June 2013. The **bold black lines** through the data points are the results of linear regression.

the negative trend in ice concentration of $-1.0 \pm 0.1 \text{ \%/decade}$. The decline in ice concentration is relatively minor and can be caused by changes in wind patterns that could cause more divergence in the region. The ice concentration anomalies also show significant drops every year from 1999 to 2012 that may be associated with more storms in the summer during these years.

Similar plots for the anomalies in ice extent, ice area, and ice concentrations but for the Southern Hemisphere are presented in Figure 10. The data show much larger interannual fluctuations in ice extent and ice area in the 1980s than those for the corresponding period at the Northern Hemisphere. Significant variability is also apparent from the year 2000. It is intriguing that anomalously high values occurred in 2008 which also coincide with a rapid recovery in the ice cover in the winter of early 2008 in the Northern Hemisphere from its record of low values in September 2007. This phenomenon is likely

due to an apparent global cooling associated with the La Niña in 2007. The trends for extent and area are shown to be positive at 1.6 ± 0.2 and $2.2 \pm 0.2 \text{ \%/decade}$, respectively, which are significantly higher than previous estimates (e.g., Zwally et al., 2002). Again, the difference in the trends for ice extent and ice area is in part associated with the slight positive trend in ice concentration which is estimated to be about $0.7 \pm 0.1 \text{ \%/decade}$.

The relatively good time resolution of the data also enables the study of the variability of the maximum and minimum extents and areas of the ice cover for each year. The identification of the actual day when the maximum and minimum extents occurred for each year is inferred from the daily data using 5 day running averages, and the plots of maximum and minimum ice extents and areas in the Northern and Southern Hemispheres for the period 1979 to 2013 are presented in Figures 11 and 12. The data provide different values than those from monthly averages

Sea Ice Concentration and Extent, Figure 11 Yearly (a) maximum and (b) minimum extents and ice area of the ice cover in the Northern Hemisphere. Dashed lines correspond to linear regression fit to the data, and trends with statistical errors are indicated.

because of daily changes that are not reflected in the latter. Large interannual variability is apparent, especially in the minimum ice extent and ice area, but the years of high variability do not coincide for the two hemispheres. In the Northern Hemisphere, the trends in maximum extent and area are -2.2 ± 0.3 and $-2.2 \pm 0.4 \text{ \%/dec}$, respectively, while the corresponding values in the Southern Hemisphere are 1.0 ± 0.3 and $1.5 \pm 0.3 \text{ \%/dec}$, respectively. The signs of the trends in the two hemispheres are different, as expected from previous analysis, but the trends are relatively low. The trends in minimum extent and area in the Northern Hemisphere are more dramatic at -11.5 ± 1.6 and $-12.4 \pm 1.6 \text{ \%/dec}$, respectively. Similar results have been reported in several publications (e.g., Comiso, 2002; Comiso et al., 2008), suggesting a rapid decline and a possible disappearance of the Arctic perennial ice cover in a foreseeable future. On the other hand, the trends in minimum extent and area in the Southern Hemisphere are positive at 3.1 ± 2.3 and $3.4 \pm 2.5 \text{ \%/dec}$, respectively, but the relatively large statistical errors suggest that these trends may not be significant.

Sea Ice Concentration and Extent, Figure 12 Yearly (a) maximum and (b) minimum ice extent and ice area of the ice cover in the Southern Hemisphere. Dashed lines correspond to linear regression fit to the data, and trends with statistical errors are indicated.

Discussion and conclusions

Passive microwave satellite data currently provide the only means to obtain a long-term and consistent record of the global sea ice cover. Through the use of an algorithm that utilizes two sets of two-channel data, ice concentration maps in both polar regions have been derived with accuracies that range from about 5 % to 10 % in highly packed ice during dry and cold conditions, around 10–15 % near the marginal ice zones and polynya areas, and 15 % or greater during the peak of the summer when the ice surface is wet and significant meltponding occurs. Consistently derived ice concentration maps at a resolution of 25 km, using SMMR and SSM/I data, have been generated and provide more than three decades of historical data that are suitable for the study of the interannual variability and trends in the ice cover. Meanwhile, newer and more accurate data sets from AMSR-E and AMSR2 with a resolution of 12 km are being generated. This offers the potential of improved characterization of the ice cover and more accurate trend analysis. However, combining AMSR-E with the historical data set for long-term analysis is not trivial because of a potential bias

associated with the different resolutions of the different sensors that causes the retrieval of slightly different extents from AMSR-E and SSM/I data during periods of overlap.

The current time series of ice extent and area data reveal significant trends in the ice cover in the Arctic but counter-intuitive trends in the Antarctic. The results of our regression analysis on monthly ice extent and area anomalies yielded trends of -3.8 ± 0.2 and -4.4 ± 0.2 % per decade, respectively, for the Northern Hemisphere. The corresponding values for the Southern Hemisphere are 1.6 ± 0.2 and 2.2 ± 0.2 % per decade. The trends are 2–3 times higher in the Arctic than the Antarctic, but the signs are opposite. The trends in the yearly maximum extent and area are -2.0 ± 0.3 and -2.2 ± 0.4 % per decade, respectively, in the Northern Hemisphere and 1.0 ± 0.3 and 1.5 ± 0.3 % per decade in the Southern Hemisphere. These trends are significant but relatively small. The trends in the yearly minimum ice extent and area in the Northern Hemisphere are more dramatic at -11.5 ± 1.6 and -12.4 ± 1.6 % per decade, respectively. These results are very important since they suggest that the perennial ice, which is the mainstay of the Arctic sea ice cover, could disappear in the foreseeable future. Trends for the minimum extents and area in the Southern Hemisphere are 3.1 ± 2.3 and 3.4 ± 2.5 which are relatively small and statistically insignificant. Sea ice thus provides a strong climate signal in the Arctic but a weak and poorly understood signal in the Antarctic. Although new insights into the slight positive trend in the Antarctic have been reported, including the possible impact of the ozone hole, further studies are needed to better interpret these results and understand their significance.

- Mean sea level.* The sea level at a single location averaged over short-term variations such as tides and storms.
- Relative sea level rise.* Change in mean sea level at a location along a coast, as would be measured by a tide gauge. Relative sea level change could be caused by changes in the ocean or by a local uplift or subsidence of the land.
- Steric sea level.* A change in sea level caused by a change in the density of the seawater.
- Thermosteric sea level.* The component of steric sea level caused by changes in ocean temperature.
- Halosteric sea level.* The component of steric sea level caused by changes in the salinity of seawater, almost always due to the addition or removal of freshwater.
- Eustatic sea level.* Although the term “eustatic” is antiquated, it is still occasionally used in the literature. Originally, the term was applied by geologists to distinguish globally averaged sea level from local or relative sea level. On geologic timescales, the primary cause of sea level change is changes in the amount of freshwater in the ocean, and steric changes were often ignored. More recently, the term has been used in some oceanographic literature to refer explicitly to the freshwater, or mass, component of globally averaged sea level rise.

Introduction

Over the past decade, popular as well as scientific interest in sea level rise has been fueled by the gradual realization that much of the modern-day rise is caused by human-induced warming of Earth's climate. Over the next century, sea level rise is expected to incur substantial socioeconomic costs due to inundation, increased likelihood of flooding of low-lying areas, loss of coastal wetlands, and many other impacts (IPCC, 2007a). Although the probability is high that sea level will continue rise as the Earth warms, projections of the amount of rise over the next century remain very uncertain (IPCC, 2007b). Nevertheless, with recent observations from satellites, a new in situ observing network for temperature and salinity, tide gauges, and ongoing efforts to reconstruct the sea level record of the past 20,000 years, great strides have been made in understanding the causes and context of modern-day sea level rise (Church et al., 2008).

Holocene

At the peak of the last glacial period about 20,000 years ago, the oceans stood around 120 m below their modern-day levels, and vast ice sheets covered much of North America and Europe. Over the next 10,000 years, the Earth's climate warmed by 4–7 °C and the massive glaciers began to melt, causing rapid sea level rise. Between 8,000 and 6,000 years ago, the rate of rise slowed, reaching modern-day levels about 3,000 years ago (Jansen et al., 2007). Since that time the level of the oceans is thought to have been fairly stable, up until the last century or two. The exact timing of the onset of modern-day sea

SEA LEVEL RISE

Josh Willis
 Jet Propulsion Laboratory, California Institute of
 Technology, Pasadena, CA, USA

Definition

Sea level rise. A general term referring to an increase in the height of the ocean over time.

level rise is not known, but the rate of rise over the past 100 years is large compared to average rates of the past few 1,000 years.

Tide gauge record

Ultimately, what matters most to societies and ecosystems that occupy coastal zones is the local variation in relative sea level or a change in the height of the ocean level relative to that of the land. Traditionally, such changes are measured by tide gauges. Despite the impressive advances of in situ and satellite-based ocean measurements of the past two decades, tide gauge measurements form the cornerstone of the instrumental record of [sea level rise](#) and remain an extremely important source of data. Tide gauge records stretching back to the 1870s ([Figure 1](#)) show that sea level rose by about 20 cm between then and the year 2000, giving an average rate of about 1.8 mm per year over that period (Church and White, 2006). However, tide gauges have several limitations, and chief among these is the fact that sea level rise does not occur uniformly. Changes in ocean circulation may cause local fluctuations that last years or even decades. On longer timescales, changes in the Earth's gravity field also reshape the ocean's surface and prevent spatially uniform sea level rise. Such changes can be driven by changes in the Earth's crust due to processes such as postglacial rebound or even melting of the large ice sheets in Greenland and Antarctica (Mitrovica et al., 2001). Tide gauge measurements also contain signals caused by vertical motion of the land. Although gravitation effects and vertical land motion are often modeled and removed, their presence in the tide gauge data complicates the problem of estimating globally averaged sea level rise (Cazenave and Nerem, 2005).

In situ measurements

On shorter than geologic timescales, the total salt content of the oceans is constant. Increases in ocean volume can therefore be attributed to a net input of either heat or freshwater. Heat-induced volume changes are quantified by globally averaged thermosteric sea level, or the volume-averaged seawater density change caused by thermal expansion. Because of their enormous heat capacity, the oceans are by far the largest reservoirs for the storage of excess heat in the climate system. Over the past 50 years, over 90 % of the excess heat retained by the Earth due to anthropogenic forcing was stored in the world's oceans (Bindoff et al., 2007). For this reason, observations of thermosteric sea level are of particular importance for understanding global warming and the impact of human activities on the climate system.

Comprehensive, high-quality measurements of upper oceans temperature and salinity did not exist prior to the widespread deployment of autonomous floats beginning in 2000 as part of the Argo Project (<http://www.argo.ucsd.edu>). Argo floats now provide global measurements of temperature and salinity in the upper half (about 2 km) of the world oceans. Prior to this, broadscale measurements of temperature were made over much of the oceans, but many were not of sufficient accuracy for climate research. Recently these observations have been recalibrated in order to make estimates of ocean warming thermosteric sea level rise over the past half century (Domingues et al., 2008). These estimates suggest that about one-quarter of the total [sea level rise](#) signal over the past 40 years was caused by thermal expansion in the upper ocean. It is likely that warming in the deep oceans also contributes to sea level rise, but observations of the deep ocean are so sparse that deep warming is difficult to assess in a globally averaged sense.

Sea Level Rise, Figure 1 Globally averaged sea level rise shows a small but significant acceleration between the 1870s and 2000 (Plot is adapted from Church and White (2006) and is based on tide gauge data and spatial patterns from satellite observations of sea level variability).

Satellite era

Beginning with the launch of TOPEX/Poseidon in 1992, satellite altimeters have revolutionized the study of sea level rise by providing nearly global observations of sea level change with local accuracies of a few centimeters. Because ocean currents cause a tilt in the sea surface, changes in ocean circulation can also cause local or regional changes in sea level. The altimeter data showed that such changes often cause local sea level to rise or fall by tens of centimeters over the course of a single year (Figure 2). Furthermore, in situ observations like those of the Argo Project have shown that most of these sea level signals can be attributed to steric, or density-related, changes in the upper oceans (Figure 2). These data have helped to quantify the magnitude and frequency of variability present in all sea level records and to determine the amount of spatial and temporal averaging needed to estimate changes in globally averaged sea level.

Although meticulous calibration and comparisons with tide gauges are still necessary, altimeters now provide the most accurate ongoing record of global sea level rise. Between 1993 and 2008, sea level rose fairly steadily at a rate of about 3 mm per year. This is larger than the 1.8 mm per year average over the last 100 years, and recent studies have attributed this to an acceleration of sea level rise over the course of the 130 year tide gauge record (Church et al., 2006).

Estimates of the contribution to sea level rise from glacier and ice sheet mass loss as well as groundwater use and

sequestration remain highly uncertain over the 130 year instrument record of global sea level rise. Since 2002, however, a pair of satellites known as the Gravity Recovery and Climate Experiment (GRACE) has observed changes in Earth's gravity from space. The gravity data are used to infer the redistribution of water mass across the surface and have provided the first direct measurements of changes in the mass of large glaciers, ice sheets, groundwater, and even the global oceans. GRACE data have shown that Antarctica is losing mass overall (Shepherd and Wingham, 2007) and that Greenland mass loss accelerated between 2002 and 2008 (Witze, 2008). Between 2003 and 2007, GRACE data suggest that the mass-related contribution to globally averaged sea level rise was 0.8 mm per year (Willis et al., 2008). Although GRACE is relatively new and interpretation of its data continues to evolve, it shows great promise as a powerful tool for observing and understanding the mass component [sea level rise](#) caused by the input of freshwater. This is extremely important as much of the uncertainty in sea level projections arises from a lack of understanding of the response of glaciers and ice sheets to anthropogenic climate change.

Future projections

Despite the socioeconomic importance of sea level rise, projections of future sea level remain problematic and controversial (Rahmstorf et al., 2006; Pfeffer et al., 2008). Global climate models predict between 20 and

Sea Level Rise, Figure 2 Change in sea level between 2006 and 2007 from satellite observations (*top panel*). Also shown are the changes in sea surface height caused by thermal expansion in the upper 750 m from the same period based on ocean temperature observations (*bottom panel*) (Updated from Willis et al., 2004).

60 cm of rise over the next 100 years (IPCC, 2007b) due to thermal expansion and simple melting process from glaciers and ice sheets. However, paleoclimate evidence (Rohling et al., 2008; Siddall and Kaplan, 2008) suggests that ice sheets can respond to climate change much more rapidly than is allowed for in the current generation of climate models. This is somewhat alarming given the several meters of sea level equivalent of freshwater contained in Greenland and the West Antarctica, the two ice sheets thought to be most responsive to climate change. Although complete loss of these ice sheets within the next 100 years seems highly unlikely, the range of possible loss rates remains a matter of scientific debate.

Summary

Sea level continues to rise at a rate that is large compared to any average rate over the past few 1,000 years. Furthermore, tide gauge and satellite data have shown that sea level rise has accelerated from an average rate of about 1.8 mm per year over the past 100 years to about 3 mm per year between 1992 and 2008. Although the instrumental record of thermal expansion in the upper ocean is much shorter, it accounted for about 1/3 of sea level rise between 1992 and 2008 and about one-fourth of total sea level rise between 1960 and 2000. Satellite observations of sea level, ocean mass, and the wasting of glaciers and ice sheets have revolutionized understanding of sea level rise and its causes, but projections of sea level rise remain highly uncertain.

SEA SURFACE SALINITY

Gary Lagerloef
ESR, Seattle, WA, USA

Introduction

Surface salinity is an ocean state variable that, along with temperature, controls the density of seawater and influences surface circulation and formation of dense surface waters in the higher latitudes which sink into the deep ocean and help drive the thermohaline circulation. The growing scientific need for global measurements stimulated the development of salinity-observing satellite sensors that have been launched in recent years. These are the European Soil Moisture Ocean Salinity (SMOS) and the US-Argentine Aquarius/SAC-D missions. Salinity remote sensing is possible because the dielectric properties of seawater which depend on salinity also affect the surface emission at certain microwave frequencies. Experimental heritage extends more than 35 years in the past, including laboratory studies, airborne sensors, and one instrument flown briefly in space on Skylab. Requirements for very low noise microwave radiometers and large antenna structures historically have limited the advance of satellite systems. New technologies in the current missions have addressed these issues. Science needs, primarily for climate studies, dictate a resolution requirement of approximately 100–200 km spatial grid, observed monthly, with approximately 0.1–0.2 error on the Practical Salinity Scale (or 1 part in 10,000). These demand very precise radiometers and that several ancillary errors be accurately corrected. Measurements are made in the 1.413 GHz astronomical hydrogen absorption band to avoid radio interference.

Definition and theory

How salinity is defined and measured

Salinity represents the concentration of dissolved inorganic salts in seawater (grams salt per kilogram seawater, or parts per 1,000, and historically given by the symbol ‰). Oceanographers have developed modern techniques based on the electrical conductivity of seawater which permit accurate measurement by use of automated electronic in situ sensors. Salinity is derived from conductivity, temperature, and pressure with an international standard set of empirical equations known as the *Practical Salinity Scale*, established in 1978 (PSS-78) which is much easier to standardize and more precise than previous chemical methods and which numerically represents grams per kilogram. Accordingly, the modern literature often quotes salinity measurements in practical salinity units (psu) or refers to PSS-78. Salinity ranges from near zero adjacent to the mouths of major rivers to more than 40 in the Red Sea. Aside from such

extremes, open ocean surface values away from coastlines generally fall between 32 and 37 (Fig. 1).

Historically, the global mean surface salinity field has been compiled from all available oceanographic observations dating back to the nineteenth century. Modern autonomous profiling buoys (Argo) are now providing near-real-time data from about 3,000 randomly distributed locations every 10 days. Nevertheless, a significant fraction of the 1° latitude longitude cells have no observations, requiring such maps as Fig. 1 to be interpolated and smoothed over scales of several 100 km. Sampling remains most sparse over large regions of the southern hemisphere. Remote sensing from satellites will be able to fill these gaps and monitor multiyear variations globally.

Remote sensing theory

Salinity remote sensing with microwave radiometry is likewise possible through the electrically conductive properties of seawater. A radiometric measurement of an emitting surface is given in terms of a *brightness temperature* (T_B), measured in degrees Kelvin (K). T_B is related to the true absolute surface temperature (T) through the emissivity coefficient (e):

$$T_B = eT$$

For seawater, e depends on the complex dielectric constant (ϵ), the viewing angle (Fresnel laws), and the surface roughness (due to wind waves). The complex dielectric constant is governed by the Debye equation, in simplified form:

$$\epsilon = \epsilon_\infty + \frac{\epsilon_s(S, T) - \epsilon_\infty}{1 + i2\pi f\tau(S, T)} - \frac{iC(S, T)}{2\pi f\epsilon_0}$$

and includes electrical conductivity (C), the static dielectric constant (ϵ_s), and the relaxation time (τ) which are all sensitive to salinity and temperature (S, T). The equation also includes radio frequency (f) and terms for permittivity at infinite frequency (ϵ_∞) which may vary weakly with T and permittivity of free space (ϵ_0) which is a constant. $C(S, T)$ is derived from the *Practical Salinity Scale*. The static dielectric and time constants have been modeled by making laboratory measurements of ϵ at various frequencies, temperatures, and salinities and fitting ϵ_s and τ to polynomial expressions of (S, T) to match the ϵ data. Different models in the literature show similar variations with respect to (f, S, T).

Emissivity for the horizontal (H) and vertical (V) polarization state is related to ϵ by Fresnel reflection:

$$e_H = 1 - \left[\frac{\cos\theta - (\epsilon - \sin^2\theta)^{1/2}}{\cos\theta + (\epsilon - \sin^2\theta)^{1/2}} \right]^2;$$

$$e_V = 1 - \left[\frac{\epsilon\cos\theta - (\epsilon - \sin^2\theta)^{1/2}}{\epsilon\cos\theta + (\epsilon - \sin^2\theta)^{1/2}} \right]^2$$

Sea Surface Salinity, Figure 1 Contour map of the mean global surface salinity field (contour interval 0.5) averaged over the years 2005–2007, interpolated from ocean buoy data (Argo), and supplemented with data from the World Ocean Atlas, 2005 (U.S. Department of Commerce, NOAA, National Oceanographic Data Center). Surface salinity ranges from about 32 to 37 psu. Highest values are in the high-evaporation regions of the subtropics, especially in the Atlantic Ocean, and the Mediterranean Sea. Lowest salinity values coincide with regions with the highest rainfall.

where θ is the vertical incidence angle from which the radiometer views the surface and $e_H = e_V$ when $\theta = 0$. The above set of equations provides a physically based model function relating T_B to surface S , T , θ , and H or V polarization state for smooth water (no wind roughness). This can be inverted to retrieve salinity from radiometric T_B measurements provided the remaining parameters are known. The microwave optical depth is such that the measured emission originates in the top 1 cm of the ocean, approximately.

The rate at which T_B varies with salinity is sensitive to microwave frequency, achieving levels practical for salinity remote sensing at frequencies less than about 3 GHz. Considerations for selecting a measurement radio frequency include salinity sensitivity, requisite antenna size (see below), and radio interference from other (mostly man-made) sources. A compromise of these factors, dominated by the interference issue, dictates a choice of about a 27 MHz-wide frequency band centered at 1.413 GHz, which is the hydrogen absorption band protected by international treaty for radio astronomy research. This falls within a frequency range known as L-band. Atmospheric clouds have a negligible effect, allowing observations in all weather except possibly heavy rain. Accompanying illustrations are based on applying $f = 1.413$ GHz in the Debye equation and using a model that included laboratory dielectric constant measurements at the nearby frequency 1.43 GHz. Figure 2 shows how T_B varies as a function of surface T and S for V and H polarization and incidence angle of 45.6° , which is one of the three incidence angles viewed by Aquarius/SAC-D (along with 28.7° and 37.8°). Note that for either polarization, it is

possible to retrieve salinity if both T and T_B are precisely known at either polarization (dashed lines). In practice, both polarizations will be measured and combined to improve the retrieval accuracy and possibly to determine other parameters such as surface roughness. (Note that at $\theta = 0$, V and H polarization brightness temperatures are identical.) Other features of this model function and their influence on measurement accuracy are discussed in a later section on resolution and error sources.

Antennas

Unusually large radiometer antennas will be required to be deployed on satellites to measure salinity. Radiometer antenna beamwidth varies inversely with both antenna aperture and radio frequency. 1.413 GHz is a significantly lower frequency than that found on conventional satellite microwave radiometers, and large antenna structures are necessary to avoid excessive beamwidth and accordingly large footprint size. For example, a 50 km footprint requires about a 6 m aperture antenna, whereas conventional radiometer antennas are around 1–2 m. To decrease the footprint by a factor of two requires doubling the antenna aperture, whereas reducing the aperture increases the footprint proportionately. Various filled and thinned array technologies for large antennas have now reached a development stage where application to salinity remote sensing is feasible.

History of salinity remote sensing

The first experiment to measure surface salinity from space took place on the NASA Skylab mission during the fall and winter 1973–1974, when a 1.413 GHz

Sea Surface Salinity, Figure 2 Brightness temperature (T_B) as a function of S , T , and polarization (V and H) for typical ocean surface conditions and incidence angle of 45.6° (as an example from one to three Aquarius/SAC-D satellite viewing angles). Salinity can be determined from either polarization if both T_B and T are known (*dashed lines*) (calculations are based on formulas in Klein and Swift, 1977).

microwave radiometer with a 1 m antenna collected intermittent data. A weak correlation was found between the sensor data and surface salinity, after correcting for other influences. There was no “ground truth” other than standard surface charts, and many of the ambient corrections were not as well modeled then as they could be today. Research leading up to the Skylab experiment began with several efforts during the late 1940s and early 1950s to measure the complex dielectric constant of saline solutions for various salinities, temperatures, and microwave frequencies. These relationships provide the physical basis for microwave remote sensing of the ocean as described above.

The first airborne salinity measurements were demonstrated in the Mississippi River outflow and published in 1970. This led to renewed efforts during the 1970s to refine the dielectric constants and governing equations. Meanwhile, a series of airborne experiments in the 1970s mapped coastal salinity patterns in the Chesapeake and Savannah River plumes and freshwater sources along the Puerto Rico shoreline. In the early 1980s, a satellite concept was suggested that might achieve an ideal precision of about 0.25 and spatial resolution of about 100 km. At that time, space agencies were establishing the oceanic processes remote sensing programs around missions and sensors for measuring surface dynamic topography, wind stress, ocean color, surface temperature, and sea ice. For various technical reasons, salinity remote sensing was only marginally feasible from satellite and other types of measurements took precedence.

Interest in salinity remote sensing revived in the late 1980s with the development of a 1.4 GHz airborne Electrically Scanning Thinned Array Radiometer (ESTAR) designed primarily for soil moisture measurements. ESTAR imaging is done electronically with no moving antenna parts, thus making large antenna structures more feasible. The airborne version was developed as an engineering prototype and to provide the proof-of-concept that aperture synthesis can be extrapolated to a satellite design. The initial experiment to collect ocean data with this sensor consisted of a flight across the Gulf Stream in 1991 near Cape Hatteras. The change from 36 psu in the offshore waters to < 32 psu near shore was measured, along with several frontal features visible in the satellite surface temperature image from the same day. This Gulf Stream transect demonstrated that small salinity variations typical of the open ocean can be detected as well as the strong salinity gradients in the coastal and estuary settings demonstrated previously.

By the mid-1990s, a new airborne Scanning Low Frequency Microwave Radiometer (SLFMR) was developed to measure salinity from light aircraft and has been extensively used by NOAA and the US Navy to survey coastal and estuary waters on the US east coast and Florida. A version of this sensor is now being used in Australia, and a second-generation model is presently used for research by the US Navy.

In 1999, a satellite project was approved by the European Space Agency for the measurement of Soil Moisture and Ocean Salinity (SMOS), which was launched in November 2009. The SMOS mission design emphasizes soil moisture measurement requirements, which is done at the same microwave frequency for many of the same reasons as salinity. The T_B dynamic range is about 70–80 K for varying soil moisture conditions, and the precision requirement is, therefore, much less rigid than for salinity. SMOS employs a 6 m aperture two-dimensional phased array antenna system that yields 40–90 km resolution across the measurement swath. For the ocean, SMOS data are averaged over 200 km and 10–30 day scales to reduce measurement noise.

The Aquarius/SAC-D is a joint mission of the USA (NASA) and Argentina (CONAE) and was launched in June 2011. The Aquarius/SAC-D design puts primary emphasis on ocean salinity rather than soil moisture, with the focus on optimizing salinity accuracy with a very precisely calibrated microwave radiometer and key ancillary measurements for addressing the most significant error sources. With this advanced radiometer system and a 2.5 m aperture antenna, Aquarius/SAC-D will yield 0.2 psu accuracy on 150 km scale, monthly.

Requirements for observing salinity from satellite Scientific issues

Three broad scientific themes have been identified for a satellite salinity remote sensing program. These themes relate directly to the international climate research and global environmental observing program goals.

Improving seasonal to interannual climate predictions

This focuses primarily on El Niño forecasting and involves the effective use of surface salinity data (1) to initialize and improve the coupled climate forecast models and (2) to study and model the role of freshwater flux in the formation and maintenance of barrier layers and mixed layer heat budgets in the tropics. Climate prediction models in which satellite altimeter sea level data are assimilated must be adjusted for steric height (sea level change due to ocean density) caused by the variations in upper layer salinity. If not, the adjustment for model heat content is incorrect and the prediction skill is degraded. Barrier layer formation occurs when excessive rainfall creates a salinity-stratified layer between a well-mixed surface layer and the thermocline, which effectively isolates the deeper thermocline from exchanging heat with the atmosphere with consequences on the air-sea coupling processes that, for example, govern El Niño dynamics.

Improving ocean rainfall estimates and global hydrologic budgets

Precipitation over the ocean is still poorly quantified and relates to both the hydrologic budget and to latent heating of the overlying atmosphere. Using the ocean as a rain gauge is feasible with precise surface salinity observations coupled with ocean surface current velocity data and mixed layer modeling. Such calculations will reduce uncertainties in the surface freshwater flux on climate time scales and will complement satellite precipitation and evaporation observations to improve estimates of the global water and energy cycles.

Monitoring large-scale salinity events and thermohaline convection

Studying interannual surface salinity variations in the subpolar regions, particularly the North Atlantic and Southern Oceans, is essential to long time scale climate prediction and modeling. These variations influence the rate of oceanic convection and poleward heat transport (thermohaline circulation) which are known to have been

coupled to extreme global climate changes in the geologic record. Outside of the polar regions, salinity signals are stronger in the coastal ocean and marginal seas than in the open ocean in general, but large footprint size will limit near-shore applications of the data. Many of the larger marginal seas which have strong salinity signals might be adequately resolved nonetheless, such as the East China Sea, Bay of Bengal, Gulf of Mexico, Coral Sea and Gulf of Papua, and the Mediterranean Sea.

Science requirements

The following four topics derive from these science themes. Preliminary accuracy, spatial, and temporal resolution requirements have been suggested as the minimum to derive scientific benefit from satellite observations: (1) barrier layer effects on tropical Pacific heat flux 0.2 (PSS-78), 100 km, 30 days; (2) steric adjustment of heat storage from sea level 0.2, 200 km, 7 days; (3) North Atlantic thermohaline circulation 0.1, 100 km, 30 days; and (4) surface freshwater flux balance 0.1, 300 km, 30 days. Thermohaline circulation and convection in the subpolar seas has the most demanding requirement and is the most technically challenging because of the reduced T_B /salinity ratio at low seawater temperatures (see below). This can serve as a prime satellite mission requirement, allowing for the others to be met by reduced mission requirements as appropriate. Aquarius/SAC-D is a pathfinder mission capable of meeting the majority of these requirements with a grid scale of 150 km and salinity error less than 0.2 psu observed monthly, as noted above. Figure 3 shows the global distribution of sea surface salinity derived from Aquarius measurements for the period August 25, 2011, to July 7, 2012. The near-latitudinal striping is an artifact of the sampling.

Resolution and error sources

Model function

From Fig. 2, it is evident that the dynamic range of T_B is about 4 K over the range of typical open ocean surface salinity and temperature conditions. At a given temperature, T_B decreases as salinity increases, whereas the tendency with respect to temperature changes sign. It is also evident that salinity contours are spread farther apart for V polarization than for H, and therefore, V is slightly more sensitive to salinity changes. The sensitivity also increases with temperature for each polarization. These properties are shown more clearly in Fig. 4. The differential of T_B with respect to salinity (absolute value) ranges from about 0.2 to 0.8 K per salinity unit. Corrected T_B will need to be measured to 0.02–0.08 K precision to achieve 0.1 psu salinity resolution. The difference in sensitivity between polarizations also increases with incidence angle. The sensitivity is strongly affected by temperature, being largest at the highest temperatures and yielding better measurement precision in warm versus cold ocean conditions. Random error can be reduced by temporal and spatial averaging. The degraded measurement precision in higher latitudes

Sea Surface Salinity, Figure 3 Global sea surface salinity derived from the measurements of the Aquarius instrument. Image provided by NASA (<http://aquarius.nasa.gov/gallery-science.html>).

Sea Surface Salinity, Figure 4 The rate that T_B varies with salinity change (sensitivity) depends on temperature, polarization, and incidence angle. The curves are shown here for the three Aquarius/SAC-D satellite mission incidence angles.

will be partly offset by averaging with the greater sampling frequency from a polar-orbiting satellite.

The T_B variation with respect to temperature falls generally between $\pm 0.15 \text{ K } ^\circ\text{C}^{-1}$ and near zero over a broad S and T range. Knowledge of the surface temperature to within a few tenths $^\circ\text{C}$ will be adequate to correct T_B for temperature effects and can be obtained using data from other satellite systems. The optical depth for this microwave frequency in seawater is about 1–2 cm, and the remotely sensed measurement depends on the T and S in that surface layer thickness. T_{BS} for the H and V polarizations have large variations with incidence angle and space craft attitude will need to be monitored very precisely. The accuracy in the proximity to land and ice boundaries will also be degraded, because these surfaces have much higher brightness temperatures than seawater. The best accuracy will be achieved over open water at distances of at least three footprint diameters from land or ice boundaries.

Other errors

Several other error sources will bias T_B measurements and must be either corrected or avoided. These include ionosphere and atmosphere effects, cosmic and galactic background radiation, surface roughness from winds, sun glint, solar flux, and rain effects. Cosmic background and lower atmospheric adsorption are nearly constant biases easily corrected. An additional correction will be needed when the reflected radiation from the galactic core is in the field of view. The ionosphere and surface winds (roughness) have wide spatial and temporal variations and require ancillary data and careful treatment to avoid T_B errors of several K.

The magnitude of the wind roughness correction varies with incidence angle and polarization and ranges between 0.1 and $0.4 \text{ K}/(\text{ms}^{-1})$. It will be the most difficult to correct for accurately and is consequently the largest uncertainty in the error budget. Sea state conditions change significantly within the few hours that may elapse until ancillary measurements are obtained from another satellite. Simultaneous wind roughness measurement can be made with an onboard radar backscatter sensor, such as is included on the Aquarius/SAC-D mission. This provides the most accurate correction possible by using a direct relationship between the radar backscatter and the T_B roughness effect, rather than rely on wind or sea state information from other sources.

The ionosphere affects the measurement through attenuation and through Faraday rotation of the H and V polarized signal. There is no Faraday effect when viewing at nadir ($\theta = 0$) because H and V emissivities are identical, whereas off-nadir corrections are needed to preserve the polarization signal. Correction data can be obtained from ionosphere models and analyses but may be limited by unpredictable short-term ionosphere variations. Onboard correction techniques have been developed that require fully polarimetric radiometer measurements from which the Faraday rotation may be

derived. Sun-synchronous orbits can be selected that minimize the daytime peak in ionosphere activity as well as solar effects.

Microwave attenuation by rain depends on rain rate and the thickness of the rain layer in the atmosphere. The effect is small at the microwave frequency used, but for the required accuracy, either the effect must be modeled and corrected with ancillary data or the contaminated data discarded. For the accumulation of all the errors described here, it is anticipated that the root sum square salinity error will be reduced to less than 0.2 with adequate radiometer engineering, correction models, onboard measurements, ancillary data, and spatiotemporal filtering with methods now in development.

Tables 1, 2 and 3 shows the accumulation of all these factors in an error budget analysis for Aquarius/SAC-D. There is an allocation for each error term, as well as a current best estimate (CBE). These are accumulated as a root sum square (RSS). The retrieval sensitivity as it varies with temperature is used to compute the mean salinity error by latitude band averaged over a month. The root mean square (RMS) of these yields the global monthly error. The CBE is less than the allocation; there is some RSS margin for additional error growth while still meeting the target of 0.2 psu global RMS error.

Sea Surface Salinity, Table 1 An error budget analysis for the Aquarius/SAC-D satellite

Margin RSS (psu)			0.14	

Summary

The technology to measure ocean surface salinity from space has advanced significantly during the past decade. The basic physical principles are well understood. New technologies for radiometer accuracy, large antenna systems, and various ambient corrections have overcome obstacles that inhibited salinity satellite remote sensing in the past. The Aquarius/SAC-D and SMOS satellites provide the unprecedented capability to map the global open ocean salinity field with the necessary resolution and accuracy, which is currently being assessed, to significantly advance the scientific understanding of the links between the ocean circulation, the global water cycle, and the climate.

SEA SURFACE TEMPERATURE

Peter J. Minnett
 Rosenstiel School of Marine and Atmospheric Science,
 University of Miami, Miami, FL, USA

Definition

Historically, [sea surface temperature \(SST\)](#) has been measured by mercury-in-glass thermometers in buckets containing seawater collected by lowering them from ships and, in recent decades, thermistors on buoys or in the engine cooling water intakes of ships. These thermometers measure a temperature at depths of tens of centimeters to a few meters, a temperature often referred to as the “bulk” SST. Recently it has become accepted that it is better to include the depth of the measurement as vertical gradients can exist in the top few meters of the water column. The remotely sensed measurements of SST from satellite infrared radiometers are of a temperature very close to the sea surface, often referred to as the skin temperature. The skin temperature is close to the temperature of the ocean that is in contact with the atmosphere and, as such, is an important parameter that controls the heat and gas transfers between the ocean and atmosphere.

Near-surface temperature gradients

There are physical processes that introduce temperature differences in the uppermost meters of the ocean: the skin effect and diurnal, or daily, heating and cooling. The heat loss to the atmosphere cools the surface by typically between 0.1 and 0.5 K. Diurnal heating can raise afternoon temperatures by several degrees, although ~0.5 K is more typical. These changes are significant given that over much of the world’s oceans the seasonal signal in SST is less than 5 K. Similarly, for the major interannual weather anomalies, such as El Niño, the amplitudes of the associated SST signals are only a few degrees.

Diurnal heating

The ocean absorbs sunlight in the uppermost meters to tens of meters, depending on the water clarity, and as

a result becomes warmer (e.g., Gentemann and Minnett, 2008; Gentemann et al., 2008). When the sea is calm, the heating remains close to the surface, whereas in windy conditions, the turbulence in the upper ocean mixes the heat through the so-called mixed layer, which is typically many tens to a hundred meters deep or more. Thus, in calm conditions, the heat absorption leads to a noticeable increase in SST, but in windy situations, the diurnal SST change can be very small. The diurnal heating is often erased at night as the ocean gives up the heat stored during the day to the atmosphere. The summation over time of the net daily change in SST and in upper ocean heat content gives the seasonal cycles of these variables, increasing in the spring and summer and decreasing in the autumn and winter. In nearly all situations, the ocean is warmer than the overlying surface layer of the atmosphere.

Skin effect

Within the ocean and lower atmosphere, the vertical transport of heat is accomplished by turbulence, but the heat flow from the ocean to the atmosphere occurs through molecular conduction. This requires a temperature gradient to exist as heat is conducted from a warmer to a cooler region. For most situations, the ocean is warmer than the overlying surface layer of the atmosphere. Thus, through molecular conduction, the surface of the ocean, the skin layer, is generally cooler than the water just below, in the subskin layer (for an explanation of the nomenclature, see Donlon et al., (2007)). The temperature difference across the skin layer is dependent on several parameters including wind speed and approaches as constant value of about −0.14 K at high winds (Donlon et al., 2002; Minnett et al., 2011).

Remote sensing of Sea surface temperature

The remote sensing of SST from satellites is based on measuring the thermal emission of electromagnetic radiation from the sea surface, using instruments called radiometers that measure the radiative energy flux at the satellite height in distinct regions of the infrared and microwave parts of the electromagnetic spectrum. The spectrum of the natural emission of radiant energy $B_\lambda(T)$ from a perfectly emitting surface, a “black-body,” at temperature T K is given by the Planck equation:

$$B_\lambda(T) = 2hc^2\lambda^{-5} \left(e^{hc/(\lambda kT)} - 1 \right)^{-1}$$

where h is Planck’s constant, c is the speed of light in a vacuum, k is Boltzmann’s constant, and λ is the wavelength of the radiation. The sea surface, as all natural surfaces, is not a perfect black body, and the radiant emission is reduced by a factor called the emissivity that is wavelength and emission angle dependent, $\varepsilon(\lambda, \theta)$. The black body temperature corresponding to the radiative flux at the satellite height, the “brightness temperature,” is not equal to the skin SST because $\varepsilon < 1$ and the electromagnetic radiation is modified by absorption, emission,

and scattering as it propagates through the atmosphere. The spectrum of atmospheric transmissivity varies between zero and one, and satellite measurements of SST are made where the atmosphere is moderately transmissive. This limits measurements to two atmospheric transmission “windows” in the infrared, at wavelengths of 3.5–4.1 and 8–12 μm . In the infrared, ε of seawater is very high, 0.95–0.98, decreasing for emission angles away from normal. The derivation of SST to useful accuracy from infrared measurements requires correction of the atmospheric and surface effects. For microwaves the frequency range where SST measurements are most feasible is 6–10 GHz, but ε is quite small (0.3–0.5) and strongly dependent on the surface roughness.

Most satellite-derived SSTs come from instruments on polar-orbiting satellites. These orbit the Earth at about 800 km above the surface and take about 100 min for a complete revolution of the Earth, passing close to the poles. Satellite radiometers take measurements across a broad swath of the Earth by using rotating mirrors or push-broom detectors in the infrared and rotating antennas in the microwave. The area scanned in one rotation is incremented by the satellite orbital motion to generate a continuous image, generally centered on the subsatellite track. In the time it takes the satellite to complete an orbit, the Earth’s rotation moves the area seen from the satellite to the west so that the entire Earth’s surface is eventually imaged. Depending on the width of the swath, complete coverage can generally be achieved in 1–3 days.

An important prerequisite for the accurate retrieval of SST from both infrared and microwave radiometers is that the brightness temperature measurements be well calibrated. This requires careful characterization of the instruments prior to launch and, very importantly, accurate calibration of the sensors once in orbit. This is achieved by building into the radiometer calibration targets which have known emissivity and whose temperatures are accurately monitored. A natural calibration target often used in conjunction with the onboard target is deep space, away from the Sun, which has a brightness temperature of 2.7 K.

Infrared radiometers

A major limitation on the derivation of SST from infrared radiometers is the presence of clouds in the intervening atmosphere as they block the emission from the sea surface from reaching the satellite height. The clouds, of course, contribute their own emission to the radiometer measurement. Thus, any measurements containing clouds in the field of view of the radiometer must be identified and removed from the SST retrieval process (e.g., Saunders and Kriebel, 1988; Kilpatrick et al., 2001; Merchant et al., 2005). Because of the need for thorough screening of clouds in the images, all infrared radiometers designed for SST retrieval include channels responsive to scattered solar radiation (in the visible or near-infrared) to help identify clouds, at least during the sunlit part of each orbit.

Atmospheric water vapor absorbs a significant fraction of the sea surface emission in the infrared atmospheric windows, even in clear-sky conditions. The variability of water vapor requires an atmospheric correction algorithm to be applied for the actual, rather than mean, conditions at the time and place of the measurements. This can be accomplished by using measurements taken in distinct spectral intervals in the atmospheric transmission windows where the water vapor effect is different. These spectral intervals are defined by the characteristics of the radiometer and are called “bands” or “channels.” The idea is that the differences in the brightness temperatures measured in two or more channels at different wavelengths are related to the difference between the SST and the brightness temperature in one of them. Despite the complexity of the interactions between the infrared radiation and the molecules in the atmosphere, simple formulation can be used to derive SST to useful accuracy. One such formulation that is currently widely used is the nonlinear SST algorithm (Walton et al., 1998; May et al., 1998):

$$SST = a_0 + a_1 T_{11} + a_2 (T_{11} - T_{12}) SST_r + a_3 (T_{11} - T_{12}) (\sec(\theta) - 1)$$

where SST_r is a reference SST (or first-guess temperature) such as one based on climatology of the area and θ is the zenith angle to the satellite radiometer measured at the sea surface. The angular term accommodates the effects of increasing path length for measurements away from nadir and for the angular dependence of ε . The values of the coefficients a_i are usually determined either by regression analysis of coincident satellite and in situ measurements, mainly from buoys (Kilpatrick et al., 2001), or of simulated satellite measurements using radiative transfer modeling (Llewellyn-Jones et al., 1984; Merchant et al., 2004).

The measurements in the 3.7 μm atmospheric window include reflected and scattered sunlight during the daytime part of each orbit, and so these data are generally used for SST measurements only at night. When used in combination with measurements in the 10–12 μm range, in an algorithm similar to the NLSST, the derived SSTs are generally more accurate than those derived from the measurements in the 10–12 μm range alone.

With improvements in the fidelity of the representation of the atmospheric state in weather forecast models and analyses, in knowledge of the infrared spectroscopy of atmospheric gases, and in computer speed, alternative approaches to the atmospheric correction that make use of radiative transfer simulation of the measurements are being developed and applied (Merchant et al., 2009). These approaches, using optimal estimation techniques, offer potential improvements over the structural limitations of the simple NLSST formulation.

The longest time series of satellite-derived SST measurements has come from the Advanced Very High Resolution Radiometers (AVHRR (Cracknell, 1997)).

Sea Surface Temperature, Figure 1 The global sea surface temperature for May 2001 derived from the measurements of the MODIS on the NASA satellite *Terra*. Black indicates land and sea ice. The effects of cloud cover have been removed by compositing the many images of the cloud-free parts. This compositing inevitably blurs some of the sharp but dynamic boundaries such as the waves which occur along the boundaries of the cold areas extending westward along the equator in the Pacific and Atlantic oceans. The image was generated at NASA Goddard Space Flight center using atmospheric algorithms developed at the Rosenstiel School of the University of Miami.

The first instrument was launched in 1978 on the TIROS-N (Television Infrared Observation Satellite), and a continuous series of AVHRRs have flown on the US NOAA (National Oceanic and Atmospheric Administration) series of polar orbiting operational weather satellites since 1980. A third generation of the AVHRR was launched on the first of a new series of European Meteorological Operational (MetOp) satellite in 2006, with the second launched in 2012. The AVHRR is a relatively simple instrument with five (six in later models) spectral bands of which three ($\lambda = 3.7, 10.5$, and $11.5 \mu\text{m}$) are used for SST retrievals. The spatial resolution at the sea surface is $\sim 1 \text{ km}$ beneath the satellite, becoming larger toward the edges of the $\sim 2,700 \text{ km}$ wide swath. The swath is scanned by a continuously rotating plane mirror inclined at 45° to the axis of rotation that is aligned with the flight vector.

The first MODerate-resolution Imaging Spectroradiometer (MODIS (Esaias et al., 1998)) was launched on the NASA satellite *Terra* in 1999, with a second instrument being launched on *Aqua* in 2002. MODIS is a complex, 36-channel radiometer with five bands being used for SST retrievals. In addition to the standard two in the $10\text{--}12 \mu\text{m}$ window which use the NLSST atmospheric correction algorithm for SST derivation, there are three bands in the $3.7\text{--}4.1 \mu\text{m}$ window, which provide superior accuracy for nighttime SST retrievals. The design of MODIS includes many innovative features intended to improve the instrument performance over that achieved by AVHRR and the accuracy of the derived

variables including SST. These include a two-sided “paddle-wheel” scan mirror and 10 detectors per band (Figure 1).

The successor to the NOAA operational satellite series and the AVHRR will be the Joint Polar Satellite System (JPSS) and the Visible/Infrared Imager/Radiometer Suite (VIIRS). VIIRS is a 22-band radiometer with four bands to be used for SST with wavelengths of $3.7, 4.0, 10.8$, and $12.0 \mu\text{m}$, thereby offering the prospect of continuing the time series of SSTs into future decades. The first VIIRS was launched on the Suomi National Polar-orbiting Partnership (S-NPP) satellite on October 28, 2011.

An alternative approach of addressing the problem of correcting the effects of the atmosphere is to take two measurements of brightness temperatures through different atmospheric path lengths. This is the approach used by a series of European infrared radiometers, the Along-Track Scanning Radiometers (ATSR), first launched in 1991. The ATSRs use an inclined conical scan, rather than the linear cross-track scan used by the other instruments described above, which provides a measurement through one thickness of the atmosphere beneath the satellite and through about two thicknesses through the inclined view ahead of the satellite. The ATSR has the same infrared bands as AVHRR with wavelengths of $3.7, 10.8$, and $12.0 \mu\text{m}$, and the linear combination of the brightness temperatures in these bands at two angles provides a more accurate SST retrieval than without the dual view (Noyes et al., 2006). Again, the $3.7 \mu\text{m}$ measurements can only be used during the nighttime part of each orbit.

The disadvantage of the conical scan is the limited width of the swath, being about 500 km centered on the subsatellite track (Prata et al., 1990; Minnett, 1995). The third instrument of this type, the Advanced ATSR, flew on *Envisat* and provided data for a decade before mission ended on 8 April 2012, following an irreversible loss of communications with the satellite.

Dual-view SST observations are planned to resume with the launch of the Sentinel-3 missions, the first of which is planned for 2014 (Donlon et al., 2012). These will be the Sea and Land Surface Temperature Radiometers (SLSTRs (Coppo et al., 2010)), which are similar to the ATSRs but will have a wider swath. Further improved coverage will be gained from the two satellites being operational at the same time.

Microwave radiometers

The atmospheric contamination of microwave brightness temperatures is primarily from water vapor, oxygen, and liquid water. While the vertically integrated oxygen absorption is effectively constant, the water vapor and liquid water are highly variable. The microwave radiometers are designed to measure in atmospheric windows for SST, but also at wavelengths that are strongly absorbing in water vapor or liquid water. This allows simultaneous measurement of these variables, which can then be used to determine SST through cloud and water vapor. Microwave radiometers require large mirrors (antennas) and have a much lower spatial resolution than infrared SST measurements. Furthermore, the ill-defined edges of the fields of view of the instruments that result from the diffraction limitation of the antenna means that measurements close to coastlines are contaminated by emission from the land surface through the antenna side lobes. This limits microwave measurements of SST to about 50–100 km offshore. The sea surface emissivity in the microwave is very dependent on the emission angle, and to minimize this effect on the brightness temperatures, the antennas rotate about a vertical axis tracing out a curved swath on the sea surface at constant zenith angle. Emissivity of the ocean surface is highly dependent on wind speed and direction, which can be estimated by measuring vertical and horizontal polarizations. A combination of the brightness temperatures results in the retrieval of SST, wind speed, and other geophysical variables (Wentz and Meissner, 2000).

Although earlier instruments were capable of measuring SSTs, the current time series of measurements began in 1997 with the launch of the TMI (TRMM Microwave Imager) on the Tropical Rainfall Measuring Mission (TRMM) satellite (Kummerow et al., 1998). As its name suggests, TRMM is focused on tropical measurements, and the SST measurements are restricted to within about 40° of the equator.

The *Aqua* satellite that carries a MODIS also has the Advanced Microwave Scanning Radiometer for the Earth Observing System (AMSR-E; Kawanishi et al., 2003),

which is the current prime source of microwave SST measurements. The polar orbit removes the latitude constraint of the TMI. AMSR-E has six frequency channels from 6.9 to 89 GHz, with the low-frequency channel providing sensitivity to SST variations. The 6.9 GHz channel has a footprint of 43×75 km, but the data are oversampled and SST is retrieved on a spatial grid of 25 km across a swath of 1,450 km width. The AMSR-E measurements were terminated on October 2011 when the torque required to turn the antenna exceeded safe limits, presumably caused by the consumption of lubricant.

The next-generation AMSR, AMSR-2, was launched on the Japanese GCOM-W1 (Global Change Observation Mission – Water) satellite on May 17, 2012. The AMSR-2 has similar characteristics to AMSR-E but with a larger, 2 m antenna.

Applications

The SST is one of the most important parameters in the Earth's climate system. It is related to the heat stored in the upper ocean and helps regulate the flow of heat to the overlying atmosphere, thus linking the two great fluid components of the climate. The heat in the upper ocean feeds the growth of severe storms (Shay et al., 2000) or, where the heat content has been diminished by the recent passage of a prior storm (e.g., Minnett, 2007), can lead to sudden weakening of a hurricane (Wentz et al., 2000). Accurate SST fields are required as input to Numerical Weather Prediction (NWP) models and the emerging activity of operational oceanography (Donlon et al., 2007). Time series of global SST fields have been suggested as sensitive indicators of the response of the climate to greenhouse gas forcing (Allen et al., 1994; Good et al., 2007). The patterns of SST reveal the structure of surface currents, the complexity of the oceanic mesoscale eddies and frontal meanders, and the characteristics of upwelling areas, and perturbations of the SST fields indicate climate anomalies, such as the El Niño–Southern Oscillation (ENSO) that modifies weather patterns over a large part of the globe for months to seasons at a time (Philander, 1989).

Accuracies of the sea surface temperatures

The usefulness of SSTs in any application is determined by the accuracy of the retrievals. Too great an uncertainty in the derived SSTs would render them unsuitable for many purposes – given the small size of the signals being sought, an accuracy of a few tenths of a degree is required. Not only is this difficult to achieve, but it is also difficult to demonstrate that it has been achieved. The usual way of determining the uncertainties in the satellite measurements is to compare them with other data taken at the same time and place, and the most bountiful source of independent temperatures are the surface drifting buoys. Over 10,000 sets of coincident measurements of wide-swath satellite imagers and drifting buoys in cloud-free conditions can be expected in most years. These provide

confident estimates of the differences between the satellite and the bulk SSTs (e.g., Kilpatrick et al., 2001), but because the buoys measure at 0.1–1.0 m depth, these statistics include contributions from the temperature differences caused by variations in the skin effect and in diurnal heating. A more accurate determination of the satellite SST uncertainties involves the use of ship board infrared radiometers to measure the skin SST (Barton et al., 2004), but the number of coincident measurements is much smaller, especially for the narrow swath ATSR series (Noyes et al., 2006). Nevertheless, the use of radiometric skin SST measurements reduces the values of the satellite SST uncertainties, by as much as a factor of 2 (Kearns et al., 2000). The best estimates of the SST accuracies from the AATSR is about 0.15–0.30 K (standard deviation) with a bias of < 0.2 K (Noyes et al., 2006; O’Carroll et al., 2008). For the AVHRR and MODIS, the standard deviations are 0.3–0.5 K, again with small mean uncertainties. AMSR-E SST uncertainties are 0.4–0.5 K (Wentz et al., 2003) and somewhat higher for TMI (Gentemann et al., 2004).

In regional comparisons, the mean and standard deviations of uncertainties can deviate from the global statistics (e.g., Kearns et al., 2000; Gentemann et al., 2008; Merchant et al., 2009). Anomalous atmospheric conditions can lead to larger errors in infrared SST retrievals, such as those that result from the presence of volcanic aerosols high in the atmosphere (Reynolds, 1993; Blackmore et al., 2012).

Summary

The accurate remote sensing of SST from polar-orbiting spacecraft is one of the major accomplishments of the satellite era. A time series of global SSTs now extends for over two decades and provides a valuable resource for studies of the climate system and many other oceanographic and meteorological phenomena. The provision of global SSTs with only a few hours delay is now an accepted part of numerical weather prediction, and research and operational efforts are currently directed at improving the accuracy of the SST fields and how they can contribute to better weather and ocean forecasting (Donlon et al., 2007). The continued measurement of SST from satellites is planned through the next decade and longer with the US JPSS, the Japanese GCOM, and the European MetOp and GMES (Global Monitoring for Environment and Security) Sentinel-3 programs.

SEA SURFACE WIND/STRESS VECTOR

W. Timothy Liu and Xiaosu Xie
 Jet Propulsion Laboratory, California Institute of
 Technology, Pasadena, CA, USA

Definition

Wind is air in motion and is basically a vector quantity with a magnitude (speed) and a direction. Ocean surface stress is another vector quantity closely related to wind; it is the turbulent transfer of momentum between the ocean and the atmosphere. Their different applications are summarized in the section “[Scientific significance](#).”

Introduction

Sailors understand both the importance and the difficulty in obtaining information on wind over oceans. The textbooks still describe global ocean wind distribution in sailor’s terms: the calms of the Doldrums and Horse Latitudes, the steady Trade Winds, and the ferocity of the Roaring Forties. Just a few decades ago, almost all ocean wind measurements came from merchant ships. However, the quality and geographical distribution of these wind reports were uneven. Today, operational numerical weather prediction (NWP) also gives us wind information, but NWP depends on models, which are limited by our knowledge of the physical processes and the availability of data.

The ocean interacts with the atmosphere in nonlinear ways; processes at one scale affect processes at other scales. Adequate coverage can only be achieved from the vantage point of space. Space-based microwave sensors observe through clouds and measure ocean surface properties, backscatter, or emissivity, which are more

directly related to stress than wind. The microwave scatterometer is the best-established instrument to measure surface stress magnitude and direction under clear and cloudy conditions, night and day, as described in the section “[Scatterometry](#).” Until the launch of the scatterometer, our knowledge of stress distribution was largely derived from winds. Wind and stress have been mixed up in the interpretation of these space-based measurements. The section “[Wind and Stress Relation](#)” helps us to understand their relation and makes better use of the scatterometer observations.

The primary functions of the radar altimeter, the synthetic aperture radar (SAR), and the microwave radiometer are not wind-stress measurements, but they give wind speed as a secondary product. Wind speed, even without direction, is important, and wind speed from these sensors can be applied with directional information derived from other means. The polarimetric radiometer was also found recently to be sensitive to wind direction. The techniques of these sensors are briefly summarized in the section “[Other sensors](#).”

Scientific significance

Ocean wind is strongly needed for marine weather forecast and to avoid shipping hazards. Space-based wind measurements have been assimilated into operational NWP and used routinely in national centers for marine warning and forecasting. Surface wind convergence brings moisture and latent heat that drives deep convection and fuels hurricanes. The significance of wind measurement is clearly felt, for example, when a hurricane suddenly intensifies and changes course or when the unexpected delay of monsoon brings drought. Detailed distribution of wind power is also needed for the optimal deployment of floating wind farms in open sea that are enabled by new technologies (Liu et al., 2008a).

Wind-induced stress drives ocean current (ageostrophic component) and generates wave. The two-dimensional stress field is needed to compute the divergence and curl (vorticity) that control the vertical mixing. The mixing brings short-term momentum and heat trapped in the surface mixed layer into the deep ocean, where they are stored over time. It also brings nutrients and carbon stored in the deep ocean to the surface, where there is sufficient light for photosynthesis. The horizontal currents, driven in part by stress, distribute the stored heat and carbon in the ocean. Stress affects the turbulent transfer of heat, moisture, and gases between the ocean and the atmosphere and is critical in understanding and predicting weather and climate changes.

Relations between wind and stress

Ocean surface stress (τ) is the turbulent transfer of momentum generated by atmospheric instability caused both by wind shear (difference between wind and current) and buoyancy (vertical density stratification resulting from temperature and humidity gradients). Direct τ

measurement has only been done in a few field campaigns in the past. For all practical purposes, our knowledge of τ is derived from winds (U) at a reference height through a drag coefficient C_D , which is defined by

$$\tau = \rho C_D (U - U_s)^2 \quad (1a)$$

where U_s is the surface current and ρ is the air density.

In a similar fashion, the turbulent fluxes of heat (H) and moisture (E) have been related to the mean parameters – wind speed U , potential temperature T , specific humidity Q at 10 m, and [sea surface temperature](#) T_s , through

$$H = \rho C_P C_H (T - T_s)(U - U_s) \quad (2a)$$

$$E = \rho C_E (Q - Q_s)(U - U_s) \quad (3a)$$

where C_P is the isobaric specific heat. The mean parameters are the measurements generally available from routine ship reports. In the past, the transfer coefficients, C_H and C_E , were approximated with the same values as C_D .

The transfer coefficient has been derived largely in field campaigns. [Figure 1](#), from Liu et al. (1979), illustrates the behavior of C_D at neutral stability. At low wind speed ($U < 3$ m/s), the flow is smooth; C_D increases with decreasing wind speed. And at moderate wind $3 < U < 25$ m/s, C_D is an increasing function of wind speed for a rough sea with open fetch. Stability and surface roughness are the main factors affecting the variability of the coefficients. Secondary factors, such as sea states and spray from breaking waves, whose data are not generally available are not included in these parameterization schemes and should be part of the errors (e.g., Bourassa et al., 1999).

Liu et al. (1979) first postulated that, in a rough sea, under a moderate range of winds, C_H and C_E do not increase with wind speed because of molecular constraint at the interface, while C_D may still increase because momentum is transported by form drag. Liu’s hypothesis, as illustrated in [Figure 1](#), was subsequently supported by measurements in field experiments (e.g., DeCosmo et al., 1996).

Emanuel (1995) argued, from theoretical and numerical model results, that the scenario of Liu et al. (1979) could not hold at the strong wind regime of a hurricane. To attain the wind strength of a hurricane, the energy dissipated by drag could not keep increasing while the energy fed by sensible and latent heat does not increase with wind speed. His argument puts limit on the increase of C_D as a function of wind speed. The postulation of the level-off of the increase of C_D with wind speed at hurricane scale winds was supported by the results of the laboratory studies of Donelan et al. (2004) and the aircraft experiments by Powell et al. (2003), as illustrated in [Figure 2](#). The result of Large and Pond (1981), derived for the range of moderate wind speeds, is extrapolated to the range of strong wind speeds for comparison in the figure. The high wind behavior of C_D may post constrain in retrieving hurricane scale winds by the scatterometer.

Sea Surface Wind/Stress Vector, Figure 1 Variation of the bulk transfer coefficients of momentum (drag coefficient), heat, and moisture with wind speed by Liu et al. (1979).

Sea Surface Wind/Stress Vector, Figure 2 Variation of the drag coefficients in strong winds.

Liu et al. (1979), for the first time, performed the bulk parameterization of the surface fluxes by solving the nondimensional flux-profile relations (also called similarity functions), thus including the effects of stability and surface molecular constraints. The functions are:

$$\frac{U - U_s}{U_*} = 2.5 \left(\ln \frac{z}{z_0} - \psi_U \right) = \frac{1}{\sqrt{C_D}} \quad (1b)$$

$$\frac{T - T_s}{T_*} = 2.5 \left(\ln \frac{z}{z_T} - \psi_T \right) = \frac{\sqrt{C_D}}{C_H} \quad (2b)$$

$$\frac{Q - Q_s}{Q_*} = 2.5 \left(\ln \frac{z}{z_Q} - \psi_Q \right) = \frac{\sqrt{C_D}}{C_E} \quad (3b)$$

where $U_* = (\tau/\rho)^{1/2}$ is the frictional velocity; T_* and Q_* are nondimensional flux parameters defined as $T_* = H/(C_P U_*)$ and $Q_* = E/(U_*)$; z_0 , z_T , and z_Q are the roughness lengths; and ϕ_U , ϕ_T , and ϕ_Q are functions of the stability parameter, which is the ratio of buoyancy to shear production of turbulence. When U_s and ϕ_U are zero, U becomes the equivalent neutral wind (U_N), which is uniquely related to U_* (or τ). U_N has been used as the geophysical product of the scatterometer.

Typical wind profiles at various stabilities are shown in Figure 3. The atmosphere is rarely exactly neutral. Even when there is no vertical temperature gradient, there is likely to be a humidity gradient. To compute U_N from conventional wind measurements of U (A on the blue

Sea Surface Wind/Stress Vector, Figure 3 Typical wind profiles at various stability conditions derived from the flux-profile relation by Liu et al. (1979). B is the equivalent neutral wind corresponding to the actual wind measurement at A.

curve in Figure 3), U_* and z_0 are computed as the slope and intercept at the surface of the curve. The neutral relation (straight line) defined by U_* and z_0 will give U_N (point B). This method has been used in algorithm development and calibration of all scatterometers launched by NASA. At a given level, U_N is larger than the actual wind (U) under unstable conditions but lower under stable condition. From Equation 1b, $U_N - U = 2.5U_*\psi_U$, assuming the dependence of z_0 on buoyancy is much smaller than on wind shear. This difference is the inherent error of using scatterometer measurement as the actual wind. While the parameterization method by Liu et al. (1979) has been improved (e.g., Fairall et al., 1996), the formulation of ψ was largely based on experimental data taken on land, validated only with small amount of measurements over ocean, and may still have considerable uncertainties.

Scatterometry

During the Second World War, marine radar operators observed noises on their radar screens, which obscured small boats and low-flying aircraft. They termed this noise “sea clutter.” This clutter was the backscatter of the radar pulses by the small waves on the ocean’s surface. The radar operators at that time were quite annoyed by this noise, not knowing that a few decades later, scientists would make important use of it.

Scatterometers send microwave pulses to the Earth’s surface and measure the power backscattered from the surface roughness. The roughness may describe the characteristics of polar ice or vegetation over land. Over the ocean, which covers over three quarters of the Earth’s

surface, the surface roughness is largely due to the small centimeter wavelength waves on the surface. These surface waves are believed to be in equilibrium with the local stress. The backscatter depends not only on the magnitude of the stress but also the stress direction relative to the direction of the radar beam (azimuth angle). The capability of measuring both stress magnitude and direction is the major, important characteristic of the scatterometer. Liu and Large (1981) were first to relate scatterometer and direct stress measurements.

There are far fewer stress than wind measurements for validation and calibration, and the equivalent neutral wind (U_N) is used as the geophysical product of the scatterometer (Liu and Tang, 1996). By definition, U_N is uniquely related to τ , while the relation between τ and U depends on atmospheric stability, as discussed in the previous section. U_N is similar to U_* and can be viewed as stress in wind units.

At incident angles greater than 20° , the radar return is governed by Bragg scattering, and the backscatter increases with U_N . The backscatter is governed by the inphase reflections from surface waves. The geophysical model function (GMF), from which U_N is retrieved from the observed backscatter, in form of the normalized radar cross section (σ_o), is largely based on empirical fits of data. The symmetry of backscatter with respect to wind direction requires observations at multiple azimuth angles to resolve the directional ambiguity. Because of the uncertainties in the wind retrieval algorithm and noise in the backscatter measurements, the problem with directional ambiguity was not entirely eliminated even with three

Sea Surface Wind/Stress Vector, Figure 4 (a) Filtered vector (*black arrows*) superimposed on vorticity (color, 10^{-6} s^{-1}) of U_N observed by QuikSCAT. (b) Filtered vector (*black arrows*) superimposed on vorticity of the surface current measured by Lagrangian drifters.

azimuthal looks in the scatterometers launched after Seasat. A median filter iteration technique has been commonly used to remove the directional ambiguity.

Although scatterometers are known to measure surface stress, they have been used and promoted as wind measuring instruments and U_N has been used as the actual wind, particularly in operational weather applications. This is justified on the assumption that, over the large expanse of ocean, ocean current is weak compared with wind and the atmosphere is under near neutral conditions. Over the Agulhas Extension and the Kuroshio Extension current with sharp horizontal current shear and temperature gradients, however, Liu et al. (2007) and Liu and Xie (2008) show that stress could be very different from winds. Over the current meanders, one would expect that the wind will be dragged in the direction of the current. Figure 4 clearly shows that where the vorticity of U_N measured by

QuikSCAT is positive, the vorticity of the surface current measured by the drifters is negative and vice versa, indicating almost opposite rotations. This is a clear indication that the scatterometer measurement has the characteristic of turbulent stress generated by shear rather than wind. The directional difference between scatterometer measurement and current exists because the scatterometer measures stress, which is the vector difference between wind and current (Park et al., 2006).

The ubiquitous spatial coherence between sea surface temperature (T_s) and U_N measured by the scatterometer found under a variety of atmospheric conditions is also the characteristics of turbulent stress generated by buoyancy. In the unstable region, atmospheric buoyancy generates turbulent momentum transport and increases the stress magnitude. Figure 5a shows the coherence over the Kuroshio Extension. Figure 5b shows similar

Sea Surface Wind/Stress Vector, Figure 5 Isotherms of filtered T_s measured by AMSR-E (0.2 °C interval) superimposed on (a) filtered magnitude of QuikSCAT U_N (color, m/s), and (b) filtered U_N computed from a uniform wind field of $u = 7.5$ m/s. Solid and broken lines represent positive and negative values, respectively.

coherence between T_s and U_N computed from a uniform wind field under similar stability condition, demonstrating that the coherence is the characteristic of stress and not wind. Factors affecting larger-scale wind, such as pressure gradient force, Coriolis force, and baroclinicity, are not important at the small scales of turbulence, and that is the reason of ubiquitous coherence under various atmospheric conditions. The higher stress over warmer water affects atmospheric wind aloft, but the influence will be subjected to these large-scale factors. Ocean parameters, such as surface current and temperature, are needed to derive wind from stress in these frontal regions.

Retrieving strong winds from the scatterometer measurements is also difficult. The problem is obvious in Figure 6, derived from NASA's scatterometer on QuikSCAT measuring at Ku-band. Data for the 12 hurricanes in the North Atlantic in the 2005 seasons, excluding those with over 10 % chances of rain, were examined.

Figure 6 shows that, in moderate winds ($U < 35$ m/s), the logarithm of σ_o (in db) increases linearly with the logarithm of wind speed, at both polarizations. At strong winds ($U > 35$ m/s), however, σ_o increases at a much slower rate with increasing wind speed. Similar saturation is found in the European Advanced Scatterometer (ASCAT), measuring at C-band. Such high wind saturation has also been observed from aircraft flying over hurricanes.

When the model function developed over the moderate wind range is applied to the strong winds, an underestimation of wind speed results. Strong efforts have been made to adjust the model function (slope in Figure 3) in strong winds and to find the right channel (combination of polarization, frequency, incident angle) that would be sensitive to the increase of strong winds (e.g., Fernandez et al., 2006). The success would be difficult if flow separation occurs at high winds and the surface roughness and stress

Sea Surface Wind/Stress Vector, Figure 6 Normalized radar cross section at two polarizations measured by QuikSCAT for 12 hurricanes as a function of colocated surface wind provided by the National Hurricane Center.

do not increase with winds as discussed in section “[Relations between wind and stress.](#)”

Direct stress retrieval

Weissman and Graber (1999) made an early attempt to build a GMF to retrieve stress instead of wind. There are many reasons for a GMF-S (stress) to retrieve stress (or U_*) directly rather than the present GMF-W to retrieve U_N . The first reason is the deficiency of the present GMF-W, which should be developed and calibrated with U_N computed from research quality in situ wind measurements, as described in the section “Relations between wind and stress.” Such computation of U_N from in situ measurements was performed before credible ocean surface wind products became available from operational NWP centers. Most of the tuning of the revised GMF after Seasat was based on NWP products that are not U_N (not corrected for stability dependence). The resultant errors are not reversible and difficult to gauge.

The second reason is the uncertainty of the drag coefficient. Ideally, stress could be derived from U_N retrieved from the scatterometer, using a neutral drag coefficient. However, if the drag coefficient is not the same as that was used to derive U_N for development of the GMF, error will be introduced through the uncertainty of drag coefficient.

The other two reasons are related to the directional difference between wind and stress. The procedure to “select” the stress direction should be different from wind direction in two ways. In the first way, we should initialize the ambiguity removal process with “nudging” fields that are more relevant to stress than wind. Where a strong ocean current exists, the stress should point to the direction of the vector difference between wind and current. The second way is to develop a flexible median filter to accommodate the small spatial scale of stress as compared

with winds. One of the problems of the selection is the lack of sufficient current information.

One of the reasons usually given for promoting scatterometer as a wind sensor instead of a stress sensor is that there is more wind than stress measurements to develop and calibrate the GMF. Such an explanation is not valid because U_N , by definition, has an unambiguous relation with stress and needs stress for computation. To provide each U_N for development or calibration of the GMF from measured wind U , stress or U_* has to be computed first as discussed in the section “Relations between wind and stress.”

The stress derived from wind in such a way is not ideal because it addresses only the stability problem but does not include current information. Such deficiency may be somewhat alleviated through the ambiguity removal process by using more appropriate filter size and nudging with the vector difference between wind and optimal surface current information that is available. The direct retrieval of stress depends not only on the fast and large-scale atmospheric circulation but also on the small-scale and slow ocean processes, as reflected in surface current and temperature.

Other sensors

Both the microwave altimeter and SAR are similar to the scatterometer in the sense that they are active sensors that send microwave pulses to the Earth’s surface and measure the backscattered power. The microwave radiometer is a passive sensor, observing the radiance emitted by the Earth and its atmosphere.

While the scatterometer views at oblique angles, the altimeter views at nadir (very small incident angles). At nadir, the backscattered energy is a result of specular reflection (the wavelets serve as small mirrors), and the backscatter is not sensitive to U_N direction. Because the

instrument is not scanning, data are only available at very narrow (2 km) repeated ground tracks. The coverage of all the past altimeters is poor compared with the scatterometer and the microwave radiometers.

A SAR looks perpendicular to aircraft path only at one azimuth angle and cannot resolve the U_N direction like the scatterometer. SAR has spatial resolutions that are much better than scatterometers, but the high resolution also introduces higher uncertainties in accuracy caused by secondary effects that affect surface roughness. The instrument and the data processing procedure are much more complicated than the scatterometer. The scatterometer GMF can be used to relate the σ_o measured by SAR to U_N . However, a particular value of σ_o may correspond to a range of U_N , depending on the azimuth angle. Hence, in order to retrieve U_N with the GMF, the U_N direction must first be specified. Whether the a priori direction information is derived from the orientation of km-scale structure in the SAR image or from operational NWP models, the spatial scales are much coarser than those of σ_o .

Ocean surface wind speed has also been derived from the radiance measured by a microwave radiometer. It is generally believed that wind speed affects the surface emissivity indirectly through the generation of ocean waves and foam. Radiometers designed to observe the ocean surface operate primarily at window frequencies, where atmospheric absorption is low. Radiances at frequencies sensitive to [sea surface temperature](#), atmospheric water vapor, and liquid water are also measured; they are used to correct for the slight interference by the atmosphere. It was demonstrated in several airborne experiments (e.g., Yueh et al., 1997) that the polarization properties of the sea surface emission vary not only as a function of the wind speed but also as a function of wind direction. The wind direction measuring capability is being tested by a polarimetric radiometer, WindSat on the Coriolis satellite, developed by the US Navy.

Potential improvements

Historically, the European Space Agency used the C-band (5 GHz), but NASA prefers the Ku-band (14 GHz) for their scatterometers. The backscatter at higher frequencies is more sensitive to shorter ocean waves. The Ku-band is more sensitive to weak wind-stress variations but is more subject to atmospheric effects and rain contamination. Attempts have been made to retrieve winds from L-band (1.4 GHz) scatterometer on Aquarius (Yueh et al., 2013). There have been calls for a multifrequency scatterometer that is sensitive to various parts of ocean surface wave spectrum and may reduce atmospheric and rain effects.

Present scatterometers are real-aperture systems and the spatial resolution is limited by the antenna size. A larger antenna will, of course, enhance the spatial resolution. Another way to achieve higher resolution is to add

a synthetic aperture capability. One of the drawbacks of present scatterometers is the ambiguity in retrieving wind-stress direction. The backscatter is a cosine function of the azimuth angle. The correlation between co-polarized and cross-polarized backscatter is a sine function of azimuth angle. By adding polarized measurement capability to the scatterometer, the directional ambiguity problem could be mitigated.

One polar-orbiting scatterometer at a low-altitude (e.g., 800 km) orbit can sample at a location on Earth not more than two times a day. Additional instrument flying in tandem will allow the description of higher temporal variability and the reduction of the aliasing (bias introduced by subsampling) of the mean wind stress. As demonstrated by Liu et al. (2008b), adding ASCAT to QuikSCAT decreases the time required to cover 90 % of the Earth from 24 to 19 h. Adding Oceansat-2 of India resolves the inertial frequency desired by oceanographers and provides 6 hourly repeated coverage required by operational weather forecasters. The adverse effect due to the demise of QuikSCAT should be mitigated by data from WindSat or the scatterometer on Haiyang-2 of China. The scatterometer on Space Station will provide new sampling opportunity.

Not all space-based ocean surface wind and stress measurements are comparable in quality. Standardizing the technology requirements for observation accuracies of different research and operational applications and international cooperation are very desirable. Many scientific reports have affirmed the need for high-quality, continuous, and consistent long time series of ocean surface vector winds and stress.

Conclusion

The basics of scatterometry and air-sea turbulence transfer are reviewed to bring out the uniqueness of the scatterometer in measuring ocean surface stress in addition to wind. The ubiquitous spatial coherence of scatterometer measurements with ocean surface temperature and current is attributed to the two ocean factors that drive the buoyancy and wind-shear production of turbulence transfer (stress); the factors are less directly influential on wind. The reduced sensitivity of the scatterometer to the increase of wind speed at hurricane scale winds is related to the failure of conventional drag coefficient caused by flow separation. A scatterometer that measures stress better than wind is still important to the estimation of the dynamic forcing and the oceanic feedback that affects the maintenance and intensification of the storm. The feasibility, advantage, and need for a geophysical model function to retrieve stress directly rather than the equivalent neutral wind (the present geophysical product of the scatterometer) are explained. The direct retrieval of stress from scatterometer measurements will enable new science applications with a new perspective, as expounded by Liu et al. (2010).

Acknowledgments

This study was performed at the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration (NASA). It was jointly supported by the Ocean Vector Winds, Ocean Surface Salinity, and Precipitation Measuring Mission Programs of NASA. Wenqing Tang provided valuable assistance.

SEVERE STORMS

Charles A. III Doswell
Doswell Scientific Consulting, Norman, OK, USA

Synonyms

Severe convection; Severe local storms; Severe weather

Definition

Severe storms. Any deep convective storm, usually associated with lightning and thunder, that produces one or more of the following: large hailstones, strong winds, and/or tornadoes. For the United States, the threshold diameter for severe hail is 2.54 cm (1 in.) and the threshold speed for severe winds is 25 m s^{−1} (50 knots), but *any* tornado is considered severe (tornadoes are ranked in six categories according to the *Enhanced Fujita scale* (Fujita, 1971), ranging from EF0 to EF5). In many countries,

heavy rainfall is also considered a severe storm, with varying thresholds for rainfall per unit time (Doswell III et al. 2009).

Introduction: deep, moist convective storms

Any type of weather can be called severe: extremely high or low temperatures, extended periods without rainfall, heavy snowfall, freezing drizzle or rain, and so on. However, the generally accepted use of the term “severe weather” is for the events produced by deep convective storms (Ludlam, 1963; Doswell III, 2001). Such storms are typically accompanied by lightning and thunder caused by that lightning, but in some cases, the clouds are not sufficiently electrified to produce lightning discharges while still capable of some forms of severe weather.

Severe convection is the result of a condition broadly referred to as *conditional instability* (Schultz et al., 2000). This type of instability results from an excess of latent and sensible heat at low levels, which in turn is due to incoming solar radiation that both heats the surface and enhances evapotranspiration of water into the atmosphere in vapor form. The heated surface conducts its heat to the atmosphere immediately above the surface, which then carries that heat upward by *convection*. As meteorologists use the term, convection refers to the transport of atmospheric properties in the vertical by the motion of the air itself – it can be considered a form of mixing that is a response to the imbalance created when the air is heated from below.

Water vapor plays a critical role in the development of severe convection by releasing latent heat – which became “latent” when the liquid water evaporated into the overlying air or was “exhaled” during transpiration by plants – during the process of condensation into cloud droplets. It is the energy associated with latent heat release that powers deep convective clouds and which then can be manifest in the various forms of severe weather. Condensation of this water vapor into cloud droplets and, ultimately, into various forms of precipitation is the result of air containing sufficient amounts of water vapor being forced upward by some external process, such as a so-called front or by flowing up the side of a mountain. Pressure in the atmosphere decreases upward owing to the effect of gravity, so ascent results in expansion of the ascending air currents (*updrafts*). Surrounding air is drawn into the developing updraft, producing what is known as *inflow*. Following the laws of thermodynamics, the air’s expansion during its ascent results in cooling. For all practical purposes, it can be assumed that rising air exchanges no heat with its surroundings during its ascent, which means the process is *adiabatic*. The rate of cooling with height in the rising air prior to condensation is called the *dry adiabatic lapse rate*, corresponding to a constant value of $9.8\text{ }^{\circ}\text{C km}^{-1}$. During dry adiabatic ascent, the water vapor content of the rising air current remains constant, so that ultimately, the rising air reaches a level at which

the relative humidity becomes high enough for condensation to begin (near 100 % relative humidity, where the air is said to be *saturated* with water vapor). Condensation can begin slightly before attaining a relative humidity of 100 % owing to the presence of tiny particles called *condensation nuclei*, which promote condensation because of their hygroscopic properties.

Once condensation begins, the released latent heat causes the ascending air to cool at a lesser rate, known as the *moist adiabatic lapse rate*, but this value is not a constant. Rather, the rate is smallest at low levels (around $6\text{ }^{\circ}\text{C km}^{-1}$) and approaches the dry adiabatic rate asymptotically as the air continues to rise. Because of the release of latent heat, the ascending air may become less dense than its surroundings (when temperature decreases with height sufficiently in that environment) and so becomes positively *buoyant*. If the lapse rate in the environment is between the dry and moist adiabatic values, then that environment is considered conditionally unstable – it is stable for ascent without condensation, but can become unstable when the ascending air becomes saturated. Positive buoyancy results in a strong acceleration of the air’s ascent – it has become unstable and continues to rise on its own after having been lifted initially by some external mechanism. In extreme cases of this updraft instability, the vertical speed can reach values as high as 50 m s^{-1} or more during an ascent to 10 km or beyond.

As the air in the updraft continues to rise, it eventually reaches a level where it loses its buoyancy, primarily because most of the moisture has condensed and its lapse rate increases to approach the dry adiabatic value. The height of this level also depends on the vertical temperature profile in the environment. Owing to the inertia of its ascent accumulated during its buoyant acceleration, it will overshoot this *equilibrium level* before dropping back downward and spreading out in the upper parts of the storm, forming the so-called anvil cloud (Figure 1). The cloud material the storm produces eventually will accumulate at the equilibrium level and ultimately re-evaporate.

Various processes within the developing convective cloud cause the conversion of cloud droplets, which are initially very small (perhaps only $20\text{ }\mu\text{m}$ in diameter) into precipitation-size particles (a few mm in diameter), which are large enough to have terminal velocities sufficient to let them fall out of the cloud (a few m s^{-1}). The development of precipitation within a convective cloud (Lamb, 2001) signals a transition in the evolution of a convective storm. The presence of precipitation results in the creation of descending air currents, or *downdrafts* through two physical processes. When precipitation falls into unsaturated environmental air, it begins to evaporate. Evaporation causes that environmental air to cool (by absorbing the latent heat of vaporization), so it can become negatively buoyant and begin to sink. Further, the physical presence of precipitation particles exerts a drag on the surrounding air, causing that air to descend

Severe Storms, Figure 1 A deep convective storm cloud (called a *cumulonimbus* cloud), with its anvil spreading out at the equilibrium level and being carried by the upper-level winds from *left to right*. The *top* of an overshooting updraft is visible above the anvil (compare to [Figure 2b](#)) (Photograph © 1999 C. Doswell).

along with the precipitation. Downdrafts of precipitation-cooled air eventually reach the surface and spread out, forming pools of cold, stable air. The leading edge of the *outflow* caused by downdrafts is called a *gust front*, as it is usually associated with gusty surface winds.

Only part of the water vapor condensed into cloud droplets ultimately falls out as precipitation. The fraction of the input water vapor deposited on the ground is known as the *precipitation efficiency*. Some storms are very inefficient, with only 10 % or less of the input water vapor falling out as precipitation. Others have efficiencies exceeding 50 %.

Any deep convective storm is made up of one or more of what are called *cells*. Each cell begins as a current of ascending air. These are discrete elements in space because of a property of fluids known as *mass continuity* – when air in one place arises, air from its surroundings must descend to take its place. The understanding of the cellular nature of convective storms was the result of a field observational campaign in the years following World War II, known as the Thunderstorm Project (Byers and Braham, 1949). During those field experiments, thunderstorms were observed by radars (which were then a relatively new technology) and penetrated by aircraft at multiple levels. The life cycle of an individual cell was determined from these observations to be about 20–40 min, corresponding roughly to the time it takes air to ascend from near the surface to the top of the storm. This life cycle is illustrated schematically in [Figure 2](#). Most thunderstorms

encompass multiple cells, and so can have lifetimes exceeding that of any individual cell.

Convective storms have updrafts that lift warm, moist air into the upper parts of the troposphere, usually resulting in precipitation. That ascent removes the excess latent and sensible heat at low levels, depositing it in the upper troposphere. Conversely, the storm's downdrafts take potentially cold air from middle and upper tropospheric levels and cause it to descend – which replaces warm air at low levels with that potentially cold air. Thus, updrafts and downdrafts both serve to alleviate the condition of excess heat at low levels. Once the instability that gave rise to the storm is reduced far enough by overturning within the deep convective storms, those storms will cease to exist. Convective storms can be seen as a response to a disturbance to equilibrium that results from solar heating (or from any anomalously warm underlying surface, such as warm surface currents in the oceans).

Severe convective storms

To this point, the processes described are common to both severe and nonsevere deep convective storms. What is it that makes a storm *severe*? To some extent, because there are thresholds for defining what constitutes a severe weather event involving hail or strong winds (Galway, 1989), the definitions are rather arbitrary. Is a storm producing a 1.8 cm hailstone qualitatively different from

Severe Storms, Figure 2 Schematic depiction of the life cycle of a single thunderstorm cell – (a) towering cumulus stage, (b) mature cumulonimbus stage, and (c) dissipating stage (From Doswell III (2001)).

a storm producing a 1.9 cm hailstone? Although any quantitative threshold between categories is arbitrary, as a given event passes a particular threshold, there is an increasing likelihood that important damage will result from that event. The impact of a storm also depends strongly on what it is affecting – a severe storm over open grassland is unlikely to do much damage to that grassland unless the

events become extreme. But within inhabited areas, damage with important consequences to humans could result from convective storm events even slightly below a particular threshold. Ultimately, any deep convective storm producing lightning has the potential to do damage and cause casualties, but lightning does not meet any of the existing formal criteria for a nominally severe storm.

Severe Storms, Figure 3 An example of an event with a line of severe thunderstorms as seen by radar.

Severe weather is strongly associated with the degree to which the convective storms are organized. There are two basic modes by which convective storms become organized: into more or less continuous *lines* of individual convective cells, or as *discrete, relatively isolated* systems of cells. The ultimate form of discrete organization is the so-called supercell storm, which is characterized by a systematic rotation of the entire storm system through most of its depth. As will be discussed below, the main factor governing the degree of organization is the variation of winds with height.

The weakest degree of organization to a severe storm is the so-called pulse severe storm. Such an event is characterized by a very brief period (only a few minutes duration) of marginally severe weather, followed by rapid dissipation of the storm. Another pulse severe storm might develop in the vicinity, but it would be a distinctly different storm. Marginally severe hail and/or surface winds are the predominant events associated with pulse-type storms. At times, even weak updrafts can produce isolated strong downdrafts. The processes that control updraft strength are different from those controlling downdraft strength, so there is no physical reason to assume a high correlation between updraft and downdraft intensity in any given storm. Storms with weak updrafts might not even produce lightning but may result in small but powerful downdrafts called *microbursts* that can have

important human consequences, especially for aircraft taking off or landing (Fujita and Caracena, 1977).

When multiple storms develop in relatively close proximity, it is common for their surface outflows to merge, forming large pools of relatively cold air spreading outward along. The gust front at the leading edge of these merged outflows often serves to initiate new convective cells that then contribute their outflows to the cold pools, which then initiate another series of new convective cells, and so on. Furthermore, many storms are initiated along lines of ascent (typically, frontal boundaries), which imposes a linear structure on the resulting convective system. This linear organization (as in Figure 3) is very efficient at overturning large regions of unstable conditions. Strong surface winds arise when the downdrafts of such storms become intense, sometimes producing so-called bow echo morphology to the convective line (Figure 4). Severe hail is also common with such storms. The size of organized convective lines can vary from 20- to 200 km long, or even larger. At times, lines of storms (often referred to as *squall lines*) can produce swaths of damaging winds over regions encompassing 2,000 km² or larger – these events, meeting certain arbitrary criteria, are called *derechos* (Johns and Hirt, 1987). Derechos are an extreme form of convective wind event and if they happen to hit a populated area, the result can be devastating. Some derechos incorporate embedded supercell storms,

Severe Storms, Figure 4 Example of a bow echo as seen on radar, with white lines and arrows indicating the airflow. See text for discussion.

which often are responsible for the most intense winds and the largest hail. Tornadoes can occur with such linear structures, although not typically of the highest intensities unless they occur in association with embedded supercells.

Another form of organization arises when the environment favors the development of new convective cells in roughly the same storm-relative position, resulting in an *isolated* multicellular storm (Marwitz, 1972b). Although it appears to be a single storm on radar, it really consists of a series of individual cells that are forming, maturing, and dissipating in an organized way. In effect, each cell is moving through the storm system as a whole. Such storms can produce strong winds and large hail, and occasional tornadoes. The severity of such events in a few cases can be quite high, but typically, the severe weather is of marginal to moderate intensity. However, such storms are a primary mode for the occurrence of heavy rainfall, when the storm system moves slowly while the individual cells move through the system (Figure 5).

The supercell (Browning, 1964; Marwitz, 1972a; Doswell III and Burgess, 1993) is the most organized type of severe storm, and almost all supercells produce some form of severe weather. The most extreme forms of severe weather are associated with supercells (Figure 6). If hailstone diameters reach 5 cm or more, the storm that produced them is likely to be a supercell. The most violent

tornadoes are almost exclusively confined to supercell storms (Davies-Jones et al., 2001). Even supercells possess multicellular characteristics (Foote and Frank, 1983), with an internal evolution cycle governed by the rotation process embedded within them, known as the *mesocyclone*. Mesocyclones evolve with time as the individual convective cells move through the storm, resulting in the cyclic production of severe weather, sometimes including families of tornadoes. In a few cases, supercells persist for many hours, producing swaths of severe weather that can be 200 km long or even longer.

Ingredients for large hail

The processes that result in large hail (Browning, 1977; Knight and Knight, 2001) are not entirely understood, but some conditions clearly are necessary. A strong updraft is required to hold the growing hailstone aloft long enough to attain their size – for a giant hailstone (say, 6 cm or larger), these updrafts must be about 50 m s^{-1} or more. Supercells are unique in that they occur in environments where the winds increase rapidly with height (i.e., strong *vertical wind shear*). When an updraft develops in an environment with strong vertical wind shear, the updraft can interact with that shear to produce a *perturbation* pressure gradient force that can augment the effect of positive buoyancy. That augmentation to the updraft's

Severe Storms, Figure 5 Schematic illustrating the passage of individual convective cells through an isolated multicellular storm. Individual cells, labeled with Roman numerals I–V, form on the left and move to the right. The outflow's gust front is denoted by the black line with triangles. Precipitation intensity is indicated by the green shading. The point indicated by the circled "X" is a fixed point on the ground, which experiences repeated episodes of heavy rain coming from a sequence of cells moving through the storm system. The time required for the evolution in (a–c) is on the order of 20–30 min (Adapted from Figure 7 in Doswell et al. 1996).

acceleration can result in a contribution as large as that from buoyancy alone. Thus, supercells generally have the strongest updrafts of any deep convective storms, which enhances their potential for giant hailstones. Not all supercells produce large hail, however. This implies that there are other ingredients for large hail. One likely candidate is the presence of large amounts of supercooled water in the updraft.

Liquid water condensing in clouds is typically very pure water and if carried above the level in the storm where the internal cloud temperature is 0°C , such pure

water may not freeze immediately. Very pure water's temperature can be lowered to about -40°C , the so-called homogeneous nucleation temperature, before it freezes, unless there is a *freezing nucleus* present. One type of freezing nucleus is water already frozen: a frozen raindrop or a snow particle, for example. In strong updrafts with copious condensed water within them, the presence of supercooled water is likely. When a supercooled water droplet makes contact with ice, it freezes quite rapidly, so hailstones grow by a process of accreting supercooled liquid water – called *wet growth*. Hailstones also can grow

Severe Storms, Figure 6 Schematic view of a supercell storm as it might appear on radar, showing the location of important features associated with such storms, with small *black arrows* indicating the low-level airflow. The *dashed black line* is the gust front associated with the forward-flank downdraft, while the *dash-dot black line* is that associated with rear-flank downdraft. The location of a mesocyclonic tornado is shown by the *purple inverted triangle*.

Severe Storms, Figure 7 A cross section of a large hailstone, showing the “growth rings” produced by alternating wet and dry growth of the hail. On the *left*, the view is through crossed polarizers, showing the internal crystalline grain structure. On the *right*, through ordinary transmitted light – it is evident that cloudy ice has smaller grain sizes (Photograph courtesy C. Knight (used with permission)).

by *dry growth*, which is the conversion of water vapor directly into solid form (sometimes called *riming*). As the growing hailstone alternates between periods of wet and dry growth, its internal structure exhibits layering

between nearly transparent ice from wet growth and translucent ice from dry growth (Figure 7). The notion of hailstones acquiring this layered structure from repeated ascent to high levels and descent to low levels in the storm

Severe Storms, Figure 8 Schematic cross section of the airflow in a typical mesoscale convective system (MCS). The deep convective cells are along the leading edge of the system, with updrafts depicted in the *red lines* and downdrafts shown in *blue*, but airflow also goes *in between* the cells along an ascending path from front to rear (*heavy black line*). In some systems, a rear-to-front descending inflow jet (*heavy black line*) develops, entering the storm at middle levels and can result in a bow echo configuration for the line of storms (as in [Figure 4](#)). The box outlined with *dotted lines* and colored *light yellow* contains the active deep convective part of the system (cf. the *red colors* indicating heavy rain and possibly hail in [Figures 3 and 4](#)).

has now largely been discredited (Knight and Knight, 2001). Minor height fluctuations and movement within the storm can cause the growth mode to alternate between wet and dry without requiring cycles of substantial ascent and descent through the storm.

In order to reach the ground as a large hailstone, once the hailstone grows large enough to begin its descent from the growth zone, it should not experience an extended period of melting once it falls below the melting level (0°C). It turns out that a relatively dry environment inhibits melting during descent, as well. There likely are microphysical factors that promote or inhibit the development of large hail, but these remain unknown at present.

Ingredients for strong winds

As discussed earlier, two primary factors promote strong downdrafts, with their associated strong surface winds: negative buoyancy produced by evaporation (or by direct conversion of ice to vapor, known as *sublimation*), and precipitation loading (Wakimoto, 2001). It is possible that another contribution to strong outflow is perturbation pressure gradient forces. At present, the extent to which such pressure forces are involved is not known comprehensively. The interaction between a downdraft and the surface produces strong vertical deceleration of the updraft, which results in an outward-directed perturbation pressure gradient force that drives the outflow once the downdraft descends far enough to feel the effects of the surface. There may also be an interaction between

the downdraft and the environmental vertical wind shear, but the importance of that is yet to be shown.

In supercell storms, the mesocyclone provides an augmentation of the pressure gradient force that causes a swirling airflow. This results in an increase of the magnitude not only of the downdraft's outflow, but also the updraft's inflow. Thus, some supercells may have narrow channels of potentially damaging winds in their inflows, as well as within their outflows.

In large systems of deep convection, called *mesoscale convective systems* (or MCSs) (Fritsch and Forbes, 2001), a relatively narrow band of inflow can develop a few kilometers above the surface and enter the storm system from the rear (illustrated schematically in [Figure 8](#)). As precipitation falls into this rear inflow, it is cooled by evaporation and can descend to the surface where it can augment the convective storm-scale downdrafts driving the gust front. This process may explain the bowed-shaped morphology of many bow echoes. Because of the relatively narrow jet of strong winds into the rear of an MCS, strong horizontal wind shear on its flanks produces counterrotating vortices on the ends of bow echoes, called "bookend" vortices (cf. [Figure 4](#)). Also shown in [Figure 8](#) is the inflow that passes *between* deep convective cells forming on the leading edge of the outflow and ascends gradually toward the rear of the storm. This carries precipitation toward the trailing side of the storm, where it falls out as moderate rainfall. Generally speaking, the *cyclonic* vortex (see the next section) can be augmented by the

Coriolis effect (an apparent acceleration of the airflow due to the Earth's rotation) over the life cycle of an MCS, whereas the *anticyclonic* vortex is inhibited by the Coriolis effect.

Ingredients for tornadoes

Not all tornadoes arise the same way, so the task of describing the factors that promote the development of tornadoes (tornadogenesis) is somewhat challenging. It has been mentioned that tornadoes occasionally form from isolated non-supercell storms (Wakimoto and Wilson, 1989), but even within supercells, it appears that tornadoes can develop in different ways. Hence, the distinction made here is between tornadoes that occur embedded within mesocyclones and those that occur in the absence of, or some distance away from, a mesocyclone (Davies-Jones et al., 2001). The former are mesocyclonic tornadoes, the latter are non-mesocyclonic tornadoes (Brady and Szoke, 1989).

For discussing tornadoes, it is useful to define a quantity associated with fluid motion called *vorticity*. Vorticity is a vector, denoted by $\mathbf{\Omega}$, defined as the curl of the velocity field:

$$\mathbf{\Omega} \equiv \nabla \times \mathbf{V},$$

where the velocity vector $\mathbf{V}$ has components (u, v, w) in the eastward, northward, and upward vertical directions, respectively in a rectangular Cartesian coordinate system (x, y, z) , with unit vectors $(\mathbf{i}, \mathbf{j}, \mathbf{k})$. Vorticity follows a "right-hand rule" convention. If the direction of the vorticity vector is parallel to and in the same direction as the thumb on the right hand, the slightly curled fingers are aligned with the sense of rotation (counterclockwise) and the vorticity's magnitude is positive. Negative vorticity is antiparallel to the thumb of the right hand. Vorticity has three components:

$$\mathbf{\Omega} = \left(\frac{\partial w}{\partial y} - \frac{\partial v}{\partial z} \right) \mathbf{i} + \left(\frac{\partial u}{\partial z} - \frac{\partial w}{\partial x} \right) \mathbf{j} + \left(\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} \right) \mathbf{k} \equiv (\xi, \eta, \zeta).$$

The vorticity in a tornado is primarily about a vertical axis (the ζ -component of the vector vorticity). For a tornado, the peak value of the vertical vorticity is on the order of 1.0 s^{-1} , whereas for a mesocyclone, the peak value is of order $1.0 \times 10^{-2} \text{ s}^{-1}$, two orders of magnitude less (Doswell III and Burgess, 1993).

When speaking of cyclones and anticyclones, in the Northern Hemisphere, the vorticity in a cyclone is positive (counterclockwise) and negative (clockwise) in an anticyclone. In the Southern Hemisphere, the vorticity of a cyclone is negative and positive in an anticyclone.

The issue of tornadogenesis concerns the mechanism(s) by which the vertical vorticity becomes so large, especially near the surface (Davies-Jones et al., 2001). At one point in the study of tornadoes, it was felt that it was simply a matter of amplification of the mesocyclone's vorticity by conservation of angular momentum within the updraft. However, observations using Doppler radar have

made it clear that this simple idea is not so easily applied. Mesocyclonic tornadoes typically form near the interface between updraft and downdraft (Lemon and Doswell, 1979), whereas if they were associated only with simple conservation of angular momentum, it would be expected they would form near the center of the updraft. While there can be no doubt that conservation of angular momentum is involved, the specific internal storm and environmental processes that promote tornadogenesis in a few storms and not in most others remain unknown. Only around 20 % (or perhaps less) of supercells produce tornadoes (the percentage for other storm organization levels is much lower than for supercells), so the presence of mesocyclonic vorticity is not by itself sufficient to explain tornadogenesis. Further, the fact that some convective storms without mesocyclones can produce tornadoes means that other, presently unknown factors must be involved.

The primary mechanism for producing supercells is reasonably well known. When an environment is characterized by strong vertical wind shear through a deep layer (6 km or more above the surface), with magnitudes of order $3 \times 10^{-3} \text{ s}^{-1}$ or more, this implies ambient vorticity about a horizontal axis. The two components of this horizontal vorticity vector are $\mathbf{\Omega}_h = (\xi, \eta)$ and for storm environments, that horizontal vorticity is dominated by the two terms involving the vertical wind shear, so that on large scales,

$$\xi \approx -\frac{\partial v}{\partial z}, \quad \eta \approx \frac{\partial u}{\partial z},$$

because the vertical component of the airflow (w) in a convective storm's environment is at least two orders of magnitude smaller than the horizontal components. This means that the horizontal component of the environmental vector vorticity is very nearly perpendicular to the vertical wind shear vector, $\mathbf{S}$, given by $\mathbf{S} \equiv \partial \mathbf{V}_h / \partial z$, where $\mathbf{V}_h = (u, v)$.

The horizontal vorticity also can be decomposed into components along and perpendicular to the airflow, known as *streamwise* and *crosswise* vorticity, respectively. Davies-Jones et al. (2001) demonstrate that an updraft causes crosswise vorticity to be tilted into the vertical to form a pair of counterrotating vortices: one cyclonic and the other anticyclonic. When the vorticity vector is parallel to the airflow, that vorticity is either streamwise or antistreamwise. Supercell environments favor streamwise vorticity through a deep layer, which is what we generally observe, although in some circumstances, supercells can occur with a large component of crosswise vorticity, as well. In such instances, a common observation is the production of counterrotating supercells, the cyclonic one moving to the right of and slower than the mean wind through a deep layer, and the anticyclonic one moving to left of and faster than the mean wind (Figure 9), in the Northern Hemisphere. As usual, things work the opposite way in the Southern

Severe Storms, Figure 9 Tracks of left- and right-moving supercells, as shown by the accumulated rainfall amounts over the life of the echoes. The fast-moving left movers do not accumulate much rainfall, but the relatively slow-moving right movers produce heavier rainfall amounts and so show brighter colors along their tracks.

Hemisphere – the cyclonic storm moves to the left and slower than the mean wind, whereas the anticyclonic supercell moves to the right and faster than the mean wind.

Although the physical understanding needed to define the specific ingredients for tornadogenesis is lacking, empirical results suggest two factors that seem to be important (Doswell and Evans, 2003; Thompson et al., 2003). The first is the presence of strong vertical wind shear in the lowest kilometer of the atmosphere – vertical wind shear values approaching $1.0 \times 10^{-2} \text{ s}^{-1}$ seem to be common in tornadic storm environments, be they supercells or not. The second is high relative humidity near the surface, which seems to be related to yet another empirical finding about tornadic supercells (Figure 10): Their downdrafts tend to be relatively warm and may even retain some buoyancy if lifted far enough. A cold, very stable outflow from a storm reduces the likelihood of tornadoes and such outflows are promoted by low relative humidity in the near-surface air. Again, there is as yet no comprehensive physical explanation for these empirical results.

Much less is known about tornadoes produced by non-supercell storms. It appears that in at least some cases, the existence of preexisting maxima of vertical vorticity on a scale larger than that of the convective storm (called *misocyclones*) means that it may be simple

amplification of that vorticity by developing updrafts through conservation of angular momentum which can explain this type of tornado (Brady and Szoke, 1989). Non-mesocyclonic tornadoes have not been studied very extensively, so much continues to be unexplained. It should be noted that waterspouts are simply tornadoes over the water, and some of them also seem to be associated with supercell storms and others with non-supercellular deep convection. There are areas around the world that produce frequent waterspouts from primarily non-supercellular storms. Many of these waterspouts arise in deep convection that has very little or no lightning activity, at least prior to waterspout development.

An important scientific question relating to tornadoes is their role in the atmosphere. Most meteorological processes have a well-defined purpose; for example, deep, moist convection is a response to the excessive sensible and latent heat at low levels and convective storms result in alleviating the instability that gives them birth. Tornadoes almost certainly have some role to play, because the alternative would be that they are just random events associated with deep convective storms, which seems unlikely. Our inability to predict which storms will produce tornadoes is evidently related to this currently unanswered question. The atmosphere is an example of

Severe Storms, Figure 10 A tornadic supercell, with annotations, showing the location of the rear-flank (*white dash-dot line*) and forward-flank (*white dashed line*) gust fronts (cf. Figure 6) at cloud base level. This example is looking roughly toward the northeast at a storm like that illustrated in Figure 6. The rear-flank downdraft is creating the *turquoise-colored* “hole” in the clouds seen above and toward the left of the tornado (Original photograph © 2005 C. Doswell, annotated version © 2008 C. Doswell).

a nonlinear dynamical system (Lorenz, 1993) and it is known that such systems can be difficult to predict even when the underlying dynamical processes are understood perfectly. Gaps in that understanding make it even more challenging to anticipate such events.

Convective storm observations

Because convective storms are small relative to the sparse conventional in situ observing systems, a great deal of what we know about them has been derived from remote sensing – primarily radar. The development of Doppler radar for probing convective storms began in the late 1960s and has become the basis for our existing operational severe weather warning system. Recently, the implementation of polarimetric capability for the operational Doppler radars has begun, which will give additional information for observing the microphysical structure within convective storms.

Another important observing capability has been spacecraft with cameras and other active and passive remote sensors. The distribution of deep convective storms in space and time via satellite observations has been another important component in scientific understanding. Further, it is possible to obtain critical information about the distribution of environment variables relevant to deep convection using a number of different spacecraft-borne observing systems, including lightning detection capability. In the past two decades, both spacecraft and ground-based remote sensing tools have

been developed that offer considerable promise to revolutionize our ability to sample the global environment associated with deep convection.

Summary

The definition of severe weather as used here is based on arbitrary criteria for hail and strong winds. The storms that produce large hail are clearly those that include strong updrafts, and since supercells develop the strongest vertical motions of any convective storm, the largest hail is produced primarily by supercells. Not all supercells result in large hail; however, predicting the occurrence of large hail is still somewhat problematic. It is likely that the detailed microphysical processes within convective storms are important for the production of hail but much remains to be learned about microphysical processes in deep convective storms. Polarimetric radars, which are just now on the verge of becoming operational, may eventually help with understanding hail production. However, a challenge for using polarimetric radars (and other remote sensing tools) to infer microphysical properties in the atmosphere is that in situ validation of the interpretation of the observations in terms of the microphysics is needed. Are the remote sensing observations being interpreted properly? This continues to be a vexing issue.

Strong winds are arguably the easiest type of severe weather event to understand. They are almost entirely associated with strong downdrafts, the physics of which

is reasonably well understood. It is not always possible to know in detail what a particular storm is likely to do, but the general conditions for producing a strong surface wind are relatively easy to anticipate. One challenge is to know when Doppler radar-observed strong winds are actually making their way to the surface. When a shallow stable layer is present at the surface, the strong winds just above may or may not be observed at levels near the surface where they can do damage. Radars have a “horizon” problem associated with the curvature of the Earth—at its lowest scanning angle, it observes events only above a height that increases with distance. Hence, Doppler radars generally cannot confirm or deny that strong winds observed above the surface are actually reaching down far enough to do damage.

At this time, it is not clear just what role tornadoes are playing that other physical processes apparently cannot accomplish. Whatever that purpose might be, the need for it is relatively infrequent—tornadoes are rare events in a global sense. The challenge posed by tornadogenesis is connected to the reason for their existence in the first place—if their role in the atmosphere can be understood definitively, the mechanism(s) by which they are created should become more clear than at present. A major concern for hypothesized tornadogenesis mechanisms is that they need to be able to account for non-mesocyclonic tornadoes, as well. Most of our observations of tornadoes are for mesocyclonic events associated with supercells. Research in the near future is likely to remain concentrated on trying to explain mesocyclonic tornadoes, seeking to understand the physical processes that explain the empirical associations with low-level vertical wind shear and high relative humidities near the surface, but the broader topic is likely to remain problematic for some time, as non-mesocyclonic tornadoes (including waterspouts) seem much harder to predict. New technologies for observing the airflow and thermodynamic characteristics in the lowest kilometer of the atmosphere will need to be developed if much progress is to be made.

Another remaining challenge is the development of an accurate understanding of the true distribution of severe weather (Brooks et al., 2003; Doswell et al., 2005). Even in the United States, which has the best infrastructure for documenting severe weather in the world, hail and strong winds are reported as point events, whereas the reality is that both winds and hail occur in swaths. Thus, the reports of severe weather at points are likely to be providing only a biased depiction of the frequency and intensity of severe weather. Such reports depend on having a knowledgeable observer at the right place and time to observe the most intense events, an unlikely scenario. Remote sensing systems (mostly radar) do not make direct observations of severe weather events but may offer the best hope for an accurate spatiotemporal distribution of severe storms.

Tornadoes are assigned path lengths and widths, but at the moment, the occurrence of tornadoes (and other forms of severe weather) in sparsely populated regions often goes unreported. Further, there simply are not enough

available resources to devote to a careful study of each reported tornado event and the intensity determination is based almost entirely on the degree and type of damage done. When a tornado occurs in sparsely populated regions of grassland, with little or nothing to damage, no way exists at present to determine the tornado’s wind speeds. If reported at all, such tornadoes typically are given a “default” rating as weak events, which can be substantially wrong. Moreover, even when careful damage surveys are done, there is no simple relationship between wind speed and damage. Doing a damage survey to estimate wind speeds requires considerable experience and knowledge, and this is not generally available. Until some way to estimate tornado intensity objectively and remotely is developed, comparable to the Richter scale in estimating earthquake intensity, our knowledge of the distribution and intensity of tornadoes will remain uncertain.

SNOWFALL

Ralf Bennartz

Atmospheric and Oceanic Sciences Department,
 University of Wisconsin-Madison, Madison, WI, USA

Definition

Snow. Low-density ice particles. The density is typically in the order of 0.1 g/cm^3 . Individual snowflakes can exhibit a wide variety of different forms. Other frozen particles include graupel or hail. Graupel particles are medium-density ice particles with a density of about 0.4 g/m^2 . Graupel is produced when ice particles fall through extensive layers of supercooled cloud liquid water. Hail particles are of a very high density of about 0.9 g/m^2 . Hail fall is associated with intensive convection and is formed via a series of melting and refreezing processes.

Melting layer. The melting layer is the layer in which falling hydrometeors transition from the ice into the liquid phase. The top of the melting layer coincides with the 0°C isothermal.

Bright band. The bright band is a band of enhanced radar reflectivity associated with melting precipitation particles. It is typically found in stratiform precipitation. The bright band roughly coincides with the melting layer.

Introduction

Frozen precipitation exists in a huge variety of different forms depending on weather situation as well as on cloud microphysical processes. Precipitation-sized ice particles can be broadly categorized into three classes: snow, hail, and graupel. All deep convective and frontal precipitation events involve the ice phase even if ice particles will melt before reaching the ground. Snowfall at the surface constitutes a large fraction of polar, boreal, and mid-latitude winter precipitation. In the northern hemisphere, winter snowfall is ubiquitous north of roughly 40°N to 50°N . In most mid- and high-latitude countries, snowstorms can have a major disrupting effect on traffic and the economy.

The atmospheric temperature profile of the atmosphere plays a key role in determining whether liquid, frozen, or mixed precipitation reaches the surface. In this regard, the problem of snowfall remote sensing can be separated into three different issues. Firstly, precipitation has to be detected. Secondly, the phase or type of precipitation at the surface has to be determined. Thirdly, the amount of precipitation has to be quantified. This entry is only concerned with snowfall at the surface and concentrates

Snowfall, Figure 1 Zonally averaged snowfall frequency and mean snowfall rate derived from 1 year of CloudSat radar observations. The uncertainty in the snowfall rate (gray-shaded area) is solely due to assumptions about ice habit (Figure from Hiley et al., 2010).

on the second and third issue. While there are various ground-based remote sensing techniques for snowfall, the main focus here is on global satellite-derived estimates. Subsequently, a distinction will be made between active (radar) and passive (microwave radiometer) remote sensing techniques.

Principles of snowfall remote sensing

Frozen versus liquid precipitation

The discrimination of frozen from liquid precipitation at the ground is clearly crucial, especially in high- and mid-latitude areas where snowfall occurrence varies widely on annual and interannual time scales. From a passive remote sensing standpoint, the determination of the phase of falling precipitation at the ground is an ill-posed problem, since passive measurements typically have broad vertical weighting functions. For instance, if the precipitation melts just a few meters above the surface, it will not have any measurable “liquid” signature that could be detected using a passive sensor. Passive instruments are therefore not directly sensitive to the phase of falling precipitation at any given level. Indirectly, the phase of precipitation at the surface can be determined with some accuracy by assessing the height of the freezing level. If the freezing level is known, the only additional information needed to assess precipitation phase at the surface is the distance it takes for the falling precipitation to melt. A reasonable value for this falling distance is in the order of

500–600 m for snowfall (e.g., Bennartz, 2007). As an example, the upper panel in Figure 1 shows the zonally averaged snowfall frequency based on temperature fields obtained from a numerical weather prediction model and precipitation identification using CloudSat’s 94 GHz Cloud Profiling Radar (Stephens et al., 2008).

Some active remote sensing techniques (radar) provide additional means to distinguish frozen from liquid precipitation. The occurrence of a bright band in radar observations is a sign for melting particles (Fabry and Zawadzki, 1995). Thus, if a bright band is identified sufficiently high above the surface, precipitation at the surface can be assumed to be liquid. Unfortunately, the reverse is not true, i.e., even if a bright band is not identified, precipitation at the surface can still be liquid. Other active techniques involve polarimetric measures (Matrosov et al., 2007; Zrnic et al., 1993). While these methods are promising for ground-based observations, Matrosov et al. (2009) point out that polarimetric observations are often not available for operational weather radars. Also spaceborne cloud and precipitation radars do not currently offer polarimetric capabilities.

Snowfall intensity

Ground-based active remote sensing techniques have been widely used for many years to measure snowfall intensity. First measurements of snow size distributions together with relationships between radar reflectivity (Z) and

snowfall rate (S), so-called Z–S relations, were first reported by Gunn and Marshall (1958). In 1970, a widely used size distribution and related Z–S relation was published by Sekhon and Srivasta (1970). Since then, much progress has been made in understanding the relation between radar backscatter and snowfall, as well as its inherent uncertainties. The variability in Z–S relations is largely driven by ice particle habit (shape) and size distribution – both highly variable in space and time. Various recent publications have theoretically assessed single particle and size distribution, averaged scattering properties, and their variability (Hong, 2007; Kim, 2006; Liu, 2004; Matrosov, 2007; Petty and Huang, 2010).

With the advent of CloudSat (Stephens et al., 2008) and its 94 GHz Cloud Profiling Radar (CPR), first global remote sensing observations of snowfall have become possible. Based on the theoretical work referenced above, Liu (2008), Kulie and Bennartz (2009), and Hiley et al. (2010) have studied snowfall occurrence and intensity using CloudSat's CPR. Exemplarily, zonally averaged results are shown in the lower panel of Figure 1. The uncertainty range given is solely due to uncertainties in choice of ice scattering models.

Spaceborne passive remote sensing of snow intensity or snowfall rate is hampered not only by the aforementioned uncertainties in ice scattering but also by relatively broad weighting functions and the strong and highly variable contribution of surface emission over heterogeneous, potentially snow- or ice-covered surfaces. Despite these issues in the last few years, some progress has been made regarding passive microwave estimates of snowfall at the ground (Kim et al., 2008; Noh et al., 2006, 2009; Skofronick-Jackson et al., 2004). While these studies show promising results, it is unclear at the point of writing to what extent the various issues related mostly to ice particle scattering and surface emissivity can be disentangled. More studies are needed to establish bounds on the uncertainty of passive remote sensing techniques for precipitation. A potentially interesting research venue might also lie in the combination of active and passive observations.

Summary

Over the last years, our capabilities to remotely sense snowfall have significantly increased. Significant progress has been made in three areas. Firstly, new in situ and ground-based remote sensing techniques allow us to better specify snowfall size distribution, fall speed, and particle shapes. Secondly, our understanding of basic interactions between nonspherical frozen particles and the radiation field has advanced considerably. Thirdly, with the advent of spaceborne radars and improved radiometers, it has become feasible to study snowfall globally from space. While initial studies show very promising results, many of the related retrieval techniques are still in their infancy. In the future, significant effort will have to be put into characterizing retrieval accuracies and uncertainties.

SOIL MOISTURE

Yann Kerr
 CNES/CESBIO, Toulouse, France

Synonyms

Water content; Wetness

Definition: what is soil moisture?

Soil moisture usually refers to the amount of water stored in the soil.

Any soil can absorb a given amount of water before being saturated. It is common knowledge that different types of soils will have different types of behavior. The best example is probably the difference between a sandy beach and a clay patch in their dry and wet states. This is mainly due to the size of the soil's particles and the way water can lodge itself between them. Actually, water locates itself between the particles of soil, either very close and with a strong link (bound water) or more loosely (free water). Typically, the free water will "move" more easily (percolation, lateral flow, or evaporation) in the ground than the bound water which is more difficult to extract. The two types of status for water in soils will have an influence on the behavior of soils at microwave frequencies.

So different soils will have different "water-holding capacities" and will evolve, depending on the outside environment, between dry and wet. The most basic way of qualifying soil moisture is to range either between dry and wet or with respect to its impact on vegetation. The terms used then are the wilting point (when vegetation starts to suffer, meaning water is difficult to extract: there is only bound water left) and the field capacity (saturation, i.e., when water is so abundant that the soil cannot hold any more and water either accumulates over the surface (ponding) or runs away (runoff)).

In all of the above, soil moisture refers implicitly to the near-surface soil moisture. Actually, depending on the use of such information, soil moisture may refer to different quantities.

The most usual distinction is made between surface soil moisture and root zone soil moisture.

Surface soil moisture corresponds to soil moisture in the first centimeters of the soil. It is the soil moisture that is most visible when walking around, which interacts directly with the atmosphere (evaporation) and which drives infiltration and hence runoff in case of rain events. However, most plants have roots near the surface but also in deeper layers (depending on soil depth), so vegetation growth and health is directly linked to the water available in the root zone. The root zone is very close to what is referred to in hydrology as the vadose or unsaturated zone.

Finally, there might be another layer of stored water, deeper, the saturated zone, or water table. This layer is used by the deepest roots of trees and by man-made wells.

Just to be exhaustive one must remember that, when dealing with mass (water) transfers between the atmosphere and the soil, there are other areas where water is stored and that have an influence:

- Water stored in the vegetation, which is pumped from the soil and can be evaporated into the atmosphere through respiration/transpiration
- Water stored above the surface (lakes, rivers, ponds, snow/ice), which can be evaporated (sublimated) or can percolate or even runoff
- Water intercepted by vegetation (during rain events or as dew), which may also evaporate, be absorbed by the leaves, or eventually fall to the ground

Introduction: why measure soil moisture?

Weather forecast and extreme event prediction

Water is one of the key elements that sustain life on Earth. It is used by most of the fauna and flora and most living bodies that are mainly made of water. Consequently, humankind has always been interested in water availability. For eons, life has been organized by the cycles of vegetation and the corresponding rain cycles, with their direct impact on crop yield: predicting whether the next season would be rather wet or dry has been a constant preoccupation. In parallel to the development of techniques and the progress of science, humankind has tried to improve both its measuring skills and its forecasting capacities. If the basic concern about the weather/water availability for the next season is still a daunting challenge, our knowledge of the factors influencing the mass and energy exchanges between the surface and the atmosphere has made some progress. Models now can simulate these exchanges, taking into account the forcings (wind, solar radiation, rain, etc.) and the state of the surface (soil moisture, vegetation type and state, local slope, roughness, etc.).

Thanks to these models and observations, we have now some insights into the various factors that are crucial to

improve weather forecasts and extreme event prediction. Among them, soil moisture plays an important role as:

- A water reservoir (water storage)
- The source for water which can be evaporated into the atmosphere (mass transfer)
- A tracer of water which fell onto the surface (rain)
- A factor influencing energy budget at the surface atmosphere interface (evaporation requires energy hence induces a decrease in temperature)

To summarize, knowledge of surface soil moisture is of paramount importance for weather forecast.

Extreme events can also be better predicted when accurate values of soil moisture are used in models. An added advantage of knowing soil moisture is that large rain events (for instance, storms), depending on the soil characteristics, can lead to extreme runoff, landslides, or flooding as water infiltration is also governed by the water content of the uppermost layer.

Water resources management

Another important use of soil moisture is to get access to important information on water availability. The most obvious example is to know whether a field should be irrigated or not depending on its state, the crop growth stage and its water requirements, and the forecasted weather. This is crucial in arid or semiarid areas where irrigation is very often required, but water is not necessarily available in adequate quantities.

How to measure soil moisture

Soil moisture is traditionally measured by taking a sample of soil (in a vessel of normalized size), weighing it, drying the sample in an oven to evaporate all the water, and weighing it again. The ratio of the two measurements gives the gravimetric soil moisture. A more commonly used unit is the volumetric soil moisture which corresponds to the ratio of the sampled volume versus the volume of water it contains. The volumetric soil moisture can be inferred from the gravimetric soil moisture by simply multiplying it by the bulk density of the soil. Volumetric soil moisture is favored by many as it relates directly to remote measurements (see microwave part below).

To achieve the goals mentioned in paragraph two, it is necessary to have access to soil moisture estimates. Punctually in space and time, this is relatively easy with gravimetric sampling. However, to have measurements representative of a larger area (such as a field), the procedure is already somewhat complex as it involves a dedicated sampling strategy. Moreover, as these measurements are time consuming, regional and, even more so, global coverage are out of question. Provided one uses automatic probes (resistive, capacitive, time domain reflectometry, etc.), it is possible to achieve larger coverage and continuous measurements, but these approaches can only be confined to well-equipped and

manned sites, as they require care and maintenance. Finally, these systems carry their own problems and inaccuracies. So global monitoring of soil moisture can only rely on remote sensing from space approaches.

From space, we have access to a global approach. (All the points are measured with the same set of tool and technique, independently of countries, of ease of access, of units, or even of locally available technology.) More to the point, the measurements are by nature area integrated and thus more representative, while ground measurements are by essence very local (gravimetric samples taken a few meters apart may lead to different measurements). Conversely, if ground measurements can be very direct and accurate, measurements from space are bound to be indirect and therefore imply caveats.

Remotely sensed soil moisture, the main approaches

A large number of remote sensing approaches have been tested. For surface soil moisture, the first ones were based on shortwave measurements and on the fact that soils get darker when wet. Obviously, due to atmospheric effects and potential cloud cover, as well as vegetation cover masking effects, this approach is bound to fail in most cases. A more promising feature is linked to latent heat effects. Wet soils have a higher thermal inertia and are "cooler" than dry soils. These properties led to various trials (thermal inertia monitoring, rate of heating in the morning, surface temperature amplitude, etc.) to assess soil moisture indirectly. All those approaches proved to be somewhat disappointing due to factors inherent to optical remote sensing (atmospheric effects, cloud masking, and vegetation cover opacity) as well as to the fact that thermal infrared: (1) probes the very skin of soils and (2) the layer probed in thermal infrared is dominated by the exchanges with the atmosphere. Consequently, to infer soil moisture from such measurements, one needs to know exactly the forcings (wind, for instance, will change drastically the apparent temperature of a wet soil).

As microwave systems measure the dielectric constant of soils, which is directly related to the water content, research has quickly focused its efforts on assessing soil moisture with radars, scatterometers, or radiometers. These systems offer, when operated at low frequency, the added advantage of being all weather (measurements are not much affected by the atmosphere and clouds) and able to penetrate vegetation. They can operate at night.

Finally, in an attempt to be exhaustive, a new approach relies on measurements of the gravity field from space. As the gravity is linked to the mass, one may consider that changes in mass are mainly linked to changes in the total amount of water. In total, one should understand here: water table; water in soil layers, possibly lakes, rivers, snow, and ice; and water in vegetation and in the atmosphere. Gravimetry should thus indicate changes in the total column of water with a spatial resolution of 500 km or more. The first results certainly show a signal but its relationship with water storage has yet to be

validated and explicated. The main problem with such measurements is that they require a very large number of corrections which can be very sophisticated (for instance, taking into account the influence of tides or of the postglacial rebound). These corrections being prone to degrade the error budget in a case where the errors and corrections are of the same magnitude as the signal to be measured.

Microwaves as a tool for soil moisture monitoring: current status

The most popular approach relies on the use of synthetic aperture radars (SAR). These systems, in use since 1977 with SEASAT, offer all weather measurements with a fine spatial resolution (tens of meters). Operationally, they however suffer – as most high-resolution systems – from a rather low temporal sampling (for instance, 35 days for the European Remote Sensing (ERS) satellite) which is not really compatible with hydrologic requirements or weather forecast models. But the most adverse characteristic of SAR is the coherent nature of the signal itself and the interactions with the scattering medium. SAR images are affected by speckle and by the scattering at the surface. The scattering can be due to the vegetation cover (distribution of water in the canopy) or the soil's surface (surface scattering when wet and volume scattering). The direct consequence of these perturbations is a signal at least as sensitive to surface roughness as to moisture itself (see also Wigneron et al., 1999), not mentioning vegetation. Obviously, these effects are frequency dependent. All these inherent difficulties might explain why no real soil absolute moisture mapping was done by the several SAR that have flown since 1977. To avoid the roughness and vegetation perturbations, an approach relying on change detection, hence relative, has been used with relative success (Moran et al., 2002). However, temporal coverage is still often an issue. The use of scatterometers offers an interesting trade-off. The spatial resolution is much coarser (tens of kilometers) but with a much wider swath allowing reasonably frequent coverage (every 4–6 days on average). It also offers the added advantage of being less subject to speckle (averaging). Consequently, several authors routinely produce soil wetness maps of many areas of the world with scatterometers. The effect of vegetation is however still significant and actually corresponds to most of the signal, as the currently available frequencies are C-band on (ERS-1) and higher. So the most interesting results were obtained over arid and semiarid regions, where vegetation and soil moisture are very highly correlated anyway. The influence of surface roughness is also significant and it is best dealt with by using change detection.

The last possibility in the microwave domain is to use radiometers. The technique is old and well mastered as many sensors, notably sounders, rely on passive microwaves. To infer soil moisture, these systems are bound to offer the best compromise if used at low frequency, as

demonstrated in the early 1970s with the very short SKYLAB mission. However, to be efficient, one needs to work in a protected frequency band to avoid unwanted man-made emissions and radio frequency interferences (RFIs) and to be sensitive to soil moisture while atmosphere is transparent and vegetation plays a limited role. At L-band, the emissivity may vary from almost 0.5 for a very wet soil to almost 1 for a very dry one, giving a range of 80–100 K for an instrument sensitivity usually of the order of 1 K. As the signal is not coherent, surface roughness and vegetation structure play a reduced role when compared to active systems. So one may wonder why L-band radiometry was not used extensively before when it has been proved to be most efficient during ground and airborne measurements (Schmugge et al., 1988). This is due to an inherent limitation: The spatial resolution is proportional to the antenna diameter and inversely proportional to the wavelength. At 21 cm, to achieve a 40 km resolution from an altitude of 750 km requires an antenna of about 8 m in diameter which is a very significant technical challenge. So the research was performed with higher frequency systems as available on the scanning multichannel microwave radiometer, SMMR (6.6 GHz) (Kerr and Njoku, 1990); the special sensor microwave imager, SSM/I (19 GHz); and now the advanced microwave scanning radiometer, AMSR-E (6.8 GHz) (Njoku and Li, 1999). Even though the frequency is not adapted, good results were obtained with SMMR (in spite of a very poor resolution due to important side lobes) and now AMSR-E (Njoku and Li, 1999). The limitations are mainly linked to the fact that the vegetation becomes rapidly opaque, the frequency is not protected and thus bound to be polluted by RFIs, and the single-angular measurement makes it difficult – in several cases – to separate vegetation and soil contributions to the signal.

The step forward

Considering the necessity to make L-band measurements, several approaches have been tested to overcome the antenna-size issue. The first was initiated in the early 1990s with the idea to apply radio astronomy techniques (very large arrays) and very large baseline interferometers to Earth remote sensing. The one-dimensional concept, electronically scanned thinned array radiometer (ESTAR) was implemented as an aircraft version and proved to fulfill the requirements (Le Vine et al., 1994). It is a system, deployable in space as a sort of large rake, that offers – at the cost of a reduced sensitivity – an acceptable spatial resolution. In parallel, another approach, using inflatable (or umbrellalike) deploying technology, was studied at the Jet Propulsion Laboratory (JPL). Both concepts were proposed without success to space agencies on several occasions. The concepts appeared to be complex to deploy and to run, or to offer too limited measurements (single angle and frequency). By 1991, a small group started to work for ESA on the development of a similar instrument working in two dimensions (Goutoule et al., 1996).

The concept was named Microwave Imaging Radiometer with Aperture Synthesis (MIRAS) and an airborne prototype was made and operated (Bayle et al., 2002). From then on, the concept evolved into a more tailored instrument which was proposed to the European Space Agency (ESA) (Kerr, 1998) in the framework of the Earth Explorer Opportunity mission under the name of Soil Moisture and Ocean Salinity (SMOS) mission. The mission was selected and is now underway. It is an ESA-led project with contributions from France and Spain. SMOS is scheduled for a launch in 2009 (Kerr et al., 2001). Similarly, a mission proposal was submitted to NASA, the Hydrospheric State Mission (Hydros) (Entekhabi et al., 2004). This mission relied on a deployable and rotating antenna linked to both a radiometer and a scatterometer. It is currently being investigated under the name of Soil Moisture Active and Passive (SMAP).

SMOS is a Y-shaped instrument consisting of 69 elementary antennas regularly spaced along the arms providing at each integration step a full image (about $1,000 \times 1,200$ km) at either two polarizations or full polarization of the Earth's surface (Kerr et al., 2001). The average ground resolution is 43 km and the globe is fully imaged twice (ascending and descending orbits) every 3 days at 6 am and 6 pm local solar time (equator crossing time). As the satellite travels on the orbit, any point of the surface is imaged at several angles, giving the angular signature of the pixel. The beauty of the concept is thus that a reasonable spatial resolution is obtained at the cost of a reduced sensitivity. Moreover, the pixels are viewed frequently at different angles and polarizations. The angular information is then used to separate the different contributions (soil – vegetation) to the signal (Wigneron et al., 2000).

Root zone soil moisture

The big caveat of the remotely sensed soil moisture is that the direct measurement only concerns the surface layer. For instance, at X-band, a few millimeters and, at L-band, 4–5 cm are probed on average (depending on soil characteristics and condition). It is necessary however, for several applications, to know the available water in the unsaturated zone. Only one direct approach can currently be considered: using even lower frequencies (wavelengths of several meters) so as to reach deeper layers. This leads to large problems in terms of spatial resolution (a few hundred kilometers) as well as problems linked to ionospheric effects. So this option is not feasible now. The indirect approaches could be either to use gravity change approaches (if really validated and provided very coarse resolutions – hundreds of kilometers – are acceptable) or to rely on assimilation techniques, i.e., to use models to infer – from regular surface measurements and forcing conditions – what the root zone soil moisture is. The approach has been validated both using simulations and using ground data. The real limitations are linked to the models' performances and to the input data quality.

Expression of needs

Obviously, apart from the fact that the unsaturated zone is only partly probed, there are some requirements that are not fully fulfilled. The main one is the spatial resolution. Some needs, notably in hydrology, can only be resolved by having a better spatial resolution while still retaining a high temporal sampling. From space, this is not straightforward, but the most promising solution is probably to use external information to redistribute the area's average moisture within the pixel: the so-called disaggregation. Several studies recently proved the feasibility of the approach with SMOS data (Pellenq et al., 2003; Merlin et al., 2006) and now the real-life validation has only to be performed.

Caveats

This is not to say all problems have been solved. There are still a number of outstanding issues which will require attention before an accurate and global soil moisture product is routinely delivered. Some problems, such as RFI, can be general issues, especially if protection is reduced in the future, which is a concern. The specific issues identified are currently being tackled and several references in the literature identify them, but, obviously, as long as the actual data (SMOS or any other) are not available, definitive conclusions and/or solutions will not be available and some unexpected issues might arise. Currently, the following issues are well identified. The most stringent is the pixel heterogeneity with components which may have very significant differences in behavior. The presence of free water within the pixel, for instance, has to be very accurately known (better than 2 %) to reach the overall accuracy of 4 % vol. in soil moisture. And water bodies can be variable as a function of season or weather. Vegetation is not totally opaque at L-band, and when the integrated water content is above $4\text{--}5 \text{ kg/m}^2$, soil moisture retrievals will be difficult and approximate. Therefore, forested canopies will impact the signal. It may be noted at this level that recent studies showed that the main contributor at L-band for forest was the branch which does not evolve so rapidly (Ferrazzoli and Guerriero, 1996). Litter on the ground may behave as blackbody, masking strongly the soil's signal. During rain events, water interception by the canopy might artificially increase the apparent vegetation's water content. Topography will induce an altered angular behavior; snow and frozen soils will induce different signals which, if not accounted for, will produce wrong estimates. Urban areas and rocks are not fully assessed in terms of emissivity. Finally, and generally speaking, good retrieval will require some a priori knowledge of the surface cover, and state and the quality of the retrievals will be linked to the quality of the input data. It must also be noted that systems like SMOS will bring inherent specificities and complexities such as image reconstruction which is still a challenging point.

Conclusion and perspectives

Soil moisture has been for a long time a very specific variable. Though well identified, there were so few global measurements that models do not use it per se. However, after many unsuccessful attempts, a real soil moisture mission is now underway. It should enable the community to have, finally, access to global fields of soil moisture. Until launched and commissioned, the concept still has to be proved but the elements available can make one very confident to such an extent that an operational SMOS follow-on is currently being studied. Nevertheless, if SMOS answers some questions, (it) still does not fulfill all existing needs and ways forward must be sought. The most important is probably to improve the spatial resolution and there the SMOS concept is close to an optimum, as increasing the arm's length will improve the spatial resolution but degrade significantly the sensitivity, to the point where it would not be useful anymore. So other techniques, such as disaggregation, will have to be found. To be more efficient, a SMOS-like instrument might gain either from being multifrequency or from having a coupled active system. To test those options, we will be expected to test these solutions using existing sensors (Advanced SCATterometer (ASCAT) and AMSR-E) when SMOS is operating. Another approach to improve spatial resolution could be to use even larger antennas, depending on the possibility of deploying them efficiently in space. In that case, to resolve the ambiguities, it will probably be necessary to improve the system by adding other frequencies while keeping the active source. This might lead to addressing the cryosphere as well, another key element in the global water and energy budget of the planet.

It was stated in the SMOS proposal that the concept, though challenging, would open a new field with new measurements – soil moisture – made with a new type of sensors, paving the way for operational monitoring of water in soils. With the inception of the SMOS mission, this step is taken, opening a whole avenue of scientific challenges and making the long-awaited tool for water resources and water cycle monitoring a closer possibility.

Definition

Soils. Soils are three-dimensional living bodies, with spatially variable biologic, physical, and chemical properties, that form the outer skin of the Earth's terrestrial surface.

Soil formation. Soils form slowly over time and develop distinguishing properties as a function of climate, geologic and organic parent materials, topography, time, vegetation type, and land use history.

Soil profile. The vertical depth of a soil body varies from a few centimeters up to several meters and contains a series of soil horizons. The surface layers are termed the "O" (organic) or "A" (mineral) horizons, while a lower zone of clay accumulation is the "B" horizon, and the lowest zone that interfaces with the parent material is the "C" horizon.

Introduction

The thin biologically active soil layer of the Earth's terrestrial surface is an integral part of the biosphere, regulating biogeochemical and hydrologic cycling of matter and energy and affecting land productivity and biodiversity. Soils perform numerous ecologic functions, as they buffer and filter pollutants that impact water quality, serve as source and sink of greenhouse gases, and partition rainfall between infiltration and runoff. Soils are home to the richest biodiversity on the planet that includes countless microorganisms that perform biochemical transformations, vital to ecosystem functioning, such as nitrogen fixation and organic matter decomposition. Reliable information on the spatial distribution of soil properties along with a better understanding of fundamental soil processes are vital to achieve sustainable land management of ecosystem services and to solve many environmental challenges facing society.

Soils exhibit great spatial variability as a result of the interactions of climate, topography, parent material, and organisms acting on the soil body over time (Amundson and Jenny, 1997). Human activities and land use history

also play important roles in determining soil properties and additionally contribute to the heterogeneous soil spatial patterns. Remote-sensing systems, with their synoptic, multi-scale, and repetitive coverage of the land surface, provide an ideal means of mapping the spatial variation and biogeophysical properties of soils for environmental and natural resource management purposes.

Soil optical properties

Soil optical properties have been extensively studied in laboratory and field measurements and found to be primarily dependent on soil biogeochemical composition, soil surface geometric-optical scattering, and surface moisture status, as reviewed in Baumgardner et al. (1985). Generally, the spectral composition and the strength of the optical signal measured are determined by the minerals and organic compounds that coat the surface layer of soil particles (Stoner and Baumgardner, 1981). In contrast to the strong absorption spectra of pure mineral samples, soil absorption features are only broadly defined as soils consist of aggregate mixtures of many mineral and organic constituents. Many quantitative tools for extracting information about the physical and biochemical characteristics of soils have been developed and recognized as the field of soil spectroscopy (Irons et al., 1989; Ben-Dor et al., 1999). As an example, Ben-Dor and Bannin (1994) utilized a visible and near-infrared analysis scheme to predict a wide variety of soil chemical constituents, including CaCO_3 , Fe_2O_3 , Al_2O_3 , SiO_2 , free iron oxides, and K_2O , from high-resolution spectra of arid and semiarid soils.

In field radiometric measurements of in situ soils, there are strong optical-geometric interactions resulting from the angles in which the sun illuminates, and the sensor views, the surface. In addition, the atmosphere influences the relative proportions of direct (sun) and diffuse (sky) illumination on the soil surface. Particle size distribution and surface-height variation (roughness) are some of the most important factors influencing the reflectance properties of in situ soils. The bidirectional reflectance distribution function (BRDF) describes the manner in which surfaces scatter radiation across all sun-surface-sensor view geometries and can be used, through models, to derive geometric descriptors of a soil, such as size, shape, and orientation of surface "roughness" elements (Irons et al., 1992). There is a general decrease in reflectance with increasing surface roughness as coarse aggregates contain a lot of inter-aggregate spaces and "light traps." With the shortest wavelengths most affected, optical-geometric interactions alter a soil's spectral signature and the inferences made of soil biogeochemical properties such as soil color and mineralogy.

When integrated across a hemisphere, the BRDF provides "albedo," the ratio of shortwave (0.4–4 μm) radiant energy scattered in all directions to the incident irradiance on the surface. Albedo is a fundamental variable in energy balance studies, climate modeling

studies, and soil degradation studies, e.g., smooth, crusted, and structureless soils generally reflect more energy and are brighter than well-structured soils. Soil moisture also has a strong influence on the amount and composition of reflected energy from a soil with a general decrease in reflectance, proportional to the thickness and energy status of the adsorbed water. Soil moisture and soil roughness impart strong, or bright, microwave signals, and image-differencing techniques can be used to separate the dynamic soil moisture signal from the relatively static soil roughness signal (Sano et al., 1998). More recently developed **LiDAR** (Light Direction and Ranging) technology enables land surface roughness to be measured, on the order of centimeters, and offers promise in mapping terrain stability and hazard analysis, such as landslides (Jones, 2006).

Space- and airborne imagery

Remotely sensed imagery from air- and spaceborne sensors integrates much of the knowledge learned from laboratory and field spectroscopy into the spatial domain and to the much more heterogeneous landscape scale. There is a wide array of airborne and satellite sensor systems currently available to study soils at the landscape level, encompassing a wide range of spatial and temporal resolutions, number of spectral bands and bandwidths, sun-view geometries, and polarization states. The derivation of soil information within landscapes may involve (1) direct measurements of exposed soils; (2) extraction of soil information from partially vegetated, open canopies; and (3) inferring soil properties from measurements of the vegetation layer. In all cases, correction and filtering of the image data are required to minimize atmosphere contamination, clouds, topography effects, BRDF influences, and sensor noise characteristics.

Galvão et al. (2008) demonstrated how a subset of exposed soil pixels from airborne AVIRIS and spaceborne ASTER imagery, collected in Campo Verde, Brazil, could be used to study several soil physical and chemical weathering properties and their relationship to landscape position. Spectral soil indices, often in the form of band ratios, and spectral mixture analysis (SMA) have been used to ascertain soil information where vegetation and litter residues mask portions of the soil surface and pure soil pixels are not observable. SMA unmixes pixels into their respective soil, vegetation, and litter signal contributions, useful in soil and vegetation mapping, land degradation, soil erosion, and land cover conversion studies (Adams et al., 1986; Smith et al., 1990; Ustin et al., 1993). As an example, Palacios-Orueta et al. (1999) used a sequential spectral mixture analysis technique that utilized laboratory-derived “training” vectors to extract soil organic matter and iron sources of spectral variation. Alternatively, one may also infer soil type and properties from remote-sensing measures of foliar chemistry, a technique known as *geobotany* (see Ustin et al., 1999).

Landscape soil processes

There have been considerable accomplishments made in understanding dynamic soil processes at the landscape scale with remote-sensing data, particularly in the areas of soil degradation, soil erosion, salinization, soil contamination, drought, carbon cycling, and climate and land use impacts. Soils are vulnerable and susceptible to poor land use practices that can yield soils with different physical properties and characteristics and thereby impact on their ability to cycle water and nutrients for sustained plant growth.

Soil degradation

Soil degradation is a major environmental concern that impacts on critical environmental issues such as food security, water quality, loss of biodiversity, and global climate change. Degraded soils exhibit an appreciable loss of soil organic matter with reduced fertility and plant productivity, deteriorated soil structures, and increases in albedo, thus altering carbon cycling and the land surface energy balance. Remote sensing provides repeatable and verifiable techniques for monitoring and assessing the spatial extent and severity of soil degradation. This is accomplished through satellite-based indicators of soil degradation that measure the loss of vegetative cover, increases in albedo, reduced soil organic matter levels, salinization, wind and water erosion, and soil crusting. Satellite data are increasingly being utilized to monitor the albedo of arid and semiarid lands given the importance of albedo as an indicator of land degradation and as a physical parameter with possible impacts on climate. Spatial heterogeneity indices from satellite images are also sensitive indicators of landscape instability, with increases in variance due to soil degradation and erosion (Pickup and Nelson, 1984).

An important threat posed by soil degradation is soil erosion, in which the upper and most fertile soil layers are removed by wind and water forces and deposited into waterways and coastal zones, resulting in loss of arable land and the silting of reservoirs. Windblown atmospheric dust may also pose public health concerns. Soil erosion is evident in remote-sensing imagery when subsoil characteristics are exposed, which contrast with the “intact” surface soil spectral signals. In very fine spatial resolution imagery, such as from QuickBird, detailed information on linear erosion features such as gullies, rills, and sand dune formations can be directly observed.

Soil carbon

There is great interest in analyzing the importance of soils as a source or sink of greenhouse gases such as carbon dioxide, methane, and nitrous oxide. The soil carbon pool is approximately twice that in the atmosphere and three times that in vegetation (Smith et al., 2008). Although the response of soils to global warming is critical, reliable estimates of carbon reserves in undisturbed soils are not available, and data on rates of carbon loss following

disturbances are lacking (Lal, 1997). Soils subject to accelerated decomposition of organic matter tend to release carbon dioxide and thus contribute to the enhanced greenhouse effect, while areas being revegetated and enriched with organic matter can absorb and sequester quantities of carbon that are extracted from the atmosphere through photosynthesis. In the context of global sustainability, it is essential to understand how the source/sink function of soils can be managed and controlled to mitigate the impact of climate change (Post et al., 1982).

Soils also play important roles in water quality, sediment and pollutant discharges into water systems, and environmental remediation efforts. The soil has the ability to filter and break down toxic waste materials and many industrial by-products and render them less harmful. New capabilities are also becoming available for soil process studies enabling the integration of environmental process models, climate data, human interactions, and Geographic Information Systems (GIS) with remote-sensing data.

Conclusion

In summary, soils exhibit tremendous spatial and dynamic variations across a landscape due to variations in moisture content, biogeochemical composition, surface roughness elements, and ongoing processes of land use, soil degradation, erosion, contamination, and global change. Although not fully developed, remote sensing remains the only viable technique to map, monitor, and manage the fragile soil resource. With over 90 % of the Earth's terrestrial surface classified as "open canopies," there is an appreciable soil component that can potentially be remotely sensed.

Many of the remote-sensing techniques used to derive soil information, however, remain undeveloped, and there are no currently available operational satellite data products on *soil properties*. In part, the extraction of soil information from landscape-scale imagery is too complex, hindering many potential end uses. As noted by Ben-Dor et al. (2008), the adoption of imaging spectroscopy techniques, although cost-effective, remains a new frontier in soil science with advances limited by the lack of availability of operational hyperspectral sensors. Nevertheless, satellite data products, such as albedo, BRDF, and vegetation indices, measure important landscape properties that are useful in deriving soil information.

Remote sensing is also only sensitive to the immediate surface, which prevents the assessments of important subsoil and root-zone soil properties. However, the soil surface is the most dynamic, biologic, and hydrologic interface that responds immediately to climatic changes and human forcings. Remote sensing can provide quantitative measurements of such changes at the surface, which are needed to address a wide range of environmental and global change issues. Further advancements are needed to infer soil properties with depth through pedotransfer functions that enable the derivation of subsoil biogeophysical products from remotely sensed surface properties.

SOLID EARTH MASS TRANSPORT

Erik Ivins
 Jet Propulsion Laboratory, California Institute of
 Technology, Pasadena, CA, USA

Synonyms

Time-variable gravity of the solid Earth

Definition

Time-variable gravity of the solid Earth. Any measurement of gravity at, or below, the Earth's surface or from above by airborne or space instruments, wherein the physical origins of the variations are solely, or interactively, caused by movements, deformations, or changes in density of the solid Earth. Generally, solid Earth time variability includes, but is not limited to, fracture or poroelastic-related crustal volatile and hydrological material transport, changes of state and solid Earth's response to periodic forcing by ocean and lunisolar tides, earthquake-related stress reorganization, or by nutation and wobble of the Earth's rotation axis. Large-scale and long-term mass variability is associated with the solid creep of the mantle in response to the surface environmental load changes associated with the last global ice age (100,000–10,000 years ago). Smaller-scale mass variability driven by flow of the upper mantle is also associated with the more recent Little Ice Age surface loading, involving time scales of 50–500 years and surface vertical motions of 1–40 mm/year. Only recently have the last two phenomena become amenable to accurate measurement by modern space gravimetry.

Introduction

The study of the Earth's gravity, topography, and seismological structure has provided several of the most basic observational cornerstones that support the dynamic theories for the evolution of Earth's mountain belts, sedimentary basins, massive continental eruptive and breakup events, ocean ridges, plate motions, slab subduction, and all phenomenon that are generally related to mantle

convection (e.g., Richards and Hager, 1984; Forte and Woodward, 1997). While inferences concerning gravity change and mass transport may be made for mantle convection, the minimum relevant time scales, τ , are defined by those for plate tectonic reorganization ($\tau \geq 5$ million years). The class of solid Earth time-variable gravity that is measurable by satellite remote-sensing methods is shorter by at least a factor of 10^4 ($\tau \leq 50$ years). Experts in near-Earth orbital dynamics developed early measurement concepts focused on simple drifts and periodic patterns in well-tracked orbital elements (Paddack, 1967; Kozai, 1968). The launch of two passive laser-ranging satellites, Starlette and LAGEOS-1 in 1976, marked the beginning of a new era in global gravity remote sensing. The key orbital elements proved to be sensitive to changes in planetary oblateness, and these were best explained by the presence of a slow viscoelastic flow of the mantle in response to the two-way transfer of ocean-to-continent-to-ocean ice sheet expansion and contraction that began about 100,000 years before present (year BP) and ended 7,000 year BP. The response phenomenon is known as glacial isostatic adjustment (GIA) of the combined solid and liquid Earth. GIA alone gave a reasonable explanation for the amplitude and sense of the nontidal part of variations in the Earth's gravity field (Yoder et al., 1982; Peltier, 1982; Rubincam, 1984). An excellent survey of the methods and theoretical representation of the static gravitational field prior to time-variable mapping has been given by Phillips and Lambeck (1980). These methods, including coefficient-normalization conventions, are applicable to time-varying gravity.

Passive satellites in constellation

With the passing of two decades since the launch of Starlette and LAGEOS-1, and the accumulation of tracking data for a virtual constellation of more than ten subsequent satellites, it has been possible to refine the best-fitting GIA models and to incorporate realistic scenarios for the mass balance of mountain glaciers, the Greenland and Antarctic ice sheets. A series of papers, each analyzing slightly different tracking-derived solutions for the zonal harmonic drift rates (e.g., Cheng et al., 1997), identified a statistically significant improvement in the residual fit to all zonal harmonic rates of drift by accounting for Antarctic and Greenland ice mass change. The solved-for drift rates are especially sensitive to the latitudinal dependencies of the low-degree zonal harmonics, hence natural antecedents to the study of both GIA and present-day mass balance of the continental cryosphere. James and Ivins (1997), Johnston and Lambeck (1999), Cox et al. (2001), and Tosi et al. (2005) used zonal harmonic rates of order $n \leq 9$ and showed that Antarctic mass loss at rates of -70 to 340 Gt/year ($1 \text{ Gt} = 10^9 \text{ t}$) was favored across a broad spectrum of mantle viscosity profiles. A critical aspect of the finely tuned relationships between nontidal satellite orbital element drifts to solid Earth GIA and cryospheric imbalance is that modeled

accelerations due to drag have appropriate error estimates and that the mass changes in the oceans have no large-amplitude, low-order, and long-term secular-like components (cf. Hughes and Stepanov, 2004).

Satellite-to-satellite tracking: a new era for time-variable gravity

Plans for a high-resolution global gravity-mapping mission with satellites at mean orbital altitudes below 800 km were well underway by the late 1970s (e.g., Kaula, 1983). The lower orbits of nonpassive satellites required new navigational and tracking strategies. Passively laser-tracked gravity satellites in nearly circular orbit have apogees, a , ranging from 7,173 to 25,001 km and are relatively drag-free. The measurement sensitivity to surface gravity falls off as $(R_e/a)^{n+1}$ where R_e is the mean radius of the solid Earth and the harmonic degree and n is related to spatial resolution as the half wavelength $\Delta\lambda \approx R_e \pi/n$. Optimistically, the limits of spatial resolution (in latitude only) of the passive satellites are $\Delta\lambda < 2,200$ km. The limitation is actually far more severe than this. At full wavelength, $2\Delta\lambda$, say, for example, the orbits of these passive satellites are responsive to mass changes at, or beneath, the combined Central Siberian Plateau and Western Siberian Plain (representing approximately one-fifth of the Eurasian land area). Yet the rate solutions for the harmonic coefficients, $\partial_t C_{nm}$, determined by passive-satellite tracking are unable to resolve the latitudinal location of the disturbing mass, for there is equal probability that the observed orbital drifts are related to mass changes in central Canada! This drawback is related to the lack of sensitivity to nonzonal harmonics (generally, nonaxially symmetric), having $m \neq 0$. This is essentially the “Achilles’ heel” of satellite laser-ranging (SLR) strategies for monitoring time-variable gravity from space.

Multiple-satellite tracking and smaller a open a new window to resolution. In fact, the German geoscience satellite launched in 2000, CHAMP, utilizing tracking by the entire constellation of high-orbit Global Positioning System (GPS) satellites, and onboard accelerometer and star-tracking data, was capable of resolving the global static field to degree $n_{\max} \approx 72$ (Reigber et al., 2003). Although sampling in polar orbit yields a degraded longitudinal resolution, effectively limiting nonzonal resolution to $m_{\max} \approx O(n_{\max})/2$, seasonal changes in mass can unambiguously detect mass changes associated, for example, to the combined Central Siberian Plateau and Western Siberian Plain. The role that a unified single tracking reference frame plays in reducing the errors in the end-product gravity mapping should not be underestimated (Rummel et al., 2005). The polar orbit also allowed, for the first time, a global gravity map to be completed that is based on a single instrument and observing scheme, as opposed to the prior generation of merging strategies required to produce global maps. The latter always contained regionally varying quality and had no possibility of representing global time-varying properties.

The Gravity Recovery and Climate Experiment (GRACE) satellite pair determines an even higher-resolution static and time-variable field. These were launched into polar orbit in 2002 and fly in tandem, separated by about 220–240 km. The two track one another with a Ka-band radar system, in addition to using onboard accelerometers and GPS tracking (Figure 1). Although degraded in resolution by the same anisotropic sampling problem as CHAMP, the resolution recovered by a standard isotropic Gaussian filtering technique (Wahr et al., 1998) is about 400 km, and a variety of more sophisticated filtering methods may reduce this by 50–130 km, depending on the sought-after frequency component and latitude (e.g., Davis et al., 2008).

Solid Earth Mass Transport, Figure 1 GRACE satellite pair with Ka band microwave tracking links. The separation is about 220–240 km. The altitude is about 550 km and the pair has roughly 15 Earth revolutions per day. Also see http://www.nasa.gov/mov/161008main_GraceBeauty1web.mov (Graphic from http://op.gfz-potsdam.de/grace/index_GRACE.html).

Solid Earth Mass Transport, Figure 2 GRACE-based static gravity field and inset photo of the passive gravity satellite Lageos-2 equipped with retroreflectors, weighing 400 kg and having a 60 cm diameter (http://www.nasa.gov/vision/earth/lookingatearth/earth_drag.html).

The higher-accuracy and complete even-degree harmonic retrieval of the fields allowed for a highly accurate determination of modeled residual drifts in the nodes of the LAGEOS-1 and 2 satellites and the later confirmed the predicted drifts of Einstein's theory of relativity. The drifts are a result of additional space-time curvature caused by the Earth's rotation (Ciufolini and Pavlis, 2004). The passive, laser-reflecting, LAGEOS-2 satellite is shown as an inset to the GRACE-gravity anomaly map shown in Figure 2.

GRACE and CHAMP determine fields and their time variability at higher latitudes with relatively enhanced fidelity. The mapped fields are inherently less prone to errors due to the greater collection of orbital mapping data. The standard (level-2) data consist of monthly (or sub-monthly) spherical harmonic coefficients, C_{nm} , as there exist a collection of well-developed methodologies for such representation and use (e.g., Rapp and Pavlis, 1990; Petrovskaya et al., 2001; Tapley et al., 2004). Important results derived from the harmonic releases for polar latitudes include the detection of huge ice loss in the south-eastern part of Greenland (Velicogna and Wahr, 2006a) and in West Antarctica (Velicogna and Wahr, 2006b; Ramillien et al., 2006). A more sophisticated method uses the raw satellite-to-satellite range and range-rate data and accelerometer data to directly infer the location and size of perturbing masses beneath the satellites without reference to global spherical harmonics. The methods use the same basic potential field representation for lunar mascons that was developed in the late 1960s (e.g., Muller and Sjogren, 1968). These direct methods have shown great sensitivity to year-to-year ice mass loss in coastal

environments such as Alaska (Luthcke et al., 2008) with resolution approaching the inter-satellite tracking separation distance (~ 240 km).

To illustrate the importance of the cryospheric measurements, adding all of the mass imbalance estimates recovered from GRACE alone since its launch in 2002, including that of Chen et al. (2007) for southern Patagonia, these add to nearly 1.7 mm/year equivalent uniform global sea-level rise, nearly half that observed for the last 15 years (Church and White, 2006) and possibly the lion's share of that inferred to be caused by all continental sources of water mass imbalance. What then is the role of monitoring solid Earth related gravity change?

Mantle deformation

To monitor the hydrological or cryospheric mass changes using a time series constructed from individual GRACE maps, or equivalently harmonic coefficients, $C_{nm}(t_i)$, a coefficient representing water mass must be constructed, $^{WE}C_{nm}(t_i)$, by finding the deviation at time t_i from the average of the sum of maps at all times, t_i . In the presence of surface water masses, the instantaneous elastic deformation of the solid Earth can be accounted for using theory for loading of a spherically symmetric radially stratified Earth model (e.g., Farrell, 1972) and an n -dependent factor $h_n^e/(1 + k_n^e)$, where h_n^e and k_n^e are the radial displacement and potential Love numbers, respectively ($h_n^e \leq -1.01$, $-0.3 < k_n^e < 0$, for all $n > 1$) (e.g., Wahr et al., 1998). For example, if surface water mass builds in a region, it depresses the solid surface and the radially stratified density structure of the entire Earth; thus, the accelerations on the satellite are *less* than those that would correspond the same water mass on a *rigid* Earth. These elastic corrections for solid Earth deformation are routine and straightforward. The main complexities arise when GIA-related solid Earth motion and gravitational potential changes are locally, or regionally, coincident with the location of the water mass changes. Such is the case in Antarctica, as has been discussed by Velicogna and Wahr (2006b) and Ramillien et al. (2006). However, the coincidence of regional changes in hydrology can also be difficult to separate from GIA, where GIA dominates the secular gravity changes, such as in central Canada and central Scandinavia. Ivins and Wolf (2008) have recently reviewed the current status of overlaps in GIA and hydrology.

The ice caps and glaciers of Iceland provide an excellent example of how this coincidence of viscoelastic GIA and ice mass change-related gravity changes are measured. There is now consensus that such ice masses are melting and raising global sea level at an accelerating pace (e.g., Kaser et al., 2006). The main center of cryospheric mass in Iceland is located in the southeastern part of the island, as seen in the cloud-free Terra Satellite image of Figure 3a, where ice- and snow-dominated regions are white in color. A large thermal plume, probably rising from the core-mantle boundary (e.g., Nataf, 2000),

Solid Earth Mass Transport, Figure 3 Iceland true color image in summer using the Moderate Resolution Imaging Spectroradiometer (MODIS) instrument onboard the Terra spacecraft (a) (Credit: http://visibleearth.nasa.gov/view_rec.php?id=6606). Vatnajökull ice cap is the larger white area in the southeast. GRACE monthly solution trends from release 04 (February 2003–April 2007) using an isotropic Gaussian smoothing filter applied to the harmonics with radius $\alpha = 282.5$ km. The units are in millimeter of water-height equivalent (b). Solid Earth uplift predictions at present day on an incompressible viscoelastic mantle half-space of viscosity 3×10^{18} Pa s under an elastic lithosphere of 25 km thickness. The ice cap evolves in accordance with the history simulated by Marshall et al. (2005) and calibrated by regional paleoclimate indicators (e.g., Flowers et al., 2008). This is a simple two-disk model of the Little Ice Age evolution of the Vatnajökull ice cap that evolves into the late twentieth century with the same observational constraints as in Fleming et al. (2007). GPS data are from UNAVCO archives and *up arrows* indicate uplift and down subsidence (with formal error estimates in red). These data are from a combination of permanent and episodic GPS tracking stations, references to International Terrestrial Reference Frame ITRF2000 on bedrock and have more than 6 years of observing history.

characterizes the regional mantle. A greatly reduced regional upper mantle viscosity is generally accepted, likely at values close to 3×10^{18} Pa s (Árnadóttir et al., 2005). This viscosity reduction greatly exacerbates both the prediction of the *sensitivity to*, and the *amplitude of*, GIA-related geodetic quantities. Icelandic paleoclimate and glacier history are relatively well known (e.g., Marshall et al., 2005; Flowers et al., 2008), as are recent mass

changes of the Vatnajökull ice cap and other major Icelandic glaciers (Magnússon et al., 2005). It is possible, therefore, to use a relatively complete ice load history and a parameter search of mantle viscoelastic properties to match the uplift patterns and magnitudes measured by GPS adjacent to the Vatnajökull ice cap as shown in Figure 3b. The model used to compute uplift in Figure 3b assumes an idealized circular disk to represent the ice cap

with the computational methods described by Ivins and James (1999) and includes the present-day responses to current ice mass changes (for a detailed description of viscoelastic GIA modeling of Iceland, readers should refer to recent work by Fleming et al., 2007). Ignoring the ice loss, the viscoelastic uplift of bedrock, $\partial_t u_b$, in response to ice mass loss (Figure 3b), the water-equivalent rate of roughly $\rho_{MC}/\rho_w \times \partial_t u_b$, where ρ_{MC}/ρ_w is the ratio of bedrock to water density, or about 2.8–3.8. The negative water-height rate deduced from GRACE spherical harmonic release 04 is in excess of 20 mm/year and has a local minima at the geographical position of the Vatnajökull ice cap (Figure 3c). Due to the unique circumstance of having GPS uplift data adjacent to the ice cap, and a well-constrained ice history, when the GIA phenomenon is correctly accounted for, the ice mass loss rate solution for eastern Iceland is roughly 5–7 Gt/year and would be almost half this value if GIA-related mantle mass variability had not been accounted for. This example of the Vatnajökull ice cap is for illustrative purposes, as the GRACE errors are quite poorly calibrated at this wavelength. The scales over which this GRACE rate is extracted from harmonic solutions are at the upper limits of resolution, shorter, for example, than the 300–400 km resolution in the example of mantle deformation and mass movement from the coseismic offsets caused by the M_w 9.1 December 2004 Aceh-Andaman earthquake (Han et al., 2006) and from Patagonian ice mass loss (Chen et al., 2007).

Conclusion

Future space-gravimetry systems, much like the highly successful polar-orbiting GRACE satellite pair, strive to meet a critical environmental remote-sensing challenge of the twenty-first century: determination of the long-wavelength mass stability of the Earth's continental fresh water supply (e.g., Velicogna and Wahr, 2006a, b; Ramillien et al., 2006; Syed et al., 2008). Terrestrial remote-sensing data have recently been directed at the severe consequences of the unprecedented warmth that has appeared during the last 100 hundred years and that now appears to be accelerating to paces unprecedented during the past 2,000 years (Mann, 2007). Monitoring the secular trends in both continental water storage and sustained ice sheet change will be of increasing societal concern. Use of space-determined gravity fields is strongly influenced by viscoelastic motions of the mantle and crust, and the study of such mass variability deep in the Earth's interior will be necessary for fully retrieving accurate and well-resolved trends in changing cryosphere and surface hydrology.

STRATOSPHERIC OZONE

Michelle Santee

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA, USA

Definition

Stratosphere. The region of the atmosphere extending from about 13 to 50 km altitude.

Ozone. A naturally occurring trace gas in Earth's atmosphere. An ozone molecule consists of three atoms of oxygen bound together in a triangular arrangement.

Introduction

The vast majority of ozone (about 90 %) resides in the stratosphere, where it plays a crucial role in protecting life on Earth from harmful solar ultraviolet radiation. Most of the remaining ozone is found in the troposphere, the part of the atmosphere between the surface and the stratosphere and the region in which most clouds and weather occur. Tropospheric ozone is an important pollutant and a greenhouse gas. In addition to its direct influence on air quality, tropospheric ozone helps to regulate the ability of the atmosphere to “cleanse” itself of many other pollutants. Anthropogenic (human-induced) increases in ozone at ground level, where it is a key component of photochemical smog, can have very deleterious effects. Thus, although all ozone molecules are chemically identical, their environmental impacts depend strongly on where they are situated in the atmosphere. In this entry, we concentrate on ozone in the stratosphere. In recent decades, anthropogenic emissions have severely compromised the stability of the [stratospheric ozone](#) layer. Stratospheric ozone depletion is a global problem that has its most dramatic manifestation in the polar regions,

especially over Antarctica, where an “ozone hole” has formed each spring for the last few decades.

Ozone production and distribution

The abundance of ozone is relatively low, with peak mixing ratios (the ratio of the concentration of ozone to that of air) of only about 10–12 parts per million by volume (ppmv) (e.g., McPeters et al., 2007). Ozone is commonly measured in terms of its column abundance, the vertically integrated density overhead at a given location. Total ozone column abundances are traditionally reported in Dobson units (DU, named for G.M.B. Dobson, who in the 1920s pioneered routine measurements of ozone column amounts), which correspond to the thickness in millimeters that the ozone column would have if all the gas were at standard temperature and pressure. Typical ozone column abundances range from 200 to 500 DU, depending on the latitude and season (e.g., Dessler, 2000).

Despite its low concentration, ozone is arguably the most important stratospheric constituent. It is an extremely efficient absorber in the ultraviolet (UV); as a result, an intact ozone layer prevents practically all solar radiation at wavelengths shorter than 300 nm from reaching the Earth's surface. Excessive amounts of UV-B (280–315 nm) radiation are particularly injurious to humans and other animals, terrestrial and aquatic ecosystems, and physical materials. It is therefore not an exaggeration to say that without Earth's protective ozone shield, life as we know it could not have evolved.

The distribution of stratospheric ozone is controlled by the interplay between chemistry and transport by the prevailing winds. Ozone is produced in the stratosphere when molecular oxygen (O_2) is photolyzed (i.e., split apart) by solar UV radiation. The resulting two oxygen atoms (O) each rapidly combine with other oxygen molecules to produce two ozone molecules (O_3). The overall result is that, in the presence of sunlight, three oxygen molecules react to form two ozone molecules. Because these reactions take place wherever UV radiation is available, the greatest ozone production occurs in the tropical stratosphere. Interestingly, however, the largest total column ozone amounts are found at middle and high latitudes in late winter and early spring (after several months of total or near-total darkness), whereas the tropics actually contain the smallest column ozone amounts. This lack of correlation between the regions of highest production and those of highest abundance underscores the importance of transport in determining the overall morphology of stratospheric ozone. Winds circulate air in the stratosphere, with rising motion in the tropics, poleward motion aloft, and sinking motion in the polar regions. Known as the Brewer-Dobson circulation, this flow carries air rich in ozone away from the tropics and toward the poles.

Although ozone molecules are continuously produced, they are also continuously destroyed in chemical reactions

with oxygen atoms and oxides of nitrogen, hydrogen, chlorine, and bromine. These reactions are termed “catalytic” because the species that initiate ozone destruction are not themselves consumed in the process, allowing the cycle to repeat many times. The net effect of the catalytic cycle is the conversion of O_3 molecules into O_2 molecules. The catalysts in these reactions are free radicals (i.e., molecules with an unpaired electron, making them highly reactive). The radicals are derived from long-lived species (which in most cases have both natural and anthropogenic sources) transported from the troposphere into the stratosphere by the large-scale circulation. Typical mixing ratios of the oxides of nitrogen are in the part per billion (ppbv) range, while those of the reactive hydrogen, chlorine, and bromine species are even lower. Thus, ozone abundances are in large part regulated by radical species present in the stratosphere in even more minute quantities.

The atmosphere normally maintains a balance, or steady state, between photochemical production and catalytic destruction of ozone, with the total level in the stratosphere remaining fairly constant. Small variations in total ozone occur because of seasonal changes in the strength of atmospheric transport, the intensity of incident sunlight, stratospheric temperatures, and other factors. Natural variations can arise from other sources as well; for example, fluctuations in UV radiation over the course of the 11 year solar cycle alter ozone production rates slightly (1 – 2 %) (e.g., Brasseur and Solomon, 2005).

Chlorine-catalyzed ozone depletion in the polar lower stratosphere

Over the last several decades, the natural balance between ozone formation and destruction has been perturbed as manufactured chemicals have entered the stratosphere. It is now understood that the severe springtime depletion of the [stratospheric ozone](#) layer over Antarctica – the so-called ozone hole – is caused by chlorine and bromine chemistry (known collectively as halogen chemistry) (e.g., Solomon, 1999; Fahey, 2007). The primary source of stratospheric chlorine is chlorofluorocarbons (CFCs), chemical compounds composed of chlorine, fluorine, and carbon. CFCs were introduced in the 1930s and used in a variety of industrial and commercial applications, including as refrigerants, solvents, and aerosol propellants, as well as in foam packaging. CFCs were used so extensively because they have low boiling points and are stable, nonflammable, and unreactive in the lower atmosphere. Other halogen source gases include carbon tetrachloride, methyl chloride, and methyl chloroform, as well as methyl bromide and the bromine-containing “halons” used as fire retardants.

Chlorine and bromine are also released at ground level through other human activities and natural processes. Common examples include emission of chlorine gases from swimming pools, wastewater treatment, and household bleach, as well as from volcanic ejecta; chlorine is also present in sea salt produced by evaporation of

ocean spray. In all of these cases, however, the chlorine is in forms that are highly reactive or soluble and are thus washed out in rain or ice in the lower regions of the atmosphere before they can be delivered to the stratosphere. In contrast, the very properties that made CFCs so useful turned out to pose a grave environmental threat. Because they are inert and insoluble in water, CFCs spread throughout the troposphere in a matter of months and are then carried along as the overturning circulation lofts air into the upper stratosphere. There, above the protection afforded by the bulk of the ozone layer, CFCs are broken down by high-energy solar UV radiation, liberating chlorine atoms. The transit time between the troposphere and the stratosphere is about 5 years. During each circuit through the Brewer-Dobson circulation, only about 10 % of the mass of the troposphere is exchanged with the upper stratosphere, and only a fraction of CFC molecules is decomposed; thus, most CFCs have long atmospheric lifetimes (about 50–500 years) (e.g., Brasseur and Solomon, 2005).

In the mid-1970s, it was recognized that chlorine released from CFCs could destroy stratospheric ozone in a catalytic cycle (Molina and Rowland, 1974), a notion that generated enormous scientific interest. For their work in helping to elucidate the sensitivity of the ozone layer to anthropogenic emissions, Mario Molina and F. Sherwood Rowland were awarded (along with Paul Crutzen) the 1995 Nobel Prize in Chemistry. Even after the connection with chlorine from CFCs was made, however, model calculations indicated that ozone loss would be gradual and moderate (5 – 20 %), limited mainly to altitudes in the upper stratosphere (near 40 km) above the peak in the ozone profile. Consequently, scientists and the public alike were shocked by the news in 1985 that ground-based measurements from the British Antarctic Survey station at Halley Bay, Antarctica, had revealed a dramatic downturn in October average column ozone over the previous few years (Farman et al., 1985). NASA satellite measurements subsequently confirmed the rapid decline in total ozone and demonstrated that the phenomenon extended over a vast geographic region roughly encompassing the Antarctic continent (Stolarski et al., 1986). Vertical profile measurements from balloon-borne ozonesondes showed the loss to be largely confined to the lower stratosphere, with virtually all ozone in the layer between about 14 and 20 km removed within a period of 4–6 weeks (Hofmann et al., 1987; Solomon, 1999; Fahey, 2007). Such severe loss in the lower stratosphere, where ozone mixing ratios are normally largest, leads to a reduction in total column ozone of as much as 60 – 70 %.

Early models failed to predict the development of the ozone hole because they focused exclusively on homogeneous (gas-phase) chemistry. A series of coordinated field campaigns to Antarctica, together with laboratory experiments and modeling studies, provided the information necessary to establish the cause of the massive ozone loss within a few years of its discovery. The first step is the formation of the “polar vortex.” In the continuous

darkness of winter polar night, temperatures drop very low, leading to a large temperature gradient near the polar terminator (the line delimiting the unilluminated region), which in turn induces a steep pressure gradient. The resulting flow is deflected by the Coriolis force, creating a band of intense westerly (i.e., eastward) winds encircling the pole. This strong wind jet provides a barrier to mixing, effectively isolating the region poleward of it, termed the polar vortex, from lower-latitude air. In the very low temperatures inside the lower stratospheric winter polar vortex, water vapor (H_2O) and nitric acid (HNO_3) condense to form polar stratospheric clouds (PSCs). PSCs were long known to occur – for example, they were described in 1911 by noted Antarctic explorer Robert Falcon Scott and his party – but they remained little more than scientific curiosities until the ozone hole was reported.

PSCs are a crucial link in the chain leading to severe ozone destruction. Their particles provide surfaces on which heterogeneous reactions (i.e., reactions in which one reactant is absorbed onto/into the particle while the other remains in the gas phase) can take place very rapidly. These reactions convert chlorine from relatively benign “reservoir” species such as hydrogen chloride (HCl) and chlorine nitrate (ClONO_2) to intermediate forms such as molecular chlorine (Cl_2) and hypochlorous acid (HOCl) that are quickly photolyzed. In this manner, vortex air is primed for ozone destruction during the cold, dark winter months. When sunlight returns to the polar regions in spring, the intermediate species are rapidly broken apart to produce highly reactive ozone-destroying forms. The predominant form of reactive chlorine in the stratosphere – the “smoking gun” that signals chlorine-catalyzed ozone destruction – is the chlorine monoxide radical, ClO .

In the mid-1980s, two sets of measurements cemented the link between elevated levels of ClO and severe ozone destruction in the lower stratosphere. First, ground-based microwave emission measurements from McMurdo Station, Antarctica, indicated greatly enhanced ClO near 20 km, with mixing ratios of more than 1 ppbv, as much as two orders of magnitude larger than predicted, based on standard gas-phase photochemistry (de Zafra et al., 1987). Second, in situ measurements from the NASA ER-2 high-altitude research aircraft (a converted U2 spy plane) revealed an abrupt increase in ClO closely correlated with a steep decline in ozone along the flight track inside the Antarctic polar vortex (Anderson et al., 1989). The large enhancements in ClO found by these studies could only have arisen through the near-total transformation of chlorine from reservoir to reactive species, and the spatial and temporal variation of the ClO/O_3 anticorrelation confirmed that ozone loss was indeed driven by chlorine chemistry. It was not until the launch of the Microwave Limb Sounder (MLS) on NASA's Upper Atmosphere Research Satellite (UARS) in September 1991 that researchers were able to map the full three-dimensional distribution of ClO in the stratosphere and

track its seasonal evolution around the globe. UARS MLS found an almost exact coincidence between enhanced ClO and depleted ozone throughout the Antarctic vortex (Waters et al., 1993).

UARS MLS measurements also verified that ClO enhancement in the Arctic polar vortex can be comparable, in terms of both magnitude and areal extent, to that in the Antarctic. Nevertheless, the Arctic has so far been spared an annual ozone hole. This interhemispheric asymmetry in the severity of ozone destruction is attributable to differences in meteorological conditions that arise in large part because of differences in the distribution of oceans and continents, in particular mountains at middle and high latitudes. Winds flowing over mountains generate waves that propagate into the stratosphere and disturb the polar vortex. As a result, the Arctic vortex exhibits much greater interannual variability than its southern counterpart and is typically warmer (by 10–20 K), weaker, more permeable, smaller, and shorter lived, leading to fewer, less persistent PSCs. In the cold, isolated Antarctic vortex, PSC particles grow sufficiently large that they undergo appreciable gravitational sedimentation. As they fall, they irreversibly remove from the stratosphere the HNO_3 (and H_2O) sequestered in them in a process known as denitrification (dehydration). Unlike the Antarctic, the Arctic generally experiences minimal denitrification. Photolysis of gas-phase HNO_3 in springtime produces nitrogen dioxide (NO_2), which combines with ClO, to reform the reservoir ClONO_2 . This reaction is the primary pathway for chlorine deactivation in the Arctic. For all of these reasons, the horizontal and vertical extent, duration, and magnitude of ClO enhancement are typically much smaller in the Arctic than in the Antarctic, and ozone loss, although it does occur in many winters, is correspondingly smaller.

Midlatitude ozone depletion

Though much less dramatic than those observed in the polar regions, statistically significant downward trends have also been detected in ozone at middle latitudes (e.g., Solomon, 1999). A substantial fraction of the midlatitude depletion is attributable to dilution with processed air exported from the decaying vortex at the end of winter, especially in the Southern Hemisphere, where polar ozone loss is severe. Another factor is in situ chemical destruction. Heterogeneous reactions akin to those that activate chlorine on PSCs also take place (albeit more slowly) on sulfate aerosol droplets, which are ubiquitous throughout the lower stratosphere even under background conditions. Major volcanic eruptions, which inject large amounts of sulfur gases directly into the stratosphere, can greatly enhance stratospheric aerosol surface area density and intensify ozone loss. In fact, substantial decreases in column ozone (on the order of 5–10%) were recorded over large regions of the globe following the eruption of Mt. Pinatubo in the Philippines in June 1991 (Solomon, 1999; Dessler, 2000). It is important to note, however, that the eruption of Mt. Pinatubo would

not have had a significant impact on global ozone had stratospheric chlorine loading not far exceeded natural levels.

Ozone recovery and climate change

At its peak around the year 2000 (Fahey, 2007), stratospheric chlorine reached levels more than six times its natural abundance. Since then, however, chlorine has been declining in response to regulations enacted under an international agreement known as the *Montreal Protocol on Substances that Deplete the Ozone Layer*. The 1987 Protocol, and subsequent more stringent Amendments and Adjustments, established legally binding controls on the production of halogen source gases. Eventually ratified by over 190 nations, these provisions averted a global environmental calamity. The stratospheric ozone layer has now stabilized, but more than 20 years after the signing of the original Protocol, large ozone holes continue to occur, attaining an areal extent of about 25 million km^2 (roughly twice the surface area of the Antarctic continent) in an average year. Because of the long residence times of CFCs, it will take several more decades to cleanse the stratosphere of excess chlorine and curtail ozone depletion. Assuming continued worldwide compliance with the Protocol, stratospheric chlorine and bromine loading are expected to return to pre-1980 values by about 2050 (Fahey, 2007).

Recovery of the ozone layer does not depend solely on diminishing anthropogenic halogen abundances, however. Earth's changing climate may have a significant effect: While the surface of the planet is warming in response to increasing greenhouse gases, the stratosphere is cooling. PSC lifetimes are prolonged in a colder lower stratosphere, exacerbating polar ozone depletion. This could delay recovery and trigger development of an ozone hole in the Arctic, where wintertime temperatures often hover near PSC formation thresholds. But assessment of the sensitivity of ozone chemistry to temperature is complicated by concomitant changes in dynamics and transport. Greenhouse-gas-induced acceleration of the Brewer-Dobson circulation is expected to alter the concentrations of water vapor and trace gases in the stratosphere, which in turn influence ozone. Moreover, lower temperatures will slow catalytic ozone destruction cycles outside of the polar lower stratosphere, hastening recovery in those regions. On the other hand, higher surface temperatures may modify emission rates of some naturally occurring halogen source gases. Increased abundances of other pollutants arising from human activities may also perturb the balance between global ozone production and loss. Separating the effects of these competing factors is challenging, making future changes in ozone difficult to predict. Current state-of-the-art models show a range of projections, with most indicating full recovery around the middle of the twenty-first century at middle latitudes and slightly later in the Antarctic (Fahey, 2007). It is important to note, however, that because of changes in

climate and other parameters, the atmosphere is unlikely to return to a state identical to that before the onset of anthropogenic ozone depletion.

Conclusion

The last few decades have seen enormous changes in the stratospheric ozone layer so vital to life on Earth. The ozone hole serves as a cautionary tale of how an apparently harmless class of chemical compounds can prove to have disastrous consequences and thus highlights how human activities can change the natural state of our atmosphere in unintended ways. But it is also a story of hope that shows how the scientific community, national governments, and industry can identify a global environmental threat and work together to mitigate it. It is imperative that we as a society continue to monitor the stability of the ozone shield to see how the story ends in light of another environmental challenge: anthropogenic climate change.

Synonyms

Collapse; Compaction; Ground motion; Ground movement; Settlement

Definition

The term “subsidence” is often misunderstood and misused, both by specialist geoscientists and by the general public. As such, the term should be avoided and more precise terms used instead. Strictly, the term has been used to mean movement of the ground surface in a generally vertical, downward direction, without reference to the areal extent of movement, the rate at which movement takes place, or the cause of the movement. For example, Keller (1985) defined subsidence as “Sinking, settling, or other lowering of parts of the crust of the earth.” However, Johnson and DeGraff (1988) took some of the factors into account by defining subsidence as “. . . displacement of the ground surface vertically over a broad region or at localized areas. It may be either a gradual lowering or a collapse.” In the public’s mind, subsidence is sometimes associated with a particular cause, for example, mining subsidence, without an understanding that there are many other causes.

As remote sensing platform instrumentation can measure both subsidence (*sensu stricto*) and “negative” subsidence (rise), it is proposed, here, that the term “subsidence” should not be used and be replaced by the term “ground movement.” The definition of this term is proposed as: “The movement of the ground, however caused, in any direction, either vertically up or down, or laterally, or components of these. The areas involved can range from less than 1 m² to several square kilometers. The amount of movement can vary from a few millimeters to more than a kilometer. The length of time for the movement to be completed can vary from a few seconds to several years.”

The synonymous term “ground motion” is best reserved for the quantitative amount of ground movement observed and measured repeatedly by remote sensing platform instrumentation over a period of time. Hence, a rate of movement can be determined for different time periods. The movement measured is likely to be in the direction of the “line of sight” of the satellite instrumentation, which may not be vertical.

Importance of ground movement information

Ground movement causes death, injury, damage to buildings, structures, and infrastructure, and, hence, financial loss. It occurs on every continent and offshore. However, the amount of injury and loss depends upon the rate of ground movement and its magnitude. Sometimes, rapid and large ground movements will be preceded by slower and smaller movements that can be monitored. Examples of this include the growth of lava domes prior to an eruption and ground level rise/fall prior to an earthquake.

Even where ground movement takes place slowly and the amount of movement is only a few tens of millimeters, the financial cost can be great. In the United Kingdom (UK), damage to buildings caused by ground movement can be insured against, and in the last 20 years, losses have averaged between £3 and 400 million per year. Most of these losses were the result of the shrinkage of Mesozoic and Tertiary clay soils in southeast and central England. This does not represent the total loss due to ground movement as losses from ground movement caused by coal mining are not included in this total. (These losses are covered by a public body called the Coal Authority).

In France, where ground movement is also covered by insurance (though in a slightly different form), losses averaged over €300 million per year between 1989 and 2003. Again, the cause was the presence of expansive clay soils (Cheetham, 2008). Almost every country in the world has several geohazards that cause ground movement activity for at least part of the year.

To summarize, large-magnitude, rapid ground movements tend to cause both significant human and financial loss. On the other hand, small-magnitude, slow ground movements cause little human loss but can still result in substantial financial loss. As a result, the acquisition of ground movement information is very important if losses are to be anticipated. Research into the prediction of large-magnitude events has yet to identify ways of reliably predicting the location, magnitude, and timing of earthquakes and volcanic eruptions. However, frequent monitoring of ground movement, particularly using remote sensing, is likely to provide a major contribution to the anticipation of these events. Smaller and slower ground movements can also be monitored remotely, though the processes are better understood and hence are more predictable. Many of these processes are related to climatic conditions, and hence, prediction of large and/or intense rainfall events and drought is important. Predicted temperature rise is also important, for example, in relation to the thawing of thermokarst. In the future,

long-term monitoring of ground movement, however caused, is likely to become increasingly important in reducing losses arising from ground movement events.

Description of ground movement phenomena

Ground movement can have a wide range of natural and anthropogenic causes. Bell (2007) specifically referred to subsidence caused by mining, groundwater extraction, and dissolution of more soluble rocks, while Johnson and DeGraff (1988) listed dissolution, collapse of lava tube roofs, groundwater, oil or gas extraction, mining and swelling and shrinking clay soils as potential causes. Bell (1998) added fault movement to the identified causes and settlement as a low-rate and low-magnitude form of subsidence. To the lists of these authors can be added isostatic movement, seismic activity, volcanic activity, mass movement (including landsliding), soil fabric collapse, soil compressibility, and settlement of waste material.

Natural causes of ground movement

Most of the causes of ground movement discussed below are explained in detail in engineering, geological, and geomorphological textbooks (e.g., Bell, 1999; Keller et al., 2008; McCall et al., 1992; Nuhfer et al., 1993).

Earth tides: Movements of the Earth’s surface caused by the gravitational effects of the moon and the sun. These can take place diurnally or over longer periods. Movements are both vertical and horizontal and may amount to up to more than a 100 mm.

Isostatic movement

Readjustment to a state of equilibrium between the Earth’s lithosphere and asthenosphere. Lack of equilibrium is brought about by factors such as ice loading during glacial periods and movement of tectonic plates. Ground level rise from glacial unloading may amount to several meters over periods of thousands of years.

Seismic activity

While earthquakes, particularly large ones, can involve considerable and rapid ground movement (“strong ground motion”), usually associated with fault activity, slower- and longer-term ground movements may take place prior to, or as a result of, an earthquake. The “strong ground motions” associated with the earthquake occurrence may have no net ground movement effect. However, permanent uplift or depression of the ground surface over several square kilometers is known. Total change in ground level may amount to a meter, or more. For example, the Limón-Telire earthquake in Costa Rica in April 1991 caused between 0.3 and 1.9 m of uplift in the Limón area on the Caribbean coast.

Volcanic activity

The movement of volcanic magma toward the surface frequently leads to the uplift and subsidence of the area around an active volcano. Bell (1999) noted that the

summit of Kilauea, Hawaii, has risen by nearly a meter prior to eruption. However, such changes in ground level are not reliable indicators of eruption.

Dissolution

Rocks such as salt, gypsum, chalk, and limestone are susceptible to dissolution that can cause voids to be formed not far below the ground surface. If these collapse, ground movement is likely to result. The amount of movement depends upon the size of the void; the rate of movement (collapse) is likely to be high. Sometimes dissolution leads to the washing down of overlying soil particles into the dissolving rock, leading to gradual ground movement. The ground movement features are known as sinkholes or dolines and may range in diameter from a few meters to, exceptionally, more than 1,000 m (Waltham et al., 2005). Similar features can also be caused by the collapse of lava tubes where molten lava has run downslope leaving a solidified cover at the surface.

Mass movement

Landslides, flows, and falls involve the downward and lateral movement of soil, rock, or debris as a result of ground failure of a slope (Turner and Schuster, 1996). Movement can involve thousands of tonnes of material moving distances ranging from a few meters to, exceptionally, more than a kilometer.

Melting of permafrost (thermokarst)

As frozen ground thaws, settlement will occur as water is expelled by the overburden pressure and any artificial load. If the soil is free draining, the amount of settlement is likely to be greater. The amount of sinking of the ground movement will depend on the soils present and the rate of thawing. Heave can take place if the soil refreezes.

Shrinkage of peat

As peat dries out, it shrinks causing a lowering of the ground surface. This can amount to several meters. For example, in the Fens of eastern England, long-term drainage of the peat for agricultural purposes has caused a lowering of the ground surface of close to 10 m. Between 10 % and 75 % of the peat volume can be lost, and the change is permanent (Bell, 1999).

Swelling and shrinkage of clay soils

The main cause of swelling and shrinkage of clay soils is the presence of clay minerals that experience significant volume changes as their moisture content changes. Montmorillonite is a particularly susceptible clay mineral. Both shrinkage (causing downward movement of the ground surface) and swelling (causing upward movement) can result in damage to buildings. Amounts of movement range from a few millimeters to many tens of millimeters.

Soil consolidation

Soils consolidate (reduce in volume) due to overburden pressure and any artificially imposed load. This is

a process that takes place gradually as soils age and as natural processes ("weathering") act upon them. Under natural conditions, settlement will be slow and will amount to a few millimeters or tens of millimeters.

Soil fabric collapse

Some soils, particularly windblown silts and fine sands (loess), have a "metastable" microfabric caused by the way in which they were deposited. Quartz particles are separated by "bridges" of clay-sized minerals. The soils have high void ratios and low densities. On wetting, the microfabric collapses due to a reduction in the bonds between particles causing a reduction in void ratio and increase in density. The amount of volume change can range from 1 % to over 20 %. In extreme cases, settlements in excess of a meter have been observed (Bell, 1999).

Anthropogenic (artificial) causes of ground movement

Mining

Mining involves the removal of an economic solid mineral either at the ground surface (pits and quarries) or underground. Partial extraction methods involve leaving some of the mineral to support the roof or walls of the mine. However, over time, the supporting pillars may deteriorate and, ultimately, fail resulting in collapse of the mine workings and lowering of the ground surface. Total extraction methods involve the removal of almost all of the mineral and the controlled collapse of the overlying material into the void created. This results in lowering of the ground surface. The advantage is that the lowering of the ground surface is controlled and predictable. The amount of lowering may range from a few tens of millimeters to ten, or so, meters. Abandoned mine entrances (shafts and adits) may also fail creating either holes at the surface or its lowering.

Fluid withdrawal

Shrinkage of peat has been described above. However, subsidence, and consequent lowering of the ground surface, can take place when a fluid, usually groundwater, oil, or brine, is withdrawn from the ground. The overburden pressure is initially borne by the solid particles and the fluid in the pore space. As fluid is withdrawn, the load is transferred to the solid particles, increasing the so-called effective overburden pressure. This, in turn, causes consolidation of the sediment. The amount of subsidence depends upon the increase in effective pressure and the thickness and nature of the sedimentary deposit. In the San Joaquin Valley of California, USA, 9 m of subsidence occurred between 1925 and 1977 due to groundwater extraction for agriculture. Recharge of the fluid into the ground can reduce the rate of subsidence and may result in some recovery, with the ground surface rising. However, full recovery cannot be achieved.

Fault reactivation

Geological faults can be locations where ground movement caused by mining is concentrated. This reactivation

of the faults may take place during mining and may continue for years afterward. Movements along a fault greater than 2 m can occur, particularly where several seams have been extracted. Fault reactivation is more associated with shallow mine workings (Bell and Donnelly, 2006).

Settlement of waste material

Though modern waste disposal sites are usually carefully controlled, both in terms of their content and of how the site is constructed, older sites and those where controls are limited may contain mixtures of materials that have not been compacted. Over time, as the waste material alters chemically and as a result of the overburden pressure from dumping of later waste, the tip will settle, lowering the level of its surface. Amounts of settlement may range from millimeters to more than a meter, depending on the nature of the fill material and the degree of control of fluids entering the tip.

Engineering compaction

Compaction is a civil engineering process by which soil is densified by expelling air from the void space to achieve a stronger material. Usually, this involves artificially placed material (“fill”) used to construct embankments, dams, and other structures. The amount of lowering of the surface might range from millimeters to several tens of millimeters.

Measuring ground movement using remote sensing data

Ground movement can be measured using a variety of spaceborne, airborne, and ground-based remote sensing systems. Measuring ground movement requires a minimum of two data acquisitions over a study area: one to establish the baseline ground position and another to capture changes to it after a period of movement. The necessary time separation depends on a trade-off between the rate of movement and the ability of the sensor to resolve the ground movement. This measurement will capture the total ground movement in a specific time period. It can be extended via repeated data acquisitions to cover more time periods, leading to the concept of monitoring ground movement. Such monitoring allows us to measure ground motion and changes to its rate over time. The cost of monitoring is higher than that of measuring but may be justified by the impact of the ground movement on lives and economies. Ground movement is typically measured on a per-pixel basis and in the line of sight of the sensor. Of course, the ground movement may actually be vertical, horizontal, or a combination of both. There are various ways of accounting for the mismatch between the geometry of the movement and the viewing geometry of the sensor measuring it, to give a true measurement of ground movement in x , y , and z .

Spaceborne measurement techniques

Satellite altimetry

Altimeters are active remote sensing instruments. That is, they operate by sending a signal from the satellite to the surface under study and measuring how long it takes to return to the sensor. The signal may be radar or light from a laser. It is used to build up an image of the surface geometry. Changes to that geometry could, in principle, be measured via a second acquisition. However, the spatial resolution of such instruments is typically insufficient for application to ground movement. They are more commonly used in oceanography applications (Cheney et al., 1986).

Monoscopic optical satellites

It is possible to work out the horizontal component of ground movement using two passively acquired optical images. Once they are geometrically rectified and registered to each other precisely, image analysis software can be used to assess whether features in the first image, such as prominent outcrops, are in a different location in the second. This gives a simple measurement of horizontal ground movement. It is not widely used, because it cannot capture the vertical component and so has limited application in a 3D science like geology.

Stereoscopic optical satellites

Stereoscopic optical imagery from satellites like Landsat and SPOT can be used to produce a digital terrain model (DTM) with a resolution on the order of meters to tens of meters in a process known as photogrammetry (Toutin, 2001). The technique uses two images of the same area taken from adjacent orbits or two positions along track. These are compared using photogrammetric software, which takes advantage of parallax between the two viewing geometries to work out the surface geometry, in a similar way to the brain processing images from two eyes to generate stereoscopic vision. If the process is repeated, a second DTM results, and the two can be differenced to quantify changes in the DTM between acquisitions. These changes measure the ground movement. The main constraint on this technique is the need for two cloud-free acquisitions.

Satellite radargrammetry

The same principle of using two viewing geometries to help extract the geometry of the surface being viewed can be extended to active radar data (Toutin and Chénier, 2009). Radar data penetrate cloud cover and can even be used at night, so the technique compensates for two limitations of optical data. It can be used to generate DTMs at similar resolutions to optical satellites of areas under perennial cloud cover, where optical sensors cannot image the ground easily. The main constraint is that the algorithms are complex for most remote sensing practitioners to implement and rarely feature in off-the-shelf software packages. So, the technique is not widely applied.

Satellite radar interferometry InSAR

A more common way of exploiting satellite radar data to extract changes in digital terrain models is InSAR (Ferretti et al., 1999). This also exploits two images, but separated in time rather than space. The technique relies on measuring a change between acquisitions in the number of radar waves from a reflector on the ground to the sensor in orbit. The simplest analogy is the radar gun used by police to measure the speed of approaching vehicles. In practice, the two images are interfered and a series of fringes result, whose width is governed by the radar wavelength. These can be thought of as contours of ground motion. Because the technique measures only the change in ground position, an existing terrain model is used for the baseline digital terrain models, against which to measure the change.

This technique is powerful because it directly measures the change in ground position as a fraction of the radar's wavelength, irrespective of its spatial resolution. So, while the spatial resolution may be 25 m, the sensitivity to ground movement is typically on the order of a few cm, depending on the wavelength used. This matches closely the order of magnitude of many ground movements, and so the technique has been applied to a wide range of such phenomena, including seismic activity, volcanic uplift, swelling and shrinking clays, and groundwater and mineral extraction. It is even more powerful when combined with a geodetic surveying technique such as GPS. InSAR gives a wide area, synoptic view of motion restricted to specific time periods. GPS is a spatially discrete, sparse measurement but can be acquired almost constantly. It can calibrate InSAR and partially fill gaps between InSAR acquisitions.

InSAR, inevitably, has several significant weaknesses. Between acquisitions, surface characteristics other than the ground's position can change; if this change is large, the two images become incomparable (they are referred to as having low coherence) and the technique does not work. Changing vegetation is a particular challenge for short-wavelength, C-band radar, and so InSAR works best in arid countries and urban areas. Longer wavelengths such as L band are less affected by vegetation, but they are also less sensitive to ground motion. Changes occur in atmospheric properties, too, and these must be removed for the technique to work. Finally, properly calibrated measurements are still in the line of sight of the sensor; this matters more for radar data than optical data, because radars are acquired with a look angle of less than 90° to the horizontal. So, the result must be transformed into x, y, and z coordinates, either by using near-contemporary image pairs from both ascending and descending satellite passes with different geometries or by integrating InSAR with data like GPS.

Persistent Scatterer Interferometry PSInSAR

To get around the coherence limitation, a technique known as PSInSAR exploits strong radar reflectors such as building corners and metal objects that persist over time (i.e., are coherent) (Ferretti et al., 2000). In this technique,

several tens of images are acquired over a decade or more and processed together to extract these persistent scatterers (PS), which are then the focus for the interferometric processing. Rather than fringes over wide areas, this results in ground movement histories for each PS identified. These can then be gridded and interpolated to make an image, typically shown as mean annual velocity or viewed as graphs of ground movement against time for individual PS. Statistics dictate that the use of large numbers of images leads to enhanced resolution, on the order of 2 mm/year for C-band data. Constraints are that the measurement is again in the line of sight of the radar, atmospheric changes must be screened, orbital effects must be removed, and the technique cannot measure ground movements the size of multiple radar wavelengths, as this leads to aliasing. So, applications like mining with larger ground movements require caution. There is also no guarantee that PS will occur where investigators want them to. This can be overcome by placing metal corner reflectors or active transponders in the study area on the features of interest, such as reservoirs or bridges (Xia et al., 2002), to act as well-located persistent scatterers.

Airborne measurement techniques

All of the above techniques can be applied from an airborne platform. The biggest advantages that this brings are increased spatial resolution and the ability to target good weather windows. A particularly powerful technique is laser ranging, or lidar (Liu, 2008). The increased resolution that results from flying much closer to the target means that cm resolution lidar DTMs can be acquired and compared. Digital terrain models at tens of cm resolution are routinely generated from stereo aerial photography (Fabris and Pesci, 2005), and repeat airborne surveys can be used to measure changes in DTM in exactly the same way as for stereo optical satellite data. Radar interferometry can also be performed from an airborne platform to give, and compare, 1 m or better DTMs (Madsen et al., 1993). The natural geometric variability of flight lines flown through the lower atmosphere is greater than that for the orbits of satellites, and so this places a high premium on geocorrection and registration. But, at these high resolutions, the major constraints are vegetation and buildings, because the DTM measures the first surface a signal is returned from, such as the top of the tree canopy or the roofs of buildings. Corrections must be applied to remove these features and produce a bare earth model of the ground. Buildings are predictable enough to be removed cleanly, but trees are variable in height and much harder to deal with. Of the three techniques, lidar comes into its own here, because lidar with sufficiently high point densities that record the entire spectrum of returns ensures that at least some of the returns come from the ground, in between the trees. By always taking the last return, a bare earth model can be constructed even in fairly heavily forested terrain (Liu, 2008).

Ground-based measurement techniques

All of the above techniques can also be applied from a ground-based platform. The biggest advantages that this brings are further increases in spatial resolution and even greater flexibility to target weather windows. Such high-resolution surveys naturally cover smaller study areas and so are best targeted on ground motion of known extent on a site-specific basis. Terrestrial lidar has been used extensively to monitor slope stability (Jaboyedoff et al., 2012), with the further advantage that vertical surfaces like cliffs that are not seen in airborne or satellite datasets can be imaged easily. When combined with photography, the models produced can provide detailed and realistic views of the surfaces under investigation. This may allow more to be said about the causes of ground movement, rather than simply measuring the motion. Terrestrial radar interferometry is starting to be used in similar ways; its ability to penetrate clouds means that it has particular utility in volcano monitoring (Rödelberger et al., 2010). One drawback is that, even for restricted study areas, these ground-based sensors generate very large datasets that have a large processing, manipulation, and storage overhead.

Interpreting ground movement measured in remote sensing data

Remote sensing measures the movement of the ground at the surface. As we have seen, this can have many and even multiple causes. For example, an average ground movement map from PSInSAR over a typical city shows motion that has a variety of causes. There may be settlement of alluvium along major river valleys, subsidence above tunneling and subsidence due to groundwater abstraction. In addition there may be evidence of tectonic motion and almost certainly some swelling and shrinking clays. The remote sensing technique does not discriminate, but merely measures the ground movement in each case. The interpretation of the data requires interaction between the remote sensing expert and the geoscientist, if the causes of motion are to be fully understood. In fact, this interaction is needed from the outset, so the best technique can be selected to measure the particular type of movement that can be expected to be found in the study area. Study of the ground movement should also go beyond measurement of the motion. All of these remote sensing datasets tell us something about the geology exposed at the surface and can be interpreted in terms of faulting, folding, and lithology, for example. Such interpretation helps us understand the observed ground movement. In addition, it may be necessary to use other types of remote sensing that do not measure the ground motion at all, but do provide further insights into the geology, such as multi- or hyperspectral optical data for lithology and mineralogy. In addition, the remote sensing should be used in combination with other techniques that are not restricted to measuring surface phenomena, such as geophysics, in order to understand ground movement in the full three dimensions in which it occurs.

Summary and conclusions

Ground movements occur for a variety of reasons including natural geological processes such as landsliding and anthropogenic activities such as mining. They have a serious impact in terms of financial losses, injuries, and even deaths. Remote sensing can measure the movement of the ground in a variety of ways, all of which can be applied from space, aircraft, or in field surveys. These include photogrammetry with both optical and radar data, radar interferometry, and ranging techniques, such as lidar. The measurement of ground movement requires two acquisitions separated in time and can be extended into the monitoring of ground motion by repeat surveys.

SURFACE RADIATIVE FLUXES

Rachel T. Pinker
Department of Atmospheric and Oceanic Science,
University of Maryland, College Park, MD, USA

Synonyms

Remote sensing of surface radiative fluxes; Shortwave and longwave surface radiative fluxes

Definition

Radiative fluxes. Electromagnetic radiation received from the sun (shortwave) (SW) or emitted from the atmosphere and/or the Earth surface (longwave) (LW).

Surface radiative fluxes. Electromagnetic radiation received at the surface of the Earth (ocean, land, and cryosphere) in the shortwave or longwave part of the spectrum.

Surface radiation balance. The sum of the incoming and outgoing shortwave and longwave radiative fluxes at the surface.

Remote sensing of radiative fluxes. Sensing of radiative fluxes by instruments away from the source of radiation such as satellites or aircraft.

Introduction

Components of surface radiative fluxes

Solar radiation (*insolation or shortwave radiation*) from the sun (0.3–4.0 μm) that reaches the Earth's surface (about 50 % of that emitted) is a major source of energy for heating our planet. At the mean distance of the Earth from the sun (1.50×10^8 km), the incident radiant flux density (*irradiance*) on a surface perpendicular to the solar beam is known as the *solar constant* quoted to be about $1,360.8 \pm 0.5 \text{ W m}^{-2}$ according to measurements from the Total Irradiance Monitor (TIM) on NASA's Solar Radiation and Climate Experiment (SORCE) (Kopp et al., 2005; Kopp and Lean, 2011). Solar radiation at any location on the Earth is determined by the *Earth–Sun distance* and the *solar zenith angle*. On its way from its source, it is partially absorbed and scattered by the atmosphere and clouds and partially absorbed by the surface. It arrives at the surface as *direct solar* and *diffuse sky radiation*; the sum is referred to as *global radiation*. The absorbed energy in the atmosphere reradiates back to the surface and to outer space in the form of longwave (*terrestrial*) radiation (4.0–100.0 μm), and similarly, part of the absorbed energy at the surface is reradiated back to the atmosphere and space. The Earth climate is a result of the balance maintained between the *solar radiation* absorbed by the Earth–atmosphere system (gain) and the *emission* of the *terrestrial* radiation back to space (loss). This balance is also referred to as *net radiation* (Q^*) or *radiation balance* composed of *net solar radiation* and *net longwave radiation* expressed commonly as

$$Q^* = \text{SW}\downarrow - \text{SW}\uparrow + \text{LW}\downarrow - \text{LW}\uparrow \quad (1)$$

where SW (0.3–4.0 μm) and LW (4.0–100.0 μm) are the shortwave and longwave components, respectively, and arrows represent the direction of the flux and Q^* is the surface net radiation (0.3–100.0 μm). The net shortwave radiation is a balance between the incoming shortwave and the reflected shortwave; the ratio of reflected shortwave to incoming shortwave radiation is also known as the *albedo* (A):

$$K^* = \text{SW}\downarrow(1 - A) \quad (2)$$

K^* is the surface *net* shortwave radiation (0.3–4.0 μm).

The net longwave radiation is a balance between the incoming longwave and outgoing longwave; the latter depends on *surface temperature* and *emissivity*:

$$L^* = (LW\downarrow - LW\uparrow) \quad (3)$$

L^* is net longwave radiation at the surface (4.0–100.0 μm), and $LW\uparrow$ can be determined as

$$LW\uparrow = \varepsilon\sigma T^4 \quad (4)$$

where ε is surface emissivity, σ is the Stefan–Boltzmann constant, and T is the surface temperature.

Absorption of solar radiation in the atmosphere is mostly from ozone, water vapor, carbon dioxide, oxygen, and clouds. Clouds play a major role in determining the net radiative balance via their optical properties and amount. The effect of clouds on the Earth's radiation balance is measured as the difference between the clear-sky and total-scene radiation results. This difference is defined as *cloud-radiative forcing*. *Cloud optical depth* is a general measure of the capacity of a cloud to control the amount of light that will reach the surface. Greater optical depth means greater blockage of the light and a larger cooling of the Earth–atmosphere system in the SW region of the spectrum.

Attempts to estimate the radiative components of the Earth–atmosphere system date as early as Budyko (1958). Annually and globally averaged climatological values as estimated by Kiehl and Trenberth (1997) are 342 W m^{-2} for incoming solar, 107 W m^{-2} for reflected solar (namely, about 30 % of the incoming solar energy is reflected back to space), and 235 W m^{-2} for outgoing longwave. These values are being continuously reevaluated based on improved satellite observations (e.g., Hansen et al., 2005; Trenberth et al., 2009; Ma and Pinker, 2012). For some time, it was believed that about 20 % is absorbed by atmospheric ozone, water vapor, carbon dioxide, oxygen, and clouds. Recent investigations based on field experiments and numerical computations indicate that the atmosphere absorbs more than 25 % of the solar radiation due to several factors, e.g., the neglect of absorption in the wavelength range beyond 2.8 μm (Cess et al., 1997; Valero et al., 2003). The effect of clouds on atmospheric absorption is small, about 3 W m^{-2} .

In reality, the energy balance distribution over the globe is not uniform, with a net energy gain in lower latitudes and a loss at higher latitudes. One major objective of remote sensing from satellites is to obtain the best possible information on the radiation balance of the Earth–atmosphere system (Trenberth et al., 2009).

Need for information on radiative fluxes

Accurate information on the various components of the radiative fluxes at global scale is needed for a wide range of climate research applications such as modeling the hydrological cycle, representing interactions and feedbacks between the atmosphere and the surface, estimating

global terrestrial and oceanic net primary productivity, and validating climate and numerical weather prediction models. Each component has significance for a different type of application. For example, net all-wave radiation (0.3–100.0 μm) is needed for hydrological modeling, photosynthetically active radiation (PAR) (0.4–0.7 μm) for modeling net primary productivity and CO_2 budgets, and surface albedo for climate change studies. Satellite observations provide a systematic source of information at global scale needed for inferring components of the radiation balance. Recent advances in satellite technology and development of inference schemes have been conducive for obtaining information on the various components of the radiation balance. Reviewed will be basic principles of methodologies used to derive the Surface Radiation Budget by methods of remote sensing, feasibility to derive such fluxes and linkage to international programs, evaluation efforts, and future prospects.

Type of satellites used for estimating radiative fluxes

Information on radiative fluxes is being derived from dedicated satellites as well as from operational weather satellites. Both observational systems are composed of two types of satellites: geostationary and polar orbiting. The U. S. Geostationary Operational Environmental Satellites are known as GOES, while the Polar-Orbiting Environmental Satellites are referred to as POES. GOES satellites circle the Earth in a geosynchronous orbit, namely, they orbit the equatorial plane of the Earth at about 35,800 km above the Earth at a speed matching the Earth's rotation. The United States normally operates two geostationary satellites in orbit over the equator, one is positioned at 75° W while the other at 135° W longitudes. Currently, the United States is operating GOES-15 (or GOES-West) and GOES-13 (or GOES-East). Complementing the geostationary satellites are two polar-orbiting ones constantly circling the Earth in an almost north-south orbit, passing close to both poles. The orbits are circular, with an altitude between 830 and 870 km, and are sun synchronous. Environmental satellites are also operated by other nations and international organizations such as METEOSAT Second Generation (MSG) operated by EUMETSAT; LANDSAT, a high-resolution Earth observation satellite managed by NASA and the USGS; METOP, the European polar orbiter; and MTSAT, a Japanese geostationary satellite.

Radiative fluxes by remote sensing: feasibility

Satellites can provide information on surface radiative fluxes at various temporal and spatial scales, and attempts to do so have been ongoing for about 40 years. Steering has been provided by the World Climate Research Programme (WCRP)/World Meteorological Organization (WMO) and by several national and international projects, such as the Global Energy and Water Budget Experiment (GEWEX), the International Biosphere/Geosphere Programme (IGBP), and the GEWEX Hydroclimatology Panel (GHP) which coordinates scientific issues related

to the development and implementation of Regional Hydroclimate Projects. Specifications of requirements on information on radiative fluxes are provided in the Inter-governmental Panel on Climate Change (IPCC, 2007). In the United States, the *Interagency Committee on Earth and Environmental Sciences* has identified clouds and the hydrological cycle to be of highest scientific priority for global change research. Under this framework efforts are in progress to derive clouds and radiative fluxes from satellite observations. These include the *Surface Radiation Budget* (SRB) activity, the *International Satellite Cloud Climatology Project* (ISCCP) (Rossow and Schiffer, 1999), the *Clouds and the Earth's Radiant Energy System* (CERES) (Wielicki et al., 1996), the *Geostationary Earth Radiation Budget* (GERB) Experiment on the EUMETSAT METEOSAT Second Generation satellites (Harries et al., 2005), and the Moderate Resolution Imaging Spectroradiometer (MODIS) (Platnick et al., 2003; King et al., 2003). The instrument packages on these satellites are known as *imagers* (*sounders* are used for inferring the vertical structure of the atmosphere) and usually have about 2–36 channels in the spectral interval of 0.3–12.0 μm that are relevant for estimating both for shortwave and longwave fluxes.

Examples of channels on selected Geostationary Operational Environmental Satellites (GOES) are presented in Table 1. The channels of the Advanced Very High Resolution Radiometer (AVHRR) on polar-orbiting satellites are presented in Table 2. METEOSAT-5 and METEOSAT-7 channels are centered at 0.75, 6.4, and 11.5 μm , while the newer SEVIRI instrument on METEOSAT-8 has 12 channels as given in Table 3. The objective of NASA's *Earth Observing System* (EOS) Program is to study the Earth from space using a multiple-instrument, multiple-satellite approach. The *Clouds and the Earth's Radiant Energy System* (CERES) is one of the highest priority scientific satellite instruments developed for EOS (Wielicki et al., 1996; Loeb et al., 2009). CERES products include both solar-reflected and Earth-emitted radiation. The CERES instrument builds upon previous similar missions such as the *Earth Radiation Budget Experiment* (ERBE). CERES instruments were launched aboard the *Tropical Rainfall Measuring Mission* (TRMM) in November 1997 and on the EOS Terra satellite in December 1999. Two additional instruments fly on the EOS Aqua spacecraft since 2002. Each CERES instrument has three channels: a shortwave to measure reflected sunlight, a longwave to measure emitted thermal radiation in the 8.0–12.0 μm “window” region, and a total channel to measure all wavelengths of radiation (0.30–100.0 μm). The CERES instrument is managed by the NASA Langley Research Center in Hampton, Virginia.

The *Geostationary Earth Radiation Budget* (GERB) instrument is similar to CERES for the EUMETSAT's METEOSAT Second Generation (MSG) satellites intended to make accurate measurements of the Earth Radiation Budget from geostationary orbit. It was

Surface Radiative Fluxes, Table 1 Summary of spectral bands on several GOES imagers

Band	Wavelength range (μm)	Central wavelength (μm)	Meteorological objectives
1	0.55–0.75	0.65	Daytime cloud cover and surface features
2	3.8–4.0	3.9	Low cloud/fog and fire detection
3	6.5–7.0	6.75 (GOES-8/11)	Upper-level water vapor
4	5.8–7.3	6.48 (GOES-12)	Surface or cloud-top temperature
5	10.2–11.2	10.7	Surface/cloud-top temperature and low-level water vapor
6	11.5–12.5	12.0 (GOES-8/11)	CO ₂ band: cloud detection

Surface Radiative Fluxes, Table 2 Summary of spectral bandwidths (μm) of several AVHRR sensors

Channel	TIROS-N	NOAA-6, -8, -10	NOAA-7, -9, -11, -12, -14	NOAA-13

Surface Radiative Fluxes, Figure 1 The Afternoon Constellation ("A-Train") consisting of five US and international satellites (Credit: NASA).

launched in January 2004 on the first METEOSAT Second Generation satellite (MSG-1), renamed to METEOSAT-8. It complements the MSG SEVIRI instrument (Schmetz et al., 2002). The development, integration, and flight of GERB on MSG are supported by EUMETSAT and the European Space Agency (ESA). GERB has capabilities to measure the shortwave and longwave radiation from the Earth every 15 min and carries a *black body* for thermal calibration and a *solar diffuser* for shortwave calibration.

A recent addition to the suite of satellites relevant for *Earth Radiation Budgets* is the CloudSat mission (Stephens et al., 2002). CloudSat is a NASA Earth System Science Pathfinder mission to provide observations necessary to advance our understanding of cloud abundance, distribution, structure, and radiative properties. CloudSat is complimented with the Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO) (launched in April 2006) (Winker et al., 2012) and subsequently joined with several satellites already in orbit to form a constellation of satellites known as the *Afternoon Constellation* or *A-Train* (Figure 1). It consists of five satellites flying in close proximity: Aqua, CloudSat, CALIPSO, PARASOL, and AURA. The orbits are sun synchronous and provide near-simultaneous and colocated observations conducive to improved information on the *Earth Radiation Budget and Atmospheric Chemistry* (primarily from Aura).

The *Advanced Baseline Imager* (ABI) is being developed as the future *imager* on the Geostationary Operational Environmental Satellite (GOES) series, slated to be launched approximately in 2015 with GOES-R (Schmit et al., 2005). The ABI will begin a new era in US environmental remote sensing with more spectral

bands, faster imaging, and higher spatial resolution than the current imagers (Schmidt et al., 2005). ABI spatial resolution will be nominally 2 km for the infrared bands and 0.5 km for the 0.64 μm visible band. ABI has 16 spectral bands; 5 are similar to the 0.6, 4.0, 11.0, and 12.0 μm windows and the 6.5 μm water vapor band on several *GOES* imagers (e.g., 8/-9/-10/-11) (Menzel and Purdom, 1994) and another is similar to the 13.3 μm on the *GOES-12-13-14-15* imagers. Indeed, multiple satellites are needed to provide adequate temporal sampling since clouds and radiative fluxes vary throughout the day.

Physical principles of inference schemes

SW radiation

An important physical principle for deriving *SW* budgets from satellite observations is the close linear coupling between *SW* (0.3–4.0 μm) reflected radiance at the top of the atmosphere (*albedo*) and the surface irradiance (Schmetz, 1989). Cloud absorption (*transmittance*) and albedo are linearly related since atmospheric constituents do not emit radiation at solar wavelengths. There is a dependence on solar zenith angle, gaseous and aerosol absorption and scattering, surface reflectivity, and clouds. A plausible scenario of a retrieval methodology of shortwave radiative fluxes both at the surface and at the top of the atmosphere (TOA) can be summarized as follows. TOA downward flux (F_{td}) can be calculated from the extraterrestrial solar spectrum, accounting for variation in Sun–Earth distance and position of the sun in the sky relative to local vertical (*solar zenith angle*). Downward flux at the surface (F_{sd}) can be obtained by determining what fraction of F_{td} reaches the surface as radiation is

transferred through the atmosphere. This fraction is referred to as flux *transmittance* (T). It can be determined from a combination of the reflected part at the radiative flux at the TOA that the satellite observes and from modeling the radiative effects of atmospheric constituents (such as ozone, water vapor, molecular scattering, and optical properties of clouds and aerosols). It also depends on the length of the path the radiation travels through the atmosphere (determined by the solar zenith angle), and to a lesser degree, on the *albedo* of the surface. Once T is known, surface downward flux is obtained as $F_{sd} = T F_{td}$. Once F_{sd} is known, upward flux at the surface (F_{su}) is calculated as $F_{su} = A_s F_{sd}$, where A_s is surface albedo. Similarly, flux reflected to space by the Earth-atmosphere system (TOA upward flux, F_{tu}) can be obtained from the product of F_{td} and the TOA albedo (A_t), namely, $F_{tu} = A_t F_{td}$. For example, the Clouds and the Earth's Radiant Energy System (CERES) instrument onboard several Earth Observing System (EOS) satellites provides a direct measurement of TOA broadband (A_t).

LW radiation

Downwelling longwave radiation $LW\downarrow$ at the surface originates from radiatively active gases in the atmosphere and depends on the vertical profiles of temperature, gaseous absorbers, and clouds. Gaseous emission is present in specific wavebands in the range 0.3–30 μm , whereas emission from clouds corresponds to black body radiation at the temperature of the cloud base. The intensity of the thermal emission from a cloud varies with its temperature and the optical thickness of the cloud.

Retrieval of $LW\downarrow$ is difficult since only *atmospheric window* radiances at the top of the atmosphere give information on the near-surface radiation field. For the remainder of the longwave spectrum, the radiation regimes at the top of the atmosphere and at the surface are decoupled; more than 80 % of the clear-sky longwave flux reaching the surface is emitted within the lowest 500 m of the atmosphere. Cloud contributions are mainly from the atmospheric window region (8.0–13.0 μm), and the relevant cloud parameters are cloud base height location and temperature, *emittance*, and cloud amount. Relative importance of cloud contribution decreases with moister atmospheres since the transparency of the window decreases due to water vapor *continuum* absorption. From cloudless skies, more than half the longwave flux received at the ground comes from gases in the lowest 100 m and roughly 90 % from the lowest kilometer. Consequently, $LW\downarrow$ is often estimated as a function of a bulk atmospheric temperature (in Kelvin) approximated by air temperature at the ground and an estimated broadband atmospheric emissivity (Prata, 1996; Dille and O'Brien, 1998). It is often assumed that the longwave emissivity of most natural surfaces is unity, so that $L\uparrow$ can be estimated from knowledge of the surface temperature. Longwave techniques could be characterized as being of distinct types:

flux calculation techniques, which use radiative transfer models to calculate the $LW\downarrow$ directly from retrieved profiles of temperature and water vapor and estimates of cloud fraction and cloud base altitude (e.g., Breon et al., 2002; Gupta et al., 2010), flux inference techniques which use direct inference from *TOVS* or *HIRS* radiance observations, and statistical inference schemes based on radiance–flux relationship developed with detailed radiative transfer models and large number of observed atmospheric soundings (for clear-sky and overcast conditions) with some built in cloud height and base information. It is often assumed that the longwave emissivity of most natural surfaces is unity, so that $LW\uparrow$ can be estimated from knowledge of the surface temperature (Prata, 1996).

Methodologies to derive radiative fluxes

Inference schemes to derive radiative fluxes from satellite observations have been implemented at a wide range of complexities, both in the SW and LW part of the spectrum. Review type of summaries can be found in Schmetz (1989, 1991), Pinker et al. (1995), and Whitlock et al. (1995); methods to derive *PAR* are described in Frouin and Pinker (1995); recent approaches for *LW* methods can be found in Zhou et al. (2007), Nussbaumer and Pinker (2011, 2012), and Niemela et al. (2001).

Methods to derive SW fluxes have been implemented on different spatial and temporal scales. Used are observations from geostationary satellites (METEOSAT, GOES, GMS) and from polar-orbiting satellites using instruments such as AVHRR, MODIS, and CERES (Stuhlman et al., 1990; Pinker and Laszlo, 1992; Gupta et al., 1999; Chou et al., 1995; Brisson et al., 1994; Li et al., 1993; Zhang et al., 1995; Ceballos et al., 2004; Hollmann et al., 1999; Zhang et al., 2004; Charlock et al., 2006; Vardavas and Taylor, 2007; Wang and Pinker, 2009; Ma and Pinker, 2012). For obtaining estimates at global scale at three hourly intervals, the International Satellite Cloud Climatology Project (ISCCP) (Rossow and Schiffer, 1991) has merged information from several satellites that has been widely used and implemented with independent algorithms. Initial work on the use of these observations started at the NASA Goddard Institute for Space Studies (GISS) (Rossow and Lacis, 1990). The validation results for the GISS ISCCP surface fluxes show that it has an uncertainty of 10–15 W m^{-2} at monthly time scales (Zhang et al., 2006, 2007). The ISCCP data in their various versions have been widely used by many groups (Stackhouse et al., 2002; Ma and Pinker, 2012) and serve as the basis for the WCRP-sponsored *Radiative Flux Assessment* intercomparison activity under which various satellite products (global and regional) are being evaluated.

Many of the current geostationary satellites are limited in their capability to accurately detect cloud or aerosol optical properties that are important elements of the

Surface Radiative Fluxes, Figure 2 Left: Monthly averaged surface LW radiation for March 2001 as derived from MODIS observations (Nussbaumer and Pinker, 2012); Right: monthly averaged surface SW radiation for March 2001 as derived from MODIS observations (Wang and Pinker, 2009).

radiation budget. Polar-orbiting satellites tend to have higher spatial resolution than the geostationary satellites, as well as more spectrally resolving bands. The MODIS instrument onboard the Terra and Aqua satellites, a state-of-the-art sensor with 36 spectral bands and onboard calibration of both solar and infrared bands, has the capability to measure atmospheric and surface properties with higher accuracy and consistency than previous Earth observation imagers. Moreover, geostationary satellites cover only part of the globe up to about 50° north and south. Polar-orbiting satellites provide coverage twice a day over the entire globe, including the high latitudes. A configuration of satellites, both geostationary and polar orbiting, is needed to cover the entire globe with observations that depict the diurnal cycle. In Figure 2 shown are mean surface SW radiative fluxes (W m^{-2}) averaged for March 2001 (Wang and Pinker, 2008) and the mean LW $\downarrow$ fluxes for the same month (Nussbaumer and Pinker, 2012) as obtained from the MODIS instrument on Terra and Aqua.

Real-time implementation of inference schemes of shortwave radiative fluxes is now a reality. Flux estimates are produced at hourly time scale by the National Oceanic and Atmospheric Administration (NOAA)/National Environmental Satellite, Data, and Information Service (NESDIS), using observations from GOES (Pinker et al., 2003). Similar efforts are ongoing in other countries such as at the *Nowcasting Satellite Application Facility* (NWC SAF) in Europe. SAFs are dedicated centers for processing satellite data. They have been developed by a consortium of EUMETSAT Member States and Cooperating States trying to benefit from METEOSAT Second Generation (MSG) and Polar Platform Satellites.

Surface Radiative Fluxes, Figure 3 Evaluation of daily mean downwelling SW flux estimated by UMD/SRB_MODIS model (Wang and Pinker, 2009) against BSRN measurements over land (January 2003–December 2005). Cases eliminated: 1.6 %.

Evaluation of satellite estimates using surface measurements

Evaluation of surface fluxes depends on the quality of the surface measurements (Shi and Long, 2002; Philipona et al., 2001). Historic surface SW measurements were

collected under the auspices of the WCRP at the World Radiation Data Centre (WRDC), A.I. Voeikov Main Geophysical Observatory, St. Petersburg, Russia. This database includes sites from all continents and contains measurements in the form of daily and monthly averages. The Swiss Federal Institute of Technology provides the Global Energy Balance Archive (GEBA) (Ohmura and Gilgen, 1993) which includes data from the WRDC. Globally distributed surface measurements over the last two decades are improving with the advent of the GEWEX Baseline Surface Radiation Network (BSRN) (Ohmura et al., 1998). BSRN is dedicated to providing long-term high-quality measurements at locations around the globe critical for satellite validation. Regional-scale networks of surface measurements are also utilized in validation (Augustine et al., 2000; Michalsky et al., 1999) as well as data from special campaigns such as the Clouds and the Earth's Radiant Energy System (CERES) program/Atmospheric Radiation Measurement (ARM) Validation Experiment (CAVE) (Rutan et al., 2001). Examples of evaluation of SW and LW results from MODIS observations against the BSRN network are shown in Figures 3 and 4. Radiative fluxes are also measured over the oceans. For instance, in situ measurements from the Pilot Research Moored Array in the Tropical Atlantic (PIRATA) moorings in the tropical Atlantic (Bourle's et al., 2008) and the Tropical Atmosphere Ocean/Triangle Trans-Ocean Buoy Network (TAO/TRITON) moorings in the tropical Pacific Ocean (McPhaden et al., 1998) are frequently used for comparisons with the satellite estimates (Figure 5). Surface radiative fluxes are needed at accuracies suitable to predict transient climate variations and long-term climate trends. The *WCRP GEWEX Surface Radiation Budget (SRB)* project is specially tasked to produce, validate, and assess long-term surface and atmospheric radiative budgets at global scale. Intercomparison between satellite products with surface sites is part of the GEWEX SRB (Stackhouse et al., 2002) and CERES-SARB programs (Charlock et al., 2006). Reported is agreement with ground observations within 10 W m^{-2} on a monthly time scale. At hourly time scales the reported differences are in the range of -50 to $+50 \text{ W m}^{-2}$. More comprehensive evaluation results are reported on in Trenberth et al. (2009), Ma and Pinker (2012), and Nussbaumer and Pinker (2012).

Future prospects

A summary of current and future satellite observations of relevance for SRB research is presented in Wielicki et al. (1996). It is believed that SRB activities could benefit from better information on the vertical structure of clouds and meteorology of the lower layer; information on cloud types; improved calibration and stability of all instruments used; better understanding of validation limitations; improvement in inference techniques; and information on aerosol optical properties, better characterization of

Surface Radiative Fluxes, Figure 4 Evaluation of daily mean surface LW flux estimated by UMD/SRB_MODIS_LW at 1° spatial resolution against 18 BSRN stations for 2007.

Surface Radiative Fluxes, Figure 5 Evaluation of daily mean downwelling SW estimated by UMD/SRB_MODIS model (Wang and Pinker, 2009) (2003–2005) against PIRATA buoy observations. Cases eliminated: 1.1 %.

land surface properties, accurate information on snow distribution, and distinction of partially cloud-filled satellite fields of view and the 3-D nature of clouds. In the short term, the SRB inference methods will benefit from activities like the CloudSat, the Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations, and the entire constellation of *A-Train* satellites.

Acknowledgments

We thank NASA for the support of our work under grant NNX08AN40A from the Science Mission Directorate-Division of Earth Science and grant NNX13AC12G from the Energy and Water Cycle Study (NEWS) program. The work also benefited from the support under NOAA grant NA09NES4400006, the Cooperative Institute for Climate and Satellites (CICS) at the University of Maryland/ESSIC.

Definition and overview

The purpose of a scientific remote sensing instrument is to estimate geophysical properties of a target from indirect measurements of its electromagnetic radiation, propagation, and scattering. Geophysical properties, such as ocean surface temperature or atmospheric abundance of a certain molecule, are deduced from their electromagnetic properties. The procedure typically requires approximations, assumptions, and the use of measurements that contain random and systematic errors. As a result, the accuracy and precision of the geophysical estimates are usually validated by some independent means. Surface truth refers to some form of independent knowledge about the geophysical property being estimated. It is used to characterize the quality of the remote sensing data product, often using such statistical measures as the root-mean-square or the average difference between the remote sensing estimate and the surface truth.

Point-to-point comparisons

In most cases, surface truth comparisons with remote sensing estimates are made on a point-by-point basis. For example, a surface truth measurement may be compared to the remote sensing estimate made from a satellite as it passes overhead. Individual remote sensing estimates usually represent an instantaneous spatial average of the geophysical parameter. For surface imagers, the average is over the horizontal resolution spot size of the sensor. For atmospheric sounders, the average is over a resolution volume that includes both horizontal and vertical resolution boundaries. Different types of surface truth measurements are averaged in different ways. Surface truth for some ocean parameters – including [sea surface temperature](#), wind speed and direction, and sea level height – is often provided by buoys and tide gauges (Wentz et al., 2000; Mitchum, 1998; Goodberlet et al., 1989). Buoy measurements are made at a single point in space but can be averaged over time. Surface truth for atmospheric profiles of temperature and humidity is often provided by radiosondes, that is, instrumented weather balloons released from the ground (Buehler et al., 2004; Ruf et al., 1994). Radiosondes make point measurements along the line of ascension of the balloon during its ascent time, which typically lasts 30–60 min through the bulk of the troposphere. For both buoys and radiosondes, their spatial and temporal sampling characteristics do not match those of the remote sensing estimate. It is therefore not necessarily the case that perfect measurements by each should agree. Allowance for the sampling differences is made when they are compared.

Another class of point-to-point comparisons makes use of numerical weather forecast models such as those maintained by the US National Weather Service's National Center for Environmental Prediction (NCEP), the European Centre for Medium-Range Weather Forecasts (ECMWF), and the US Navy's Fleet Numerical Meteorology and Oceanography Center (FNMOC). These models produce global maps of atmospheric and surface parameters that are updated at least several times per day. The spatial resolution of the models is generally coarser than that of the remote sensing measurement, so there is once again a mismatch between their spatial sampling characteristics. In addition, the times at which a model is updated generally do not correspond exactly with the time when the remote sensing measurement is made, so temporal sampling is also mismatched. In spite of these differences, numerical forecast models are often used as surface truth. Relative to in situ sources of surface truth, such as buoys and radiosondes, they are particularly useful for assembling a large intercomparison database in a short period of time that is representative of the global variability of a particular geophysical parameter. One important limitation is the fact that these models tend to underestimate large deviations of the geophysical parameters from their mean values, and they generally perform less accurately in extreme weather conditions such as heavy precipitation and very high winds.

Statistical properties as surface truth

Some statistical properties of geophysical properties can also be used as a form of surface truth. To be useful, the property must be independently predictable, and reliable estimates of it must be obtainable from the available population of remote sensing measurements. One example is the global average wind speed and prevailing wind direction, both of which can be accurately predicted from either a large, globally distributed database of buoys or from a collection of numerical forecast models of the wind field (Frielich and Challenor, 1994; Ebuchi, 1999). Another example is the lower bound on microwave thermal emission by the ocean surface, which is determined by the temperature dependence of the emissivity of water (Ruf, 2000). These statistics tend to be very stationary over time and so are good candidates for statistical surface truth. If the statistics derived from surface truth and remote sensing do not agree, it is usually an indication that either the remote sensing instrument calibration is biased or the relationship between electromagnetic and geophysical properties that is assumed by the remote sensing estimation algorithm is in error. One important difference between point-to-point and statistical surface truth comparisons is that, with the statistical approach, the measurements with which the two statistics are derived need not coincide in space or in time. This can significantly simplify assembly of a satisfactory surface truth database, and it can ameliorate many of the effects of sampling differences between the surface truth and remote sensing measurements. However, these benefits come at the cost of a less direct type of comparison that does not as specifically quantify the performance of the remote sensing estimates as does the point-to-point method.

Conclusions

Surface truth represents knowledge about the geophysical properties being estimated by remote sensing that can be used to assess the quality of those estimates. The knowledge may result from an independent measurement of the geophysical property by some other means, such as a direct, in situ temperature or humidity probe, or it may result from statistical processing of a population of independent measurements. Surface truth is often used both to calibrate and validate a remote sensing data product and to characterize its quality after calibration is complete.

SURFACE WATER

Michael Durand
 School of Earth Sciences, The Ohio State University,
 Columbus, OH, USA

Definition

Remote sensing of surface water can be defined as collecting information about lakes, wetlands, floodplains, and rivers when viewed from above using electromagnetic radiation (Rees, 2001) or gravity field fluctuations (e.g., Crowley et al., 2006).

Introduction

Spaceborne and airborne instruments are used to characterize hydrologic features of surface water bodies: lakes, wetlands, floodplains, and rivers. Such remote sensing measurements are an increasingly important complement to traditional in situ surface water hydrology measurements. Alsdorf et al. (2007a) summarize science questions related to surface water and provide a detailed review of surface water remote sensing methods.

Primary quantities of interest for surface water quantity are the spatial extent of surface water bodies (inundated area, hereafter) and the vertical elevation of surface water bodies (water surface elevation, hereafter). From these primary quantities, changes in storage and hydrologic fluxes (e.g., river discharge) can be inferred. Primary quantities of interest for surface water quality relate to the biogeochemical constituents present in the water. This review of surface water remote sensing is organized around the following three broad fields: inundated area mapping, water surface elevation estimation, and water biogeochemical constituent characterization. For each of these three quantities, the remote sensing instruments and methods are explained, and some representative

applications of the *geophysical retrieval* (see entry [Geophysical Retrieval, Overview](#)) of surface water characteristics are described.

Inundated area mapping

The radiometric reflectivity and emissivity and radar backscatter behavior of liquid water allows for surface water hydrologic features to be distinguished from other geophysical entities at a number of wavelengths in the electromagnetic spectrum, which allows for the characterization of inundated area. For instance, the reflectance of clear water at visible and near-infrared wavelengths is less than that of most naturally occurring materials (Rees, 2001). Similarly, the microwave backscatter coefficient from open water is relatively low, permitting discrimination from land (Smith, 1997). Moreover, the passive microwave emissivity from inundated land is generally low, and the emissivity polarization difference is generally large (Prigent et al., 2007).

Both passive and active remote sensing instruments have been used to map inundated area for lakes, wetlands, floodplains, and rivers. For instance, Smith et al. (2005) assessed the total area and number of Siberian lakes using passive optical/infrared systems (see entry [Optical/Infrared, Radiative Transfer](#)): Landsat-1 in 1973 and the Russian RES URS-1 satellite in 1998. The comparison allowed for the quantification of a widespread decline in lake number and area in the 25 years between the two assessments. Prigent et al. (2007) present an excellent review of visible, infrared, and microwave passive methods and synthetic aperture radar (SAR) (see entry [Calibration, Synthetic Aperture Radars](#)) methods for characterizing inundated area for wetland studies. Prigent et al. (2007) obtained monthly estimates of global time series of inundated area at a 0.25° spatial resolution by merging disparate but complementary data streams: Advanced Very High Resolution Radiometer (AVHRR) visible and near-infrared (NIR) reflectances, the Special Sensor Microwave/Imager (SSM/I) passive microwave radiometer (see entry [Microwave Radiometers](#)) measurements, and radar scatterometer (see entry [Radar, Scatterometers](#)) measurements from the European Remote Sensing satellite.

Hess et al. (2003) used the Japanese Earth Resource Satellite-1 (JERS-1) SAR data to map inundated area at 100 m resolution in the Amazon Basin for two dates representing high water and low water. These inundated estimates have been useful in assessing the contribution of wetlands to biogeochemical processes in an area where obtaining in situ data is far from trivial. The Advanced Land Observing Satellite (ALOS) launched in January 2006 represents a significant improvement over JERS-1 and will permit more detailed floodplain and wetland characterization (Rosenqvist et al., 2007).

Many rivers show significant width (and, thus, inundated area) increase with increasing discharge, although this is not always the case for channelized rivers.

For instance, Smith and Pavelsky (2008) demonstrated that for the braided Lena River in Siberia, Moderate Resolution Imaging Spectroradiometer (MODIS) estimates of effective river width show strong correlation to river discharge. In addition to making inference on fluvial processes, inundated area is crucial for characterizing river flood events and evaluating flood inundation models (e.g., Horritt and Bates, 2001).

Water surface elevation estimation

Water surface elevations can be characterized by a variety of active (as opposed to passive) remote sensing instruments: laser altimetry, profiling radar altimetry, interferometric SAR, and swath radar altimetry. Laser altimeter systems function by emitting a pulse of visible or NIR radiation, detecting the echo of the pulse, and measuring the time between emission and detection. Traditional (profiling) radar altimetry (see entry [Radar, Altimeters](#)) works on much the same principles and provides a (spatially limited) profile of elevation estimates along the flight line (Elachi, 1987). Repeat-pass interferometric SAR (see entry [Ocean Applications of Interferometric SAR](#)) utilizes multiple SAR images to estimate elevation changes (e.g., Alsdorf et al., 2000). Imaging (swath) radar altimeters provide spatially continuous elevation estimates; SAR processing is very attractive for imaging radar altimeters (Elachi, 1987).

These methods are used for assessing surface water elevations in lakes, wetlands, floodplains, and rivers. For lakes and wetlands, water surface elevations represent a primary quantity of interest. For instance, Birkett (1994) used the Geosat profiling radar altimeter to characterize water surface elevations for lakes. Elevations of surface water stored in man-made reservoirs have been characterized using Shuttle Radar Topography Mission (SRTM) imaging SAR altimeter (Kiel et al., 2006). Yi et al. (2006) characterized surface water elevations in wetlands in Louisiana, USA, using TOPEX/POSEIDON profiling altimeter data. Changes in water surface elevation can be used to estimate changes in surface water storage.

River floodplain water elevations represent a combination of upstream hydrologic conditions and complex fluvial hydraulic processes. Alsdorf et al. (2007b) used JERS-1 SAR measurements to perform repeat-pass interferometric processing, which allowed for characterization of change in water elevation between the two satellite overpasses. This temporal change measurement provided new insight into the hydraulic complexity of the Amazon River floodplain. Limitations of the repeat-pass interferometric SAR include the following: (1) It does not characterize water height at a given time, but change in water height between two satellite overpasses, and (2) it requires flooded vegetation to return the radar pulse to the antenna.

Birkett et al. (2002) used TOPEX/POSEIDON profiling radar altimetry data to estimate water surface elevations for channelized rivers (as well as floodplains

and lakes) across the Amazon Basin. A major limitation of profiling radar altimetry for fluvial hydrology applications is the very limited spatial coverage and coarse spatial resolution. LeFavour and Alsdorf (2005) used SRTM water surface elevations to calculate river slope and then to estimate discharge along the Amazon River using simple flow hydraulics analysis. A limitation of the SRTM dataset is the temporal coverage: The entire mission was a total of 11 days in duration.

The Gravity Recovery and Climate Experiment (GRACE) maps changes in Earth's gravity field. These gravity changes are a result of several factors, including changes in surface water storage. GRACE thus differs from all other remote sensing methods mentioned herein, since the latter rely on observed electromagnetic radiation. For instance, Crowley et al. (2006) characterized water storage anomalies over the Congo River Basin for a 5 year period. A major limitation of GRACE is the coarse spatial resolution, which is on the order of hundreds of kilometers.

To overcome the limitations of existing remote sensing instruments, Alsdorf et al. (2007a) describe the need for an imaging (or wide swath) interferometric SAR altimeter to characterize water surface elevations and inundated area. The proposed satellite mission has been named Surface Water and Ocean Topography (SWOT) and has been recommended by the National Research Council Decadal Survey (NRC, 2007) to measure ocean topography as well as WSE over land; the proposed launch date time frame is between 2013 and 2016.

Water biogeochemical constituent characterization

In some cases, water biogeochemistry can be inferred from remote sensing when biogeochemical constituents alter the interaction of water with electromagnetic radiation. For example, turbid water generally has a higher spectral reflectance than clear water at visible and NIR wavelengths. Wang and Shi (2008) mapped a massive algae bloom in China's Lake Taihu using MODIS data. The MODIS spectral signature was used to quantify chlorophyll-a concentrations. Similarly, Chen et al. (2007) used the visible reflectances from the sea-viewing wide field-of-view sensor (SeaWiFS) to characterize a composite pollution index for the Pearl River estuary in China.

Summary

Spaceborne and airborne remote sensing measurements have been used to characterize inundated area, water elevations, and water biogeochemical constituents. Surface water is easily distinguished from surrounding terrain by active and passive sensors at a variety of wavelengths, permitting for the characterization of inundated area. Ranging instruments have been used to characterize water surface elevations, permitting the estimation of storage changes and river discharge, which are two crucial terms in the water balance. Remote sensing instruments have also been used to map water quality in terms of biogeochemical

constituents. The recent launch of ALOS PALSAR in January 2006 is expected to greatly increase the ability to effectively map floodplains and wetlands from space. The proposed launch of SWOT in 2013–2016 has the potential to allow for more detailed characterization of surface water storage changes and discharge than has so far been possible from a spaceborne platform.

Definitions

Among key parameters characterizing seasonal snow cover in cold land regions are snow area, extent, depth, water equivalent, accumulation onset, melt onset, ice layer, melt duration, and season length. Within an area $p(i,j)$ that has a fractional snow cover of $f_S(i,j)$, the actual area that is fully covered by snow is $s_A(i,j) = f_S(i,j) \cdot p(i,j)$ at a location determined by indices i and j on the Earth's surface. Then, the total snow area S_A is the summation of all $s_A(i,j)$. Depending on the sensitivity, accuracy, and resolution of a satellite sensor, the existence of snow cover in $p(i,j)$ can be detected when $s_A(i,j)$ is sufficiently large. The composition of all areas $p(i,j)$ where snow is detectable constitutes the snow extent S_E , which is smaller than S_A unless snow fully covers all snow areas $s_A(i,j)$.

Over area $p(i,j)$, the snow volume is calculated as $v_S(i,j) = d_a(i,j) \cdot p(i,j)$ where $d_a(i,j)$ is the average snow depth in area $p(i,j)$, including the snow-free fraction $[1 - f_S(i,j)]$ in $p(i,j)$ with zero snow depth. Rather than snow volume, it is more useful for hydrologists to use snow water equivalent (SWE), which is equal to the depth of water that ensues when the snow volume melts on $p(i,j)$. Let $\rho_a(i,j)$ be the average bulk density of snow and ρ_w the

water density, then $SWE(i,j) = d_a(i,j) \cdot \rho_a(i,j)/\rho_w$ is the average SWE over area $p(i,j)$.

The first snowfall in area $p(i,j)$ may be short lived because air and land temperatures are not cold enough to sustain it. As the landscape freezes, subsequent snowfalls may accumulate and contribute the snowpack during a snow season. The day when snow starts to consistently accumulate to build up the seasonal snowpack is called the snow accumulation onset date (T_S). During a snow season, an anomalous occurrence of snowmelt may create excessive meltwater, which refreezes in the snowpack, forming an ice layer that contains large icy objects (ice clumps, lens, columns, etc.).

As winter transitions into spring and then summer, snowmelt occurs more consistently and continuously (as opposed to isolated anomalous melt in winter such as that caused by warm air advection). Snowmelt onset date (T_M) is defined as the day when a consistent snowmelt starts to occur. Snow disappearance date (T_F) is the day when area $p(i,j)$ becomes snow-free as snow completely melts away. Then, snowmelt duration is $\Delta_M = T_M - T_F$ and snow season length is $\Delta_S = T_S - T_F$. These key snow parameters can be obtained using remote sensing data from multispectral visible infrared and microwave satellite sensors for each pixel $p(i,j)$.

Significance of snow cover

Climate change at high latitudes is strongly influenced by the albedo-temperature feedback process. The snow cover influences the global heat budget (Robinson and Kukla, 1985; Foster and Chang, 1993) because it affects the planetary albedo and the Earth's outgoing longwave radiation (Groisman et al., 1994). Snow is regarded as one of the key variables in global change monitoring (Walsh, 1991; Hall et al., 2005).

While large changes have been observed in many cold land environments (sea ice, ice sheet, glacier, tundra, and

permafrost), Bartlett et al. (2005) indicate no significant trends in the mean snow onset or duration over North America from 1950 to 2002, though their averaging approach over a hemispheric scale may suppress regional snow change signatures. Other studies (Chapin et al., 2005; Schwartz et al., 2006; Bonsal and Prowse, 2003) suggest that the Arctic snow season may have already decreased by more than 2.5 days per decade and that snow is melting earlier (Foster et al., 1992; Robinson et al., 1993; Frei and Robinson, 1999; Brown, 2000). This discrepancy illustrates a need for advanced satellite measurements of snow cover from local to regional and hemispheric scales.

Consistent with many climate change projections, significant changes in snow regimes are occurring throughout the Arctic. These changes have important consequences for humans, wildlife, and ecosystems. Recent changes in temperature and precipitation have altered the timing of the snow season and the snow-cover characteristics. The amount of snow (depth and *SWE*) has probably changed as well (Groisman and Davies, 2001), though this is a difficult quantity to measure accurately over large areas (Benson, 1982; Goodison et al., 1998; Yang et al., 2005; Liston and Sturm, 2004) compared to satellite measurements of snow extent. Furthermore, winter rain is likely more prevalent (Putkonen and Roe, 2003). It is critically important to comprehensively document these spatial and temporal changes with satellite data.

Moreover, satellite remote sensing of snow has immediate applications to snowmelt, river discharge, and flood forecasting. The timing and magnitude of river discharge in the Arctic is largely controlled by cold season snow mass storage and subsequent melt. In northern watersheds, snowmelt accounts for most of the annual river discharge and often produces the highest discharge rates of the year (Lo and Serreze, 2002; Bowling et al., 2000). Heavy snowstorms with rapid snowmelt in the spring of 1997 accounted for the “flood of the century” in the US northern Great Plains (Nghiem and Tsai, 2001), causing more than four billion dollars in flood-related damages (National Climatic Data Center, 1997). The ability to identify and track changes in snow regimes with increasing accuracy is an important asset for decision makers.

Seasonal snow extent

Satellite multispectral sensors have collected global data since the late 1960s, and algorithms for snow applications have been developed and improved. Satellite visible-band radiometers detect snow by its high albedo and characteristic patterns (Wiesnet and Matson, 1979) and by its spectral signature. An archive of quality-controlled National Oceanic and Atmospheric Administration (NOAA) weekly and now daily snow products is available from the Rutgers Global Snow Lab at Rutgers University (<http://climate.rutgers.edu/snowcover/>). The Earth Observing System (EOS) Terra and Aqua spacecraft, launched in 1999 and 2002, respectively, each carry an

instrument called the Moderate Resolution Imaging Spectroradiometer (MODIS). MODIS has 36 channels covering visible to thermal infrared parts of the spectrum (0.4–14.4 μm) with a pixel size of 250 m–1 km and a swath width of 2,330 km, providing global coverage daily in most seasonally snow-covered regions.

MODIS data are used to obtain snow-cover products, including snow extent (S_E) and snow fraction (f_s), from automated algorithms at the Goddard Space Flight Center (GSFC) in Greenbelt, Maryland (<http://modis-snow-ice.gsfc.nasa.gov>). MODIS snow products are archived and distributed at the National Snow and Ice Data Center (NSIDC) in Boulder, Colorado. Global snow products are provided at 500 m, 5 km, or 25 km resolution as daily, 8 day composite, and monthly validated snow maps (Hall et al., 2002; Hall and Riggs, 2007). An example of a monthly, global MODIS snow-cover map is presented in Figure 1 for February 2004. The MODIS map shows snow extent from mid- to high latitudes over the Northern Hemisphere with smaller snow fraction at midlatitudes. Note that Western Europe (UK, France, Denmark, Germany, etc.) was either snow-free or did not have much snow cover compared to other regions at the same latitudes (Figure 1). At very high latitudes, such as in the Canadian Arctic Archipelago and Taymyr Peninsula in Siberia, there were difficulties in identifying snow due to winter darkness and cloud cover.

MODIS snow-cover maps complement existing hemispheric-scale snow maps that are available today (e.g., the NOAA maps (Ramsay, 1998)) and provide advances in spatial resolution and snow-cloud discrimination capabilities. The data archiving and distribution system provides free web-based access to the MODIS results. While MODIS has several technological advantages, the Advanced Very High Resolution Radiometers (AVHRR), with four to six channels (0.58–12.5 μm), have over three decades of data providing long-term measurements of seasonal snow extent (Foster et al., 2008a). Furthermore, active and passive microwave data can be used to supplement visible and near-infrared data over areas under clouds and darkness (Foster et al., 2008b).

Snow depth and snow water equivalent

The microwave brightness temperature emanating from the ground beneath a snow cover and from the snow itself is sensitive to snow depth, *SWE*, size of individual snow crystals, and other physical properties of snow. This interaction can be detected by spaceborne passive microwave radiometers. In the past three decades, considerable progress has been made in estimating regional and global snow depth and *SWE* using instruments such as the Scanning Multichannel Microwave Radiometer (SMMR) and the Special Sensor Microwave Imager (SSM/I). For more information on this topic, see results by Chang et al. (1987), Foster et al. (1997), Chen et al. (2001), and Pulliainen and Hallikainen (2001). Further progress has also been made in developing consistent multisensor

Terrestrial Snow, Figure 1 MODIS monthly snow-cover product (MOD10CM, Collection 5) for February 2004 showing snow extent and fraction of snow cover with a spatial resolution of 0.05° or about 5 km resolution. The color key is for fractional snow cover from 1 % to 100 %. Gray represents areas of persistent cloud cover according to the cloud mask.

passive microwave *SWE* datasets for climate studies (Armstrong and Brodzik, 2001).

The Advanced Microwave Scanning Radiometer – EOS instrument (AMSR-E) on the Aqua satellite continued the heritage of earlier passive microwave Earth observations but included enhanced spatial resolution and an expanded range of frequency bands (6.925–89.0 GHz). The AMSR-E swath width was approximately 1,450 km. Research conducted in support of the implementation of AMSR-E for snowpack monitoring (Chang and Rango, 2000; Chang and Kelly, 2002; Kelly et al., 2003) has led to an automated algorithm for global *SWE*, at a pixel resolution of 25 km. The map in Figure 2 for February 10, 2001, shows an area of high *SWE* values in Labrador, Canada, which is consistent with the snow climatology in this region. However, due to the high sensitivity of the microwave response to varying snow properties, retrieval algorithms often produce large random estimation errors. Shallow or discontinuous snowpack, complex stratigraphy, large average snow grain size, or the presence of liquid water can adversely affect the algorithm performance and thus complicate the identification of changes in snow conditions.

Backscatter measurements from active microwave sensors complement the passive microwave data. Backscatter data from satellite scatterometers can also be useful for estimating snow depth and *SWE*. The SeaWinds scatterometer operating at Ku-band (13.4 GHz) aboard

the QuikSCAT satellite (QSCAT) was launched in June 1999. This sensor collects backscatter data with a resolution from 12 to 25 km over a swath of 1,400 km for the horizontal polarization (H) and 1,800 km for the vertical polarization (V). QSCAT already obtained global data for over a decade. Ku-band backscatter is sensitive to snow accumulation (Nghiem et al., 2001; Cline et al., 2004). For example, QSCAT backscatter signatures and snow parameters at a location in the Yellowstone National Park (44.65°N , 111.1°W) in Montana, USA, are shown in Figure 3. A regression analysis between QSCAT H backscatter and *SWE* data from the National Operational Hydrologic Remote Sensing Center (NOHRSC) National Snow Analysis (NSA) yields a positive correlation coefficient of 0.970, with a change of 108 mm per dB for *SWE* up to 200 mm. For *SWE* > 200 mm, the correlation is weaker and the relationship is less accurate because of attenuation effects in backscatter data and uncertainties in NOHRSC *SWE* results. Based on the rating curve derived from NOHRSC data (Nghiem et al., 2004), QSCAT data were used to estimate *SWE* values (bottom panel in Figure 3), corresponding to a range of snow density ratio (ρ_a/ρ_w) from 22 % to 56 % at Yellowstone.

The Yellowstone case represents the “scattering regime” where backscatter increases with snow depth and *SWE*. In the “attenuation regime” (see below “Anomalous melt events and ice layers”), backscatter decreases

Terrestrial Snow, Figure 2 Map of snow water equivalent (*SWE*) in millimeter (mm) derived from satellite microwave radiometer data (NASA/GSFC).

with snow accumulation. Both scattering and attenuation regimes can exist in a given area (Figure 4), so identifying the correct regime is important to the retrieval of snow depth and *SWE*. Temporal backscatter data can help improve results obtained from passive microwave snow observations. A new composite algorithm combining both active and passive data needs to be developed for more accurate *SWE* estimates.

Snowmelt pattern

With a wavelength of 2.2 cm (13.4 GHz), QSCAT backscatter is highly sensitive to snow wetness. Wave propagation and attenuation in an inhomogeneous medium like snow are characterized with a complex effective permittivity, which is determined by a mixture of air, ice grains, and liquid water (in the case of melting snow). The attenuation of Ku-band electromagnetic waves is controlled by the imaginary part of the snow effective permittivity. For dry snow, the imaginary part for pure dry water ice is in the order of $0.002\epsilon_0$ (Tiuri et al., 1984) where ϵ_0 is the permittivity of free space. In wet snow, liquid water (no salinity) has an imaginary part of about $38\epsilon_0$ (19,000 times larger than that of dry water ice) (Klein and Swift, 1977). Thus, a small amount of wetness can significantly change the imaginary part of the snow effective permittivity and, consequently, decrease the backscatter. This snow-scattering physics has been modeled by a number of researchers (Tsang et al., 1985; Ulaby et al., 1981; Nghiem et al., 1995). This sensitivity allows the backscatter to be used for snowmelt detection.

From experimental measurements with artificial piling of snow, a backscatter decrease of more than 5 dB is observed for 3 % wetness (e.g., Stiles and Ulaby, 1980). In a natural snow field, the Alaska Experiment (ALEX 1999) for snowmelt measurements was carried out in Ft. Wainwright, Alaska. In ALEX, a tower-mounted Ku-band scatterometer similar to QSCAT monitored a taiga snowpack, starting with freezing conditions and continuing through the snowmelt process until snow completely melted away (Nghiem et al., 2000). Taiga snow is a major snow class, covering about half of Alaska and Canada (Sturm et al., 1995). Results from ALEX show that diurnal backscatter can change as much as 15 dB (more than 30 times) between cold morning and warm afternoon when the heat makes more meltwater in the snowpack. These measurements confirm the high sensitivity of the backscatter to snowmelt.

The diurnal difference method was developed by Nghiem et al. (2001) to monitor the snowmelt process. The diurnal backscatter difference is a relative quantity between morning and afternoon measurements in half a day. QSCAT data from the early morning (t_a) in an ascending orbit pass and from late afternoon (t_p) in a descending pass are collocated for each day. The diurnal backscatter change is defined as the backscatter difference in the decibel (dB) domain as $\Delta\sigma_{VV} = \sigma_{VV}(t_p) - \sigma_{VV}(t_a)$ (Nghiem et al., 2001), where σ_{VV} is the V backscatter and all quantities are in dB. We use σ_{VV} to take advantage of the larger swath and coverage. In the case of snowmelt on the Greenland ice sheet, the criteria for the melt detection is based on $\Delta\sigma_{VV}$ greater than 1.8 dB for melt and less

Terrestrial Snow, Figure 3 QSCAT signatures and snow parameters at Yellowstone (44.65 °N and 111.1 °W) in Montana, USA: (a) H backscatter from ascending orbits, (b) Diurnal V backscatter difference, (c) snow depth from the National Climatic Data Center (NCDC) Global Summary of the Day (GSOD) data, (d) minimum, average, and maximum air temperatures, and (e) SWE from QSCAT and from NOHRSC data. Snow depth and temperature data are from NCDC GSOD dataset. This area consists of 65 % coniferous forest, 23 % grasslands, 5 % woody savannas, and 4 % shrub lands (3 % unknown). Vertical blue lines indicate snow accumulation onsets, and red vertical lines mark snowmelt onsets.

than 1.0 dB for reduced melt or refreezing conditions (Steffen et al., 2004). This algorithm is adapted for snowmelt detection on land.

This method has several advantages: independence from the scatterometer long-term gain drift, independence from the cross-calibration between QSCAT and future satellite scatterometers, independence from absolute backscatter from different snow classes and snow conditions, detection of both snowmelt and refreezing, and daily coverage over most cold land regions. A unique feature of this method is that the diurnal backscatter difference stays near 0 dB before and after snowmelt. This feature holds for different snow classes under different physical conditions in different areas or regions. Therefore, a consistent and accurate method for snowmelt mapping can be applied over the continental scale. Because snowmelt is

a temporal process, each pixel is treated not as an independent measurement in time for a given snapshot, but as a part of an ongoing time-dependent process represented by a multiyear dataset for each pixel $p(i,j)$. The conglomerate of land pixels is analyzed to map snowmelt patterns at the continental scale.

The diurnal difference algorithm is applied to monitor snowmelt from mid-February to mid-June (Figure 5). The snowmelt map on March 21, 2007 (spring equinox), reveals a band of snow with reduced melt or refrozen conditions (light blue) stretching from the west of the Great Lakes toward the Pacific coast on North America. Below and adjacent to this reduced melt band was a stretch of land where the snowmelt process was completed (light brown). In Eastern Europe and Siberia, several snow regions can be observed at midlatitudes (red). Overall,

Terrestrial Snow, Figure 4 QSCAT signatures at Tunalik (70.2°N, 161.1°W) in Alaska, USA. The upper panel is for V backscatter and the lower panel is for diurnal V backscatter change. Vertical blue lines indicate snow accumulation onsets (T_S), red vertical lines mark melt onsets (T_M), and green lines are for snow departure dates (T_F). In the upper panel, horizontal blue arrows span the snow season length (Δ_S) and the red arrows mark the snowmelt period (Δ_M). The red dots on the horizontal red line (2 dB) in the QSCAT diurnal plot indicate anomalous melt events occurring in a snow season before melt onset. In the upper panel, symbol S denotes the scattering regime, A represents the attenuation regime, and N is for the neutral regime.

most of the Northern Hemispheric snowpack was in freezing conditions by the spring equinox. One month later (April 21, 2007), a very extensive melt band occurred at higher latitudes from Labrador across the Canadian Shield to Alaska, while snowmelt in Eastern Europe was completed and large areas of active melt were seen in eastern Siberia. By May 21, 2007 (a month before the summer solstice), most of the snowpack was melted except at very high latitudes in the Canadian Arctic, the Alaskan North Slope, and the Taymyr Peninsula in north Siberia. It is fortuitous that the QSCAT dataset covers this decade when significant changes have occurred, and this dataset is therefore invaluable for observations of changes in the Arctic snowmelt pattern.

Anomalous melt events and ice layers

Passive microwave emission is dependent on temperature and moisture in snow (Hallikainen et al., 2002). Melting

and refreezing of snow results in wet and dry snow metamorphism and changes in snow grain size (Colbeck, 1986; Colbeck et al., 1992). Refreezing of liquid water, from either melt or rain, can form an ice layer with large scatterers. These changes modify the passive microwave signature and may affect its sensitivity to snow accumulation.

For QSCAT backscatter, the scattering at Ku-band frequency follows the Rayleigh scattering law (Nghiem and Tsai, 2001), which dictates the scattering cross section to be proportional to the sixth power of grain size. Thus, QSCAT data can be used as a highly sensitive indicator for changes caused by snow metamorphism from processes such as melt and refreezing. For example, an anomalous event occurred at Tunalik on October 31, 2003 (Figure 4), when in situ meteorological data showed melt and rain, followed by refreezing. This event is characterized by a sharp peak in the QSCAT backscatter at the time indicated by the second red dot on the red horizontal line in the QSCAT diurnal plot in Figure 4. Collocated and

Terrestrial Snow, Figure 5 QSCAT snowmelt patterns on the 21st day of March, April, and May in 2007. White represents frozen snow, red is for active snowmelt, blue for snow with reduced melt or refrozen conditions, light brown for areas where the snowmelt process is completed, dark brown for land where QSCAT cannot detect snowmelt, and dark blue for water (oceans and lakes).

contemporaneous data from AMSR-E and SSM/I revealed that brightness temperature started to decrease on the same date; however, the minimum brightness temperature would not occur until 1 week later.

The sharp increase in QSCAT backscatter on October 31, 2003, and the decreasing trend in backscatter afterward indicate the formation of an ice layer in snow (Nghiem et al., 2005). Such detection allows a determination of the formation timing and extent of the ice layer. Moreover, QSCAT backscatter decreased as snow accumulated after the ice layer formation (October 31, 2003), indicating that the strong backscatter from the ice layer was attenuated by the subsequent overlaying snow accumulation (attenuation regime). In the previous years when there was no anomalous melt to form an ice layer, backscatter increased as snow accumulated from the start of each snow season, indicating that scattering increased with snow accumulation (scattering regime). In the snow season from September 2004 to May 2005, QSCAT backscatter did not show a clear trend with snow accumulation after the anomalous melt on October 3, 2004 (third red dot in the lower panel, Figure 4), indicating a neutral regime with a balance between scattering and attenuation effects. The detection of the switch between scattering and attenuation regimes or the identification of the neutral regime is useful for a better interpretation of passive microwave data for applications to *SWE* retrieval.

Timing of snow accumulation, melt onset, disappearance, and season length

Snow accumulation onset date (T_S), melt onset date (T_M), and disappearance date (T_F) are denoted, respectively, with blue, red, and green vertical lines in Figure 4 for the location at Tunalik in Alaska. Snow accumulation onset corresponds to the minimum in backscatter at the start of a snow season (Nghiem and Tsai, 2001). Snowmelt onset causes a large change in QSCAT diurnal signature consistently maintained in time without the long subsequent refreezing in the case of anomalous melt in winter. Snow disappearance occurs when backscatter is minimized and diurnal signature returns to a value near 0 dB. At Tunalik, snowmelt duration (Δ_M) varied from 15 to 25 days, while snow season length (Δ_S) changed as much as a month in the 6 years (1999–2005) of the QSCAT data. In 2002, snowmelt onset was the earliest, followed by the longest snow-free season (Figure 4).

Snowmelt typically results in an increase in grain size at the snow surface due to preferential melting of smaller grains or due to multigrain coalescence. MODIS has sufficient sensitivity to observe the spectral signatures resulting from the change in surface grain size and has been used to distinguish grain size categories (e.g., small, medium, and large) where there is continuous snow cover. A combination of AMSR-E, QSCAT, and MODIS signatures (satellite data collocated in space and closest in time) can better constrain the identification of snow onset, melt events, and snow season length.

Rain on snow-free land may have a similar diurnal signature in microwave data and thus cause a misidentification of snowmelt over such area. Here, MODIS data can help prevent the misidentification

Terrestrial Snow, Figure 6 Blended snow product (April 20, 2003) with a combination of snow extent (white) obtained from MODIS data and active snowmelt areas (red) derived from QSCAT data in North America (land inside the red boundary).

because of the capability of MODIS data to determine snow-covered and snow-free areas better than microwave data for thin snow areas.

Blended products

Because each type of satellite sensor, such as MODIS, AMSR-E, or QSCAT, has different sensitivities to different snow parameters, combinations of measurements from different sensors can be used to complement and improve the accuracy of snow measurement in a way that cannot be achieved by using a single sensor. Moreover, for many practical applications, combining different snow measurements from disparate products based on different satellite datasets with various resolutions, acquisition times, coverages, and formats is indisputably challenging for many users and decision makers. In this view, development of a snow mapping product that blends together different snow measurements is beneficial. Efforts to blend multiple snow datasets into a single, global, daily, and user-friendly product, such as the Air Force Weather Agency/National Aeronautics and Space Administration Snow Algorithm (ANSA), and to improve these products were supported in a research project (see Foster et al., 2008b for further details).

A simple example of a blended product is presented in Figure 6. This product combines snow extent measured by MODIS together with actively melting areas obtained from QSCAT data. The map of blended MODIS-QSCAT product (Figure 6) shows melt areas that consistently

occur within the limit of snow extent on April 20, 2003, in North America. An extensive melt band was observed across North America from Newfoundland, Canada, to Alaska, USA, between 50° and 70° latitudes. There are snow areas at lower latitudes or lower elevations that are not detected by QSCAT. This can be due to the low sensitivity of QSCAT backscatter to thin snow in such areas. Future developments for blended products will combine more snow products and will utilize more complex algorithms to account for temporal and spatial differences.

Summary

Satellite remote sensing of key parameters characterizing terrestrial snow cover, including snow extent, depth, water equivalent, snowmelt patterns, and seasonal snow dynamics (timing of accumulation onset, melt onset, disappearance, and length of snow season), have been presented. Data from optical infrared sensors (e.g., MODIS and AVHRR), passive microwave radiometers (e.g., SSM/I and, in the recent past, AMSR-E), and active microwave scatterometers (e.g., QSCAT) are used to measure snow parameters from local to regional and global scales on a daily to weekly basis. Techniques to blend different snow products into a single user-friendly global product are under development. Furthermore, different signatures corresponding to different scattering and attenuation regimes are identified based on snow physics. Such information will be valuable in the development of future satellite missions for global snow measurements, such as the

Cold Regions Hydrology High-resolution Observatory (CoReH₂O) Mission (Rott et al., 2007) and the Snow and Cold Land Processes (SCLP) Mission (National Research Council, 2007).

Acknowledgments

The research carried out at the Jet Propulsion Laboratory, California Institute of Technology, was supported by the National Aeronautics and Space Administration (NASA) Terrestrial Hydrology Program and by the US Air Force (USAF) under an agreement with NASA. The research at the NASA Goddard Space Flight Center was also supported by the USAF. The authors would like to thank Janet Y. L. Chien for preparing Figure 1 and D. Cline of NOAA NOHRSC for the NSA SWE data at Yellowstone.

THERMAL RADIATION SENSORS (EMITTED)

Simon Hook
 Jet Propulsion Laboratory, California Institute of
 Technology, Pasadena, CA, USA

Synonyms

Thermal infrared sensors

Definitions

Radiant energy. The energy of electromagnetic waves or sometimes of other forms of radiation. The quantity of radiant energy may be calculated by integrating radiant flux (or power) with respect to time, and, like all forms of energy, its SI unit is the joule. The term is used particularly when radiation is emitted by a source into the surrounding environment (Source: Wikipedia).

Thermal radiation. Electromagnetic radiation emitted from the surface of an object which is due to the object's temperature (Source: Wikipedia).

Infrared radiation. Electromagnetic radiation whose wavelength is longer than that of visible light but shorter than that of terahertz radiation and microwaves (Source: Wikipedia).

Sensor: Device that measures a physical quantity and converts it into a signal which can be read by an observer or by an instrument (Source: Wikipedia).

Introduction

In this entry, we consider sensors that remotely measure the emitted thermal radiation from the surface of the Earth and the associated atmosphere at wavelengths between 3 and 14 μm . These measurements are typically made from three vantage points: (1) in situ measurements, where the sensor is placed within a few meters of the surface; (2) airborne measurements, where the sensor is mounted on an aircraft flying at 100 m to many kilometers above the surface of the Earth but still within the Earth's atmosphere; and (3) spaceborne measurements, where the instrument is on a satellite platform orbiting the Earth. The emitted radiation that is sensed depends on the temperature and composition of the surface and the atmosphere and thereby provides a means for measuring changes in composition or temperature of the surface and/or atmosphere. These same sensor types are used to measure emitted thermal radiation from other planetary bodies over extended wavelength regions and can provide additional information on the composition of the surface depending on the composition of the overlying atmosphere. On Earth, within the 3–14 μm wavelength region, there are two atmospheric “windows.” These are regions where the energy from the surface is not as strongly blocked by the atmosphere; these are referred to as the mid infrared (MIR) and thermal infrared (TIR). In this entry, we consider the MIR window to extend between 3 and 5 μm and the TIR window between 8 and 12 μm . The terms MIR and TIR are used loosely and therefore it is best to define the wavelength region that is being considered when the term is first used. Since the signal from the surface of the Earth is strongest in the MIR and TIR, sensors that measure the emitted radiation in these wavelength regions are typically used to study the surface of the Earth. In contrast, studies of the Earth's atmosphere will typically make measurements over the entire wavelength region since the effect of gases within the Earth's atmosphere is pervasive throughout the region albeit stronger at selected wavelengths.

Remote measurement of emitted radiation

Remote sensing within the 3–14 μm wavelength region is based on the measurement of the radiance emitted from the surface and modified by the atmosphere; its basic goal is to recover the kinetic temperature and emissivity from the measured at-sensor radiance of the surface and/or the atmosphere. The at-sensor radiance (L_s) for a given wavelength (λ) in this wavelength region, excluding any reflected solar contribution which occurs below 5 μm , can be written as

$$L_{s\lambda} = [\varepsilon_\lambda L_{bb\lambda}(T) + (1 - \varepsilon_\lambda) L_{sky\lambda}] \tau_\lambda + L_{atm\lambda} \quad (1)$$

where ε_λ is the surface emissivity at wavelength λ , $L_{bb\lambda}(T)$ is the spectral radiance from a blackbody at surface temperature T , $L_{sky\lambda}$ is the sky radiance (spectral downwelling radiance incident upon the surface from the atmosphere), τ_λ is the transmittance (spectral atmospheric transmission), and $L_{atm\lambda}$ is the path radiance (spectral upwelling radiance from atmospheric emission and scattering that reaches the sensor).

The effect of τ_λ is to reduce the amount of ground-emitted radiance measured at the sensor; $L_{atm\lambda}$ adds a component unrelated to the ground and $L_{sky\lambda}$ serves to reduce the spectral contrast since the deeper an emissivity feature, the more it is “filled in” by reflected downwelling radiation due to Kirchhoff's Law. Any algorithm that is used to produce a fundamental geophysical parameter such as surface radiance, temperature, or emissivity must compensate for these atmospheric effects.

Once the atmospheric effects have been removed, the surface radiance is given by

$$L_\lambda = \varepsilon_\lambda L_{BB\lambda}(T) \quad (2)$$

Or

$$L_{BB\lambda} = \frac{C_1}{\lambda^5 \pi \left[e^{\left(\frac{C_2}{\lambda T}\right)} - 1 \right]} \quad (3)$$

where

L_λ = emitted radiance

$L_{BB\lambda}$ = blackbody radiance ($\text{Wm}^{-2} (\text{m} - \Delta\lambda)^{-1} \text{sr}^{-1}$)

λ = wavelength of channel (m)

T = temperature of blackbody (Kelvin)

C_1 = first radiation constant = $3.7415 \times 10^{-16} \text{ (Wm}^2\text{)}$

C_2 = second radiation constant = $0.0143879 \text{ (m deg)}$

ε_λ = surface emissivity (0–1)

The surface temperature (T) is not an intrinsic property of the surface; it varies with external factors such as the irradiance history and meteorological conditions. Conversely, emissivity is a characteristic of the material making up the surface and is independent of the temperature. For most terrestrial surfaces, $200 \text{ K} < T < 340 \text{ K}$, although a more restricted range of $\sim 270\text{--}310 \text{ K}$ probably brackets most of the temperatures outside the polar regions and deserts. The emissivities for most natural surfaces in MIR and TIR wavelength typically range vary $\sim 0.7\text{--}1$ (Prabhakara and Dalu, 1976) with surfaces with emissivities < 0.85 are largely restricted to arid and semiarid regions.

Equation 3 describes the radiance from a homogenous, isothermal surface. However, many surfaces at the resolution of current instruments consist of several materials at different temperatures and emissivities.

Airborne and spaceborne sensors

From the standpoint of most researchers, the ideal instrument would be one that provided measurements of the emitted radiation at very small wavelength increments and was able to resolve differences in energy at these

Thermal Radiation Sensors (Emitted), Table 1 Characteristics of the main emitted radiation detector types used in airborne and spaceborne instruments today

Detector type	Quantum efficiency	Operating temp	Residual nonuniformity	Response time	Cutoff wavelength ^a
HgCdTe	>80 %	40–80 K	High	Fast	12 μm
QWIP	30 %	40 K	Very low	Fast	12 μm
Uncooled Microbolometers	N/A	Room temp	Low	Slow	Flat response

Land surface temperature (LST) and emissivity are key variables for explaining the biophysical processes which govern the balances of water and energy at the land surface. This table summarizes the science requirements for the LSTE-ESDR

wavelength increments over very small distances on the surface of the Earth. Unfortunately no technology currently exists that meets these requirements, and as a result, most sensors provide data at very small wavelength increments (high spectral resolution) from large areas of the Earth's surface (low spatial resolution) or data at low spectral resolution over small distances on the Earth's surface (high spatial resolution). These trade-offs are necessary so the detector(s) in the sensor can receive sufficient radiation to enable measurement. There are three main detector types in operation today. These are Mercury Cadmium Telluride (MCT) detectors, microbolometers, and Quantum Well Infrared Photodetectors (QWIPs). MCT detectors and microbolometers are more widely used than the newer QWIP technology. Some of the characteristics of these detectors are summarized in Table 1. More detail on the types of detectors is available in Miles and Chow (1996). Microbolometer detectors do not require cooling which can provide a large power saving (cooling takes power), but they respond slowly. As a result, they are used with instruments that can either stare and integrate the radiation over long periods of time or, if used in an application that requires rapid imaging, provide measurements with low spatial and spectral resolution. MCT detectors require cooling but that cooling can be either passive (radiative coolers) or active (mechanical coolers). Radiative coolers are more desirable since they require less power but typically can only reach temperatures around 80 K. At these temperatures, either high spectral resolution and low spatial resolution measurements or low spectral resolution and high spatial resolution measurements are possible but not both, that is, high spatial and high spectral resolution. In order to reach the temperatures required for both high spatial and high spectral resolution, the detector needs to be cooled to temperatures around 40 K, typically requiring active cooling. Within the last decade, spaceborne mechanical coolers have become more available and there are two common types: either sterling cycle or pulse tube and modern sensors that push the current measurement capability use mechanically cooled MCT or QWIP detectors. All three types of detectors are available as one- or two-dimensional arrays. Arrays allow multiple points on the surface to be imaged at once at several wavelengths which provide more signal to each detector (longer integration time) when the time available to make the measurement is short and

consequently detector arrays are widely used today. QWIP detector arrays are more uniform than MCT arrays, which are much more desirable to enable consistent quantitative detection. These different trade-offs have the result that future high spectral and spatial resolution airborne and spaceborne sensors, where the time available to make the measurement is short, will likely use mechanically cooled detector arrays, either MCT or QWIPs. The so-called megapixel arrays ($1,000 \times 1,000$ elements) are now available for both types of detector. Other detector types continue to be developed which may replace MCT and QWIPs, but the adoption of new detector types such as strained layer super lattice detectors tends to be very gradual.

Table 2 provides a summary of a selection of the currently available spaceborne sensors and plans for future spaceborne sensors. These sensors represent the current and planned spaceborne state of the art however; they do not include any high spatial and high spectral resolution sensors. Such sensors do exist but currently only operate from airborne platforms. Airborne platforms are ideal for developing new spaceborne sensors since they provide a large platform with ample power and ready access to the instrument in flight. Many airborne instruments provide example datasets for future spaceborne instruments as well as more detailed spectral and spatial information as spaceborne instruments, allowing the performance of the spaceborne instruments to be validated.

Calibration and validation

Most airborne and spaceborne emitted radiation sensors include some form of onboard calibration. Typically this involves one or more blackbodies. A blackbody has an emissivity of 1.0, and therefore, the radiation emitted from it depends entirely on its temperature. This known temperature is used as a reference to bracket the scene temperatures together with a space look which also provides a blackbody measurement. A typical example of a spaceborne instrument is the Moderate Resolution Imaging Spectrometer (MODIS) which acquires data at several wavelength intervals (channels) between 3 and 14 μm (Barnes et al., 1998; Salomonson et al., 1989). MODIS scans 55° from nadir and provides daytime and nighttime imaging of any point on the Earth every 1–2 days with a continuous duty cycle. MODIS data are quantized in

Thermal Radiation Sensors (Emitted), Table 2 Examples of current and planned spaceborne emitted thermal radiation sensors with their spatial and spectral resolution ranges

Subproduct	Spatial resolution	Temporal resolution	Current data sources	Future data source
Global	10–20 km	Hourly	AIRS GOES MSG	CrIS GOES MSG
Regional	1–5 km	2–4 times daily	MODIS AVHRR ATSR	VIIRS AVHRR ATSR
Local	30–100 m	Once every 8–16 days	ASTER Landsat	

Atmospheric Infrared Radiation Sounder (AIRS), Geostationary Operational Environmental Satellites (GOES), Meteosat Second Generation (MSG), Moderate Resolution Imaging Spectroradiometer (MODIS), Advanced Very High Resolution Radiometer (AVHRR), Along Track Scanning Radiometer (ATSR), Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER), Cross-track Infrared Sounder (CrIS), Visible Infrared Imager/Radiometer Suite (VIIRS)

12 bits and have a spatial resolution of ~ 1 km at nadir. They are calibrated with a cold space view and full aperture blackbody viewed before and after each Earth view (Salomonson et al., 1989; Barnes et al., 1998). There are many different types of blackbody; MODIS, for example, uses a flat blackbody with a V-groove. Flat blackbodies with a V-groove are often used instead of cone blackbodies since they occupy less physical space. However, from a scientific standpoint, the most accurate blackbodies are cone blackbodies. These are used, for example, on the European Along Track Scanning Radiometer series of instruments. Great care is taken to calibrate emitted thermal radiation sensors used for research such as the two sensors mentioned. This allows measurements from the sensors made over long periods of time (decades) to be tracked to observe small changes in incoming radiation and enable a variety of research studies such as climate change. While onboard calibration is essential, an independent measurement is needed to ensure that the onboard system is working correctly. This independent measurement is used to validate the onboard calibration system. Typically the validation measurement involves measuring the radiation from a sensor close to the ground or in an aircraft and then propagating that measurement through the Earth's atmosphere with a radiative transfer model (Berk et al., 1989) to obtain the radiance that the satellite instrument should observe and comparing it with what the satellite instrument measures. In the last decade a validation site was established at Lake Tahoe CA/NV, USA, where these measurements are made on a continuous basis and data from the site have been used to validate several sensors including ASTER, MODIS, Landsat (TM and ETM), and ATSR (Barsi et al., 2003; Hook et al., 2003, 2005, 2006; Tonooka et al., 2005).

Conclusion

Over the last few decades, multiple emitted radiation sensors have been launched into orbit around the Earth as well as other planetary bodies. Data from these sensors have

been used in a wide variety of studies from mapping the surface composition of a region to studying climate change and forecasting the weather. The instruments that have been launched were typically based on prototypes deployed from aircraft. Our ability to make even higher spectral and spatial measurements from space is limited by the available technology. As the technology evolves, so does the measurement capability and science that the sensors can be used to address. One area of concern is the lack of future sensors capable of making high spatial resolution thermal infrared measurements such as those currently provided by ASTER and Landsat (Yamaguchi et al., 1998; Barsi et al., 2003). Currently the research community is calling for such measurements, but it remains to be seen whether such measurements will be available in the future.

Acknowledgments

The research described in this entry was carried out at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the National Aeronautics and Space Administration.

TRACE GASES, STRATOSPHERE, AND MESOSPHERE

Nathaniel Livesey
 Jet Propulsion Laboratory, California Institute of
 Technology, Pasadena, CA, USA

Synonyms

Atmospheric chemistry; Atmospheric composition; Middle atmosphere (common term used to refer collectively to the stratosphere and mesosphere)

Definitions

Trace gases. Minor constituents in Earth's atmosphere typically having abundances from as large as hundreds of parts per million (e.g., CO_2) to parts per trillion (e.g., BrO and OH) or less.

Stratosphere. The region of Earth's atmosphere between ~15 and ~50 km characterized by temperatures that generally increase with increasing altitude.

Mesosphere. The region of Earth's atmosphere between ~50 km and ~80 km characterized by temperatures that generally decrease with increasing altitude.

Introduction

Earth's atmosphere is divided vertically into regions defined by the vertical gradient of temperature. The lowermost region, the troposphere, ranging from the surface to the "tropopause" at 10–15 km altitude, is characterized by temperatures that mainly decrease with increasing altitude. Above is the stratosphere, where temperatures generally increase with height, up to ~50 km where the "stratopause" separates the stratosphere from the mesosphere, within which temperatures generally decrease with altitude again (up to the "mesopause" around 80 km). Collectively, the stratosphere and mesosphere are often referred to as the "middle atmosphere."

Trace gases play disproportionately important roles in these regions, both chemically and radiatively, despite their small abundances ranging from hundreds of parts per million to as low as parts per trillion or less. For example, the absorption of solar ultraviolet radiation by the [stratospheric ozone](#) layer, in addition to shielding terrestrial organisms from harmful exposure, also heats the stratosphere, giving rise to its increase in temperature with increasing altitude. This positive vertical temperature gradient results in vertical atmospheric stability, leading to the stratification for which the region is named. Thermal emission by carbon dioxide (in addition to methane and other minor trace gases) is the main vehicle for radiative cooling in the stratosphere and mesosphere. Despite being the most abundant species in the atmosphere, molecular oxygen and nitrogen play relatively minor roles in the radiative balance and chemistry of these regions.

In addition to trace gases, aerosols also play a significant role in the chemistry of the middle atmosphere. Most notably, key chemical reactions giving rise to the Antarctic ozone hole take place on the surface of polar stratospheric cloud (PSC) particles (see the companion article on stratospheric ozone). In addition, sulfate aerosol is ubiquitous in the lower stratosphere at small background levels, with occasional significant enhancements resulting from injection of SO_2 directly into the stratosphere by large volcanic eruptions (e.g., Mt. Pinatubo in 1991).

In situ observations of the middle atmosphere, while having provided valuable information, are by their nature limited to those available from high-altitude aircraft and balloons, with sounding rockets the only source of in situ

data in the upper stratosphere and mesosphere. Remote sounding has accordingly formed a cornerstone in scientific investigation of the composition of the stratosphere and mesosphere.

Principals and techniques

Information on stratospheric and mesospheric composition can be obtained from observations over a large range of electromagnetic wavelengths, from the microwave (mainly associated with molecular rotational transitions) to the infrared (mainly vibrational transitions) to the visible and ultraviolet (mainly electronic transitions). Signals observed may arise from thermal emission by the atmosphere itself, from atmospheric absorption and/or scattering of solar, lunar, or stellar radiation or of radiation actively emitted, for example, by laser. Observations are made from the ground and from air- or spaceborne platforms. Variations in viewing angle and/or wavelength observed can give information on the vertical distribution of trace gases. Many space-based measurements have been pioneered by balloon or aircraft precursor instruments, and such instruments are frequently used (in conjunction with in situ instrument) for ongoing scientific investigations and to “validate” satellite observations.

Molecular spectral lines are broadened in the atmosphere by a combination of the ensemble of Doppler shifts from the thermal motion of the molecules (“Doppler” broadening) and by collisions with other molecules (“collision” or “pressure” broadening). The latter generally dominates line widths of infrared and microwave signals in the stratosphere, while for visible and ultraviolet wavelengths, Doppler broadening dominates throughout the middle atmosphere. Accurate knowledge of molecular spectroscopy, including line positions, strengths, and broadening parameters, underpins the accuracy of middle atmosphere composition remote sounding, and fundamental laboratory spectroscopy measurements are an integral part of atmospheric composition research programs.

Pressure broadening of spectral lines can provide valuable information on the vertical distribution of trace gases, with frequencies further from line centers conveying information on lower regions of the atmosphere where lines are broad enough to contribute to the observed signals. For wavelengths where pressure broadening is insignificant, vertical distribution information can still be obtained in some viewing geometries by observing in multiple spectral regions having different atmospheric absorptions (and thus penetration depths).

In the stratosphere and lower mesosphere, the atmosphere is generally in local thermodynamic equilibrium (LTE), that is to say, molecular collisions are frequent enough that the kinetic temperature of the air is in equilibrium with the rotational and vibrational temperature of the emitting and absorbing molecules. At lower pressures (typically smaller than 0.1 hPa, ~60 km), where the mean time between collisions increases, some molecular transitions (particularly infrared vibrational transitions) can be

in non-LTE, that is to say, their “vibrational temperature” differs from the underlying atmospheric kinetic temperature. This complicates the interpretation of observed signals.

Most observations give a measure of number density for a particular molecule, either total column or vertical profile. For profile measurements, knowledge of atmospheric density (i.e., temperature and pressure) is needed to convert these to mixing ratio. Typically, this is inferred by also measuring the number density of a well-mixed gas whose abundance is known well (e.g., O₂ or CO₂).

Direct solar absorption and related approaches

Observation of the absorption of solar radiation by the atmosphere provides some of the most precise remotely sensed measurements of stratospheric and mesospheric composition. The strong solar illumination gives a good signal-to-noise ratio for quantification of atmospheric absorption features. Such observations are possible in all spectral regions having significant solar emission, from the infrared to the ultraviolet. Dobson’s ground-based observations of absorption of solar UV by ozone are one of the earliest examples of remote sounding of atmospheric composition. For ground-based solar absorption observations, vertical distribution information can be obtained from measurements at different sun angles (assuming temporal variations are small).

Low-Earth-orbiting satellites can make “occultation” observations of atmospheric absorption of solar radiation during each satellite sunrise and sunset (giving ~30 measurements per day). Observing variations in absorption as the sun rises/sets through the atmosphere gives high vertical resolution (~1 km) information on trace gas distribution. However, horizontal coverage of such measurements is limited. The latitudes of the sunrise and sunset observations drift slowly from day to day, as dictated by the spacecraft orbit, with (in many but not all cases) all latitudes covered in about a month. Increased coverage can be obtained by making lunar and/or stellar occultation observations. However, such measurements have a poorer signal to noise than solar occultation.

There is a rich history of stratospheric and mesospheric composition measurements from solar occultation instruments, with a continuous record available from the 1984 launch of the Stratospheric Aerosol and Gas Experiment II (SAGE II) instrument (McCormick et al., 1989), followed by SAGE III, the Polar Ozone and Aerosol Measurement (POAM) series of instruments (e.g., Lucke et al., 1999), the Halogen Occultation Experiment (HALOE) (Russell et al., 1993) on the Upper Atmosphere Research Satellite (UARS), and, most recently, the Atmospheric Chemistry Experiment Fourier Transform Spectrometer (ACE/FTS) (Bernath et al., 2005), the only such instrument still currently operating. Additional occultation observations have been made by the Atmospheric Trace Molecule Spectroscopy (ATMOS) instrument flown on the Space Shuttle ATLAS program

(Gunson et al., 1996) and the Improved Limb Atmospheric Spectrometer instruments (ILAS I and II) on the Japanese Advanced Earth-Orbiting Satellites (ADEOS I and II) (e.g., Sasano et al., 2001).

Viewing geometries: nadir, limb, and zenith

In addition to occultation, two other geometries have been extensively employed to observe middle atmosphere composition from low-Earth orbit. “Nadir sounding” instruments view the atmosphere directly below the orbiting spacecraft (or in some swath either side of vertical). “Limb sounding” instruments observe the atmosphere “edge on,” tangent to the Earth, scanning their field of view vertically across the atmosphere, offering better vertical resolution (typically 2–5 km) than nadir observations. In addition, the longer path length associated with limb sounding results in stronger signals for trace gases than for nadir sounding. However, this same long path length results in poorer horizontal resolution for limb observations that is, in principle, possible for nadir sounding. For ground-based and airborne observations, zenith (upward looking) observations of scattered sunlight or thermal emission are commonly employed.

UV/visible scattering measurements

Satellite observations of backscattered UV/visible sunlight constitute the longest continuous record of stratospheric composition observations, most notably ozone, from space. The 1978 launch of the Nimbus-7 Total Ozone Mapping Spectrometer (TOMS) and Solar Backscatter Ultraviolet (SBUV) instruments (Heath et al., 1975) heralded the start of nearly continuous observations using this technique. In addition to measuring total ozone column (e.g., TOMS) and [stratospheric ozone](#) profile (e.g., SBUV), column measurements of SO₂ were made from TOMS, along with a measure of aerosol amount (mainly indicating tropospheric aerosols). More recent instruments include the Global Ozone Monitoring Experiment (GOME) on ERS-2 (Burrows et al., 1999), the SCanning Imaging Absorption SpectroMeter for Atmospheric CHartography (SCIAMACHY) instrument on Envisat (Bovensman et al., 1999), the Ozone Monitoring Instrument (OMI) (Levelt et al., 2006) on Aura, and GOME-2 on METOP (Munro et al., 2006). These continue the TOMS record and also measure column abundances of additional species (e.g., NO₂, HCHO). However, these additional gases are mainly of interest in the troposphere (see the related entry on tropospheric composition observations in this volume). By their nature, solar backscatter observations cannot be made at night (months at high latitude during polar night). Most such observations are made from sun-synchronous low-Earth-orbiting spacecraft (where observations are made at fixed local time).

While most UV/visible stratospheric observations have been made in nadir (or swath), a limited number of instruments have observed the scattering of solar UV/visible

(and near-infrared) radiation in a limb geometry. However, the accuracy of such observations is highly dependent on knowledge of spacecraft attitude. UV/visible limb sounding instrument includes SCIAMACHY, OSIRIS on Odin (Llewellyn et al., 2003; Murtagh et al., 2002), and the profiling component of the “Ozone Mapping and Profiling Suite” (OMPS) on the NPOESS (National Polar-orbiting Operational Environmental Satellite System) Preparatory Project (NPP).

Thermal emission observations

In contrast to UV/visible observations, measurements of atmospheric composition from observations of thermal emission in the infrared and microwave can be made both day and night. While nadir sounding at these wavelengths can yield useful information on stratospheric and mesospheric composition (e.g., for ozone), the majority of space-based thermal emission observations of stratospheric and mesospheric composition have been made in a limb-viewing geometry. Pressure broadening of spectral lines in principle enables instruments viewing limb emission to independently measure both composition and atmospheric pressure for a given limb view, making the overall measurement system less sensitive to knowledge of spacecraft attitude than for UV/visible limb sounding.

Limb sounding instruments in the thermal infrared have included the Limb Radiance Inversion Radiometer (LRIR) flown on Nimbus-6, the Nimbus-7 Limb Infrared Monitor of the Stratosphere (LIMS) (Gille and Russell, 1984), Stratospheric and Mesospheric Sounder (SAMS) (Drummond et al., 1980) instruments, the Improved Stratospheric and Mesospheric Sounder (ISAMS) (Taylor et al., 1993) and the Cryogenic Limb Array Etalon Spectrometer (CLAES) on UARS (Roche et al., 1993), the Michelson Infrared Passive Atmospheric Sounder (MIPAS) (Fischer et al., 2008) on Envisat, the Sounding of the Atmosphere using Broadband Emission Radiometry (SABER) instrument (Russell et al., 1999) on the Thermosphere, Ionosphere, Mesosphere Energetics and Dynamics (TIMED) spacecraft, and the High Resolution Dynamics Limb Sounder (HIRDLS) (Gille et al., 2008) on Aura.

Atmospheric composition instruments observing thermal microwave emission in the limb include the Microwave Limb Sounder (MLS) instruments on the UARS and Aura spacecraft (Barath et al., 1993; Waters et al., 2006), the Microwave Atmospheric Sounder (MAS) flown on the space shuttle ATLAS program (Croskey et al., 1992), the Submillimeter Radiometer (SMR) on Odin (Murtagh et al., 2002), and the planned Superconducting Submillimeter-Wave Limb-Emission Sounder (SMILES) (Ozeki et al., 2001) to be attached to the International Space Station.

Observations in the microwave region of the spectrum are unaffected by scattering or emission by stratospheric aerosols. By contrast, infrared limb (or occultation) instruments can readily observe stratospheric aerosols

(notably PSCs or strong volcanic enhancements), but the accuracy of their trace gas observations may be reduced by strong aerosol emission and scattering.

Active techniques: LIDAR

While direct measurements of atmospheric absorption between a source and a distant detector are frequently made at ground level, such approaches are impractical in the middle atmosphere (although many in situ instruments work on the same principal but over short distances, often augmented by multipath reflection optics). However, ozone and water vapor in the middle atmosphere can be measured by observing the atmospheric absorption of backscattered laser light from a Light Detection and Ranging (LIDAR) instrument, either ground based or airborne. The backscatter can be either elastic (Rayleigh scattering) or inelastic (Raman scattering). Observations are typically made at multiple wavelengths that have different levels of absorption by the molecule of interest. Observing differences in the backscattered signal received at the different wavelengths gives a measure of the total molecular absorption between the laser source and the atmospheric layer at which the backscatter occurred. In addition, by observing spectral differences, measurements are insensitive to changes in laser output power. High-speed detection of the backscattered signals enables high vertical resolution (typically hundreds of meters) for LIDAR compared to other techniques.

Notable findings from remote sounding observations

Remote sounding observations of trace gases have provided profound insights in to the behavior of the middle atmosphere, in particular, the complex interplay of chemical, dynamical, and radiative processes that govern the budget of [stratospheric ozone](#). For example, the Antarctic “ozone hole” was originally observed in long-term records of ultraviolet absorption over Halley Bay in Antarctica (Farman et al., 1985). Also, ground-based microwave emission sounding at McMurdo Sound confirmed the role of the chlorine monoxide (ClO) radical in the ozone hole (de Zafra et al., 1987), while UARS MLS measurements showed that similar levels of ClO were present in the Arctic stratosphere (Waters et al., 1993).

Remote sounding of the atmospheric distribution of gases with relatively long lifetimes gives valuable insights into transport of air into, out of, and within the stratosphere and mesosphere. Such transport is fundamental to the spatial distribution of stratospheric ozone and also plays an important and complex role in polar chemical ozone loss (see Sect. 6.2 of Solomon (1999) and references therein). Observations of long-lived trace gas distributions are an important means to quantify the slow overturning circulation of air within the middle atmosphere (the so-called Brewer-Dobson Circulation), which may be impacted by changes in climate. Remote sounding observations have also been essential to our understanding

of how air is transported from the troposphere into the stratosphere (e.g., Mote et al., 1995).

While space-based observations have provided valuable global insights into middle atmosphere composition and processes that affect it, the limited lifetime of space-based instruments makes the extraction of long-term trends problematic. The majority of the information on long-term trends and variations in stratospheric and mesospheric composition has come from ground-based observations. Notable among these are those in the “Network for the Detection of Atmospheric Composition Change” (NDACC, formerly the “Network for the Detection of Stratospheric Change,” NDSC). This network brings together a variety of highly accurate measurement techniques, including LIDAR, and passive observations in the ultraviolet, infrared, and microwave (along with in situ sonde observations) at locations across the globe.

Outlook

The number of space-based instruments observing middle atmosphere composition has decreased significantly in recent years. At the time of writing, this overall decreasing trend is set to continue. All of the spacecraft currently making stratospheric and mesospheric observations are now or will shortly be operating beyond their mission design lifetimes. The only confirmed mission to continue observations is the Japanese Superconducting Submillimeter-Wave Limb-Emission Sounder (SMILES) instrument, to be attached to the International Space Station (ISS) in 2009. Plans for future middle atmosphere composition observations are unclear, with a long gap anticipated between NASA’s Aura satellite and the expected Global Atmospheric Composition Mission (GACM) and a similar gap likely between ESA’s Envisat and expected Sentinel-5 missions. Although concept missions to fill this gap have been proposed or are in formulation, the only confirmed observations are [stratospheric ozone](#) profile observations by OMPS on NPP.

Conclusion

Our understanding of the chemical, dynamical, and radiative processes that govern the behavior of the stratosphere and mesosphere has advanced dramatically over the last two decades, thanks in large part to the wealth of remote sounding composition observations. Notable findings from remote sounding include the discovery of the ozone hole, insights into its origins (in conjunction with in situ observations), and understanding of the large-scale transport processes that operate in the middle atmosphere.

Introduction

The increase of human activity over the last 100 years has resulted in an enormous increase in atmospheric

concentrations of various gases of anthropogenic origin, polluting the atmosphere and changing climate on Earth. The detection of the [stratospheric ozone](#) hole raised awareness that human activities can lead to dramatic changes in atmospheric composition, with large consequences for life on Earth. The satellite maps of air pollution and greenhouse gases in the troposphere (this is the lower 10–16 km of the atmosphere) over the last 5–10 years made people realize that our lifestyle does not only influence the ozone layer but also our daily living environment and the air we breathe.

Trace gases in the troposphere

The atmosphere consists of nitrogen (78 %) and oxygen (21 %), with only a minor contribution from other gases (1 %), which are called trace gases due to their low abundance. Although their abundance is low, trace gases play a key role in climate change and air quality. Ozone (O_3) is one of the most abundant minor trace gases. Ozone resides mainly in the stratosphere – the so-called ozone layer – protecting us from the harmful ultraviolet radiation from the Sun because it efficiently absorbs this high-energy radiation. Ozone also plays an important role in the troposphere, where it is a greenhouse gas as well as an air pollutant. Other important tropospheric trace gases are carbon dioxide (CO_2), water vapor (H_2O), methane (CH_4), nitrogen oxides (NO_x), sulfur oxides (SO_x), carbon monoxide (CO), NH_3 and VOCs (volatile organic compounds) like formaldehyde ($HCHO$). CO_2 and H_2O are important greenhouse gases. H_2O plays a major role in the hydrological cycle and is the gas that in reaction with O_3 forms the highly reactive radical OH . OH is the key species in cleansing the atmosphere of pollutants. All other mentioned gases play a role as greenhouse gas or air pollutant and/or as a precursor for a greenhouse gas, aerosols, or air pollutant. For example, NO_2 is an air pollutant and an important precursor for the greenhouse gas ozone and aerosols, as the air pollutant SO_2 is also an important precursor for aerosols. Other nongaseous atmospheric constituents that are of paramount importance for climate change and air pollution are aerosols and clouds.

The trace gases CO_2 , CH_4 , NO_2 , SO_2 , $HCHO$, NH_3 and CO , which can be observed from space and are increasing due to human activities, will therefore be the focus of this entry. H_2O is a natural gas and will therefore not be considered. OH in the troposphere is undetectable from space.

History of detection of trace gases from space

In the early 1970s, the first measurements of (stratospheric) ozone were made from space by the SBUV satellite instrument (Hilsenrath et al., [1995](#)), later followed by the TOMS instrument (McPeters et al., [1996](#)). These were the first measurements of the chemical composition of the atmosphere from space. In addition to stratospheric ozone, TOMS also observed SO_2 from volcanic eruptions. GOES was used to retrieve aerosol optical depth (Fraser et al., [1984](#)). Fishman et al. ([1987](#)) used ozone columns from

TOMS to investigate an episode with ozone smog over the eastern United States. An important step forward was made with the launch of the GOME instrument in 1995 (Burrows et al., [1999](#)), which could measure several of the minor trace gases using the backscatter technique. This instrument was followed by SCIAMACHY (2002, Bovensmann et al., [1999](#)), OMI (2004, Levelt et al., [2006](#)), and GOME-2 (2006, Callies et al., [2000](#)). Apart from the solar backscatter technique, measurements of tropospheric trace gases can also be made in the thermal infrared. MOPITT (1999, Deeter, [2009](#)), AIRS (2002, Aumann et al., [2003](#)), TES (2004, Beer, [2006](#)), and IASI (2007, Blumstein et al., [2004](#)) are instruments that use this wavelength range.

All instruments that have been observing tropospheric trace gases were on board satellites in a Sun-synchronous orbit, providing at most one (backscatter techniques) or two (thermal infrared) measurements at the same local time per day.

Retrievals and validation

What can be detected from space on tropospheric trace gases? Since the species of interest reside in the troposphere, and the instruments are orbiting the Earth at around 500–800 km altitude, observing in nadir, it is quite a challenge to detect the minor constituents in the lower 10–15 km of the atmosphere from space. There are basically two methods used to measure the troposphere, both based on passive remote sensing techniques: the solar backscatter technique and the thermal infrared technique. In the solar backscatter technique, the instrument measures the solar radiation that has been absorbed and scattered by the atmosphere. This so-called Earth radiance spectrum contains the specific absorption features of the molecules of interest (due to electronic-vibrational-rotational transitions in the molecule, see [Figure 1](#)). In the thermal infrared technique, the thermal emission of the Earth-atmosphere system is measured, revealing the specific absorption features of the trace gases (see [Figure 2](#)). Due to the specific spectroscopic “fingerprint” of the molecule, it is possible to determine the trace gas concentration, using very sensitive detectors and optimally designed optical instruments. The solar backscatter instruments usually provide tropospheric columns of the trace gases. The technique has the advantage to be sensitive to the surface, since the atmosphere is transparent in the visible wavelength range. With the thermal infrared technique, also some vertical information can be obtained, approximately two layers in the troposphere, but the sensitivity to the surface is less so that accurate total column amounts are more challenging.

The retrieval of tropospheric trace gas concentrations from satellite measurements is a so-called ill-posed problem. For ill-posed problems, the information from the measurement is not enough to derive all unknowns independently. This means that to retrieve trace gas concentrations from satellite measurements, assumptions have to be

Trace Gases, Troposphere - Detection from Space, Figure 1 Total absorption optical thickness for tropospheric trace gases in the UV-vis wavelength range, as calculated for a mid-latitude atmosphere in summer. Note that a logarithmic scale is used, thus the absorption by ozone decreases by six orders of magnitude in the wavelength range from 270 to 360 nm (Image courtesy: P. Stammes (KNMI)).

made on, for example, the reflectivity of the surface and the approximate vertical distribution of the trace gas. One of the most widely used retrieval techniques is optimal estimation (Rodgers, 2000). For the solar backscatter technique, also differential optical absorption spectroscopy (DOAS) retrieval is widely used (Platt, 1994).

Satellite measurements of tropospheric trace gases are hampered by clouds that reflect radiation to space, effectively screening the gas concentrations in the most polluted layer below the clouds. For fully clouded scenes algorithms are therefore fundamentally limited to retrieving above-cloud concentrations. But in situations with partial cloud cover, radiance signals still contain information on trace gas concentrations in the lowest layers, and tropospheric column retrievals are possible. By reducing the size of the ground pixel, the probability of encountering a completely cloud-free pixel increases. Therefore, recent developments have focused on limiting the pixel size, thereby increasing the amount of measurement samples in order to obtain more cloud-free observations while retaining global coverage.

In order to check their accuracy, satellite measurements are validated by comparisons with ground-based and aircraft measurements and atmospheric models. Ground-based and aircraft campaigns are often performed for validation for specific atmospheric conditions and are thus limited in scope. Networks of ground-based instruments of known quality are thus a valuable tool for validation of satellite measurements over the whole mission lifetime.

Extensive networks exist only for a limited set of trace gases (for instance, ozone and CO_2). For other trace gases, like NO_2 , SO_2 , and HCHO , the development of consistent ground-based networks is much called for, but only starting.

The advantages of satellite observations

The capability of satellite instruments to measure the tropospheric pollution first became apparent by measurements of GOME on NO_2 (Leue et al., 2001) and MOPITT on CO (Edwards et al., 2004). These instruments enabled for the first time global measurements of pollutants in the troposphere in the form of maps of monthly or yearly averaged concentrations. Up to that point, only models provided such information, and independent data to validate these models was sparse. SCIAMACHY extended the measurements of the troposphere to greenhouse gases like methane (Frankenberg et al., 2005). The GOSAT satellite (Hamazaki et al., 2004) was launched in 2009 is dedicated to measure CH_4 and CO_2 with very high accuracy. Recent results suggest that GOSAT CO_2 retrievals are useful to constrain surface fluxes of CO_2 (Butz et al., 2011). In 2014 NASA's OCO satellite (Crisp et al., 2004) will be launched dedicated to measure CO_2 .

Because of its small pixels and daily global coverage, OMI provides much more measurements of the troposphere than previous instruments were able to. Instead of monthly averaged maps, OMI is able to provide daily maps. In Figure 3, four consecutive frames are shown of

Trace Gases, Troposphere - Detection from Space, Figure 2 IASI-normalized radiance spectrum (*top panel*, recorded by IASI/ MetOp, over west of Australia, on December 20, 2006) and transmittance simulated molecular contributions to identify the main absorbing gases (*middle panels*) and the weaker (*bottom panel*) (From Clerbaux et al., 2009).

OMI measurements. The figure clearly shows the Sunday dip in NO_2 concentration due to reduction of traffic during the weekend resulting in less NO_2 emissions.

These instruments clearly showed the unique capability of satellite measurements to obtain global coverage and consistent quality of the measurements. For instance, ground-based networks for most of the tropospheric trace gases are sparse and the quality of the data is sometimes station dependent.

The chemistry of the troposphere is complex and involves many trace gases and chemical reactions. Combining the observations of trace gases from satellite instruments is therefore a great advantage. The added value of satellite observations of key species is illustrated in Figure 4. This figure shows the prominent global impact of human activities on the composition of the troposphere. Figure 4 shows satellite maps of concentrations of NO_2 , CO, CH_4 , HCHO, and particulate matter. Also shown is a map of the population density. The sources for NO_2 and CO are fossil fuel combustion by power plants, industry, and traffic. For CH_4 , important sources are wetlands (including rice agriculture), energy, livestock, landfills and waste, and biomass burning. Formaldehyde sources include biogenic emissions, as

well as biomass burning and fossil fuel burning. Most of the particulate matter is formed in the atmosphere from the trace gases.

Research themes and operational applications

Measurements of tropospheric trace gases are important for air quality monitoring and forecasting. Especially, observations of longer-lived trace gases such as CO have proven useful in analyzing the impact of distant sources to local air pollution levels (e.g., Gloudemans et al., 2009). Air quality prediction systems increasingly use satellite observations to improve their forecasting capability.

Satellites provide top-down constraints on emission inventories, which traditionally rely on rapidly outdated bottom-up estimates, and generally go unchecked by measurements. As a result of the unique global character of satellite data and their consistency (one retrieval algorithm for all measurements), satellite measurements provide an exceptional tool for checking emission databases. Examples include Lamsal et al. (2011) who combined a top-down approach with a bottom-up a priori inventory to produce an optimal a posteriori inventory for NO_x emissions. Mijling et al. (2012) recently applied a new

Trace Gases, Troposphere - Detection from Space, Figure 3 Four consecutive frames of OMI tropospheric NO₂ measurements. The figure clearly shows the Sunday dip in NO₂ concentration due to reduction of traffic resulting in less NO₂ emissions (Image courtesy: R. Noordhoek (KNMI); data courtesy: KNMI/NASA/NSO and www.temis.nl).

inversion technique to use daily satellite observations for fast updates of emission estimates at high spatial resolution ($25 \times 25 \text{ km}^2$) for eastern Asia. VOC emissions were first derived from GOME retrievals of HCHO over North America using an inversion based on the relationship between HCHO columns and VOC emissions scaled by their HCHO yields (Palmer et al., 2003). Important developments include simultaneous multispecies inversions to infer CO and NO_x emissions from MOPITT and GOME information (Müller and Stavrakou, 2005), and recently, Beirle et al. (2011) estimated megacity NO_x emissions and lifetimes directly from the decay-with-distance of NO₂ concentrations downwind of megacities.

The satellite data can also be used to evaluate models. Comparison of air quality models – traditionally focusing on the lower troposphere – to satellite measurements, for instance, has shown the need to accurately represent the free troposphere in these models (Blond et al., 2007).

Using SCIAMACHY NO₂ columns, Bertram et al. (2005) were able to improve the model description of microbial soil NO_x emissions that depend on humidity, fertilizer application, and temperature.

Satellite data are also very suitable to extent our knowledge on the atmospheric composition by analyzing the long-term records. Richter et al. (2005) showed the increase of NO₂ pollution over eastern Asia over the last 10 years. Van der A et al. (2008) extended this work and analyzed spatially resolved trends in NO₂ concentrations for the entire globe. Recently, Castellanos and Boersma (2012) showed that reductions in NO₂ concentrations over Europe reflect a combination of environmental policy and economic activity. Especially the 2008–2009 global economic recession triggered a distinct change in anthropogenic activity in Europe, indicated by sharp downturns in grossdomestic product and industrial production, and, consequently, in air pollution.

Trace Gases, Troposphere - Detection from Space, Figure 4 Global concentration maps. Color scale concentrations range from red, via yellow and green, to blue, which represents very high, high, medium, and low values, respectively. For population (lower right) white represents small, and dark brown, red represents large population numbers. From top-left to bottom-right: (a) OMI tropospheric column NO_2 , average for 2007, (b) POLDER/PARASOL (Tanré et al., 2011) fine-mode aerosol optical thickness, June–August 2006, (c) MOPITT CO average mixing ratio between 0–2 km and 7 km altitude, 7 year average (2000–2007), (d) SCIAMACHY methane column-averaged mixing ratio, Jan 2003 – Oct 2005, (e) SCIAMACHY formaldehyde, average for year 2004, (f) World population map from the Center for International Earth Science Information Network (CIESIN), Columbia University, and Centro Internacional de Agricultura Tropical. (Image courtesy Henk Eskes, KNMI and http://esamultimedia.esa.int/docs/SP1313-6_TRAQ.pdf).

For air quality prediction, usually data assimilation systems are used, where satellite data and ground-based data are integrated with the model data in order to improve the forecast. This technique is only effective when the data are available within a few hours of measurement, also called near real time (NRT). Nowadays, measurements from most backscatter instruments can be obtained within this time frame (e.g., Boersma

et al., 2007). In the thermal infrared, the IASI instrument is also delivering in NRT. The NRT SO_2 measurements from volcanoes are used for aviation control, relaying aircraft after a volcanic outburst. Figure 5 shows a SO_2 plume from a volcanic outburst as observed by OMI in June 2009. The observations clearly indicate the locations that should be avoided by intercontinental flights.

Trace Gases, Troposphere - Detection from Space, Figure 5 The image shows average column sulfur dioxide concentrations between 11 and 17 June 2009, based on data from OMI. The high SO₂ amounts originate from an eruption of the Sarychev Volcano (Kuril Islands, northeast of Japan) on June 12, 2009 (Images like these are used to redirect aircrafts. Image courtesy: S. Carn (Michigan Technology University)).

Future

To improve the measurements of the tropospheric trace gases, smaller ground pixels are essential to reduce cloud contamination and obtain highly resolved information on suburban scales. New instruments will target at a $5 \times 5 \text{ km}^2$ spatial resolution. In 2015 the TROPOMI instrument will be launched on ESA's sentinel-5 precursor (Veefkind et al., 2012) with a spatial resolution of $7 \times 7 \text{ km}^2$. From 2020 onward this instrument will be followed by ESA's sentinel 5 instrument on METOP-SG as part of the EU Copernicus program (Ingmann et al., 2012). Special cloud-observing capabilities are in development so that extra cloud information can be measured and the accuracy of the trace gas retrievals for partly cloudy pixels can be improved. By developing combined retrieval techniques that take advantage of backscatter as well as the thermal infrared spectral measurements, vertical profiles of tropospheric trace gases with more than two pieces of information in the troposphere are anticipated. Such combined techniques can be used when both instruments are located on the same satellite. Adding a dedicated aerosol instrument to such a platform would allow for simultaneous observations of all anthropogenic influences on the troposphere for the first time. The METOP-SG satellite is expected to have this combination of instruments on board (Berger et al., 2012).

Apart from a Sun-synchronous orbit, also non-Sun-synchronous as well as geostationary orbits could be used. The Sun-synchronous orbit will provide full global measurements with one or two observations a day. From the geostationary orbit, hourly observations can be made for a relatively small part of the world (e.g., Europe or North America). The non-Sun-synchronous-inclined orbit (see e.g., http://esamultimedia.esa.int/docs/SP1313-6_TRAQ.pdf) combines global coverage (apart from the polar regions) and frequent measurements (about five per day). Two to three of these non-Sun-synchronous satellites are needed to provide high temporal measurements throughout the year for the whole globe, except the poles. Which orbit to use is dependent on the specific scientific or operational purposes of the satellite. For climate observations, the global coverage of the measurements is of paramount importance. For regional air quality, the high temporal sampling is more important than global coverage. In the timeframe 2017-2020 three geostationary missions are planned: the Sentinel 4 (Ingmann et al., 2012) as part of the EU Copernicus programme over Europe, the South Korean GEMS (Kim et al., 2012) over Southeast Asia, and the U.S. TEMPO (Fishman et al., 2012) over North America. These instrument form a constellation of geostationary air quality missions, can be linked to the Low-Earth-Missions like the sentinel 5 precursor and

METOP-SG that provide the global coverage and thus interconnect the regional missions.

Summary

In the last 15 years, observing trace gases in the troposphere from space has been a tremendously fast developing field. Sophisticated retrieval techniques have been developed in order to obtain tropospheric trace gas concentrations, and these techniques have been validated successfully. Satellite instruments now provide daily observations of the chemical composition of the troposphere with spatial detail as fine as urban scale. Satellite observations have been successfully used to provide constraints on emissions of pollutants, to evaluate and improve atmospheric models, and to identify trends in air pollution. In the future, pixel sizes will even decrease further, and combined measurements from backscatter and thermal infrared will provide better vertical profiles in the troposphere.

TRAFFICABILITY OF DESERT TERRAINS

Charles Hibbitts
 Applied Physics Laboratory, Laurel, MD, USA

Definition

Trafficability (of desert terrains): The ability to traverse a surface in a cart vehicle.

The trafficability of desert terrain is controlled by soil strength, surface roughness, and the propensity for a surface to generate dust (dust loading) that would obscure vision or impair engine performance. This entry focuses on the most important and treacherous factor in desert trafficability, soil strength. Surface roughness and dust loading are mentioned in context with specific terrain types. Finally, methods for remotely estimating these factors are briefly discussed. Perhaps the most difficult to recognize, and likely the most important factor for trafficability in desert terrains, is soil strength, which itself is dependent upon several factors that can be measured or estimated: soil moisture, grain (or clast) size, and composition. It is the combination of soil strength and vehicle footprint (the area over which the weight of the vehicle is distributed) that dominates a surface's trafficability.

Contributing factors to soil strength

Soil grain size

In general, as the amount of fine-grained material ($<125\ \mu\text{m}$, or 200 sieve) in a soil increases, its load-bearing strength decreases and trafficability worsens. The “critical depth,” defined as the depth at which soils provide sufficient strength to support a specific vehicle type, increases, and the terrain becomes more difficult to traverse as the fine-grained component increases. Coarse soils under both wheeled and tracked vehicles generally have a critical depth of no more than 6" (wheels sink $\sim 6''$ until traction is obtained), while the critical depth of support for wheeled vehicle on fine-grained soils can be as deep as 12" for heavy vehicles and deeper for tracked vehicles. Coarse-grained soils provide better support for several reasons: (a) the strength of coarse soils tends to increase more rapidly with depth than do fine-grained soils, ensuring the critical depth is near the surface; (b) they do not readily remold, meaning the traction of vehicles behind the lead are improved as long as they remain in the ruts formed by the first; (c) the trafficability of coarse-grained soils can be improved by reducing tire pressure (distributing the vehicle weight over a wider area) more so than can trafficability in fine-grained soils.

Very fine-grained soils pose an additional problem affecting visibility; they can be readily airborne. Significant loading of the atmosphere by windblown dust occurs for particles smaller than $20\ \mu\text{m}$ (clay-size particles that are common in low-lying areas), which are easily lofted by vehicular and foot traffic. While this fine-grained dust may be found exposed on the surface such as on playas, it can also be present in large quantities in the near subsurface, commonly occurring as several centimeter thick deposits immediately under, and protected from erosion but not from vehicular traffic, in geologic terrains called “desert pavements” commonly found on alluvial fans.

Soil composition and moisture

Fine-grained soils can also contain a significant component of clay minerals, which because of their composition are both hygroscopic (stay wet) and often expansive and tacky when wet, compounding the hazard of their traversing. Furthermore, a wet subsurface is not easy to discern. It can often be camouflaged by a thin dry top surface, especially in dry lake beds and sabkhas. Together, these characteristics multiply the hazard posed by moist soils. Soil moisture content begins to dramatically degrade trafficability at $\sim 20\%$, with a soil becoming liquid at $\sim 40\%$ volumetric water. Clay minerals can absorb many percent of water interstitially (within themselves) and upon compressing when traversed will tend to release this water, increasing the amount of available water in the surface further degrading trafficability.

Relevant desert terrain types

It is important to distinguish specific desert terrain types because the trafficability of a terrain is quite dependent

on its geology, which controls the major factors of soil strength: grain size, water content, and composition. Mountainous deserts often possess several different geologic provinces such as active alluvial fans (including dissected fans, washes, alluvial terraces), rocky highlands, and pediments. Badlands, alluvial plains, playas, and sand dunes are also common in many deserts.

Dry lakes

Playas and variants such as alkali flats, sabkhas, mud flats, and salt flats result from the evaporation of closed bodies of water and pose significant hazards because of both fine grain, sticky clay, and commonly a wet near subsurface. Sabkhas are supratidal salt flats, and thus form near coastlines, and are common in the Persian Gulf area. Like playas, mature sabkhas have standing water only after intense rain storms. All these evaporate landforms, though, can have wet soils (mud, salt) immediately under a dry crust easily broken through by all vehicle types. A wet near surface can persist due to groundwater recharge by continental waters. With a slope of $<1\%$ and slow evaporation due to the hygroscopic nature of the salt and clay-rich soil, groundwater is almost always present within 2 m of the surface, and thus, these surfaces can be more hazardous to tracked vehicles than wheeled vehicles. However, once compacted, the soils do not absorb water as well; thus, unimproved roads can provide a safe traverse when otherwise impassible. These landforms also accumulate significant very fine-grained windblown siliceous and salt-rich dust, easily lofted by traffic or wind.

Alluvial fans

These are apron-like deposits of material eroded from the mountains at their base. They can often be found adjacent to playas. In general, they are of poorly sorted material that is carried down in flash floods from the mountains. Their horizontal extent is on par with their mountainous source regions, and individual fans can merge to form composite landforms extending hundreds of kilometers. Surface roughness ranges from impassible boulder-strewn fields to smooth gravel plains. Fans are also often dissected by internal drainage channels requiring a meandering path to navigate. The horizontal profile of a fan is characteristic of the dominant size of material. Fans of large stones and boulders have a decidedly convex profile and are thus rough and difficult to traverse. These tend to be active young fans. Older, mature fans are broader and flatter, often covered by surfaces of interlocking flat-lying small stones (a geologic feature called “desert pavements”). These “pavements” are easily broken through by all vehicle types exposing a very fine-grained soil, again easily airborne, and if wet, potentially difficult to traverse.

Badlands/Malpais

Badlands are formed through the erosion of sedimentary rocks and soils by wind and water leaving a series of plateaus and steep valleys that can be often navigated.

They should not be confused with Malpais, which are heavily eroded volcanic flows, with very angular stones and a surface roughness at vehicle and pedestrian scales making them difficult or impossible to traverse.

Dunes/dune fields

These unconsolidated sands of quartz, gypsum, and carbonates are deposited through aeolian processes. The largest dunes and fields are longitudinal, oriented parallel to the prevailing wind direction. Each can be hundreds of kilometers long and hundreds of meters high, forming fields of dunes over a hundred kilometer wide. The size and shapes of the grains controls the stability of these surfaces, and trafficability can vary dramatically.

Remotely determining trafficability

Measurement techniques to determine relevant soil properties range from passive to active sensors, from radar to acoustics, and from simple one-parameter measurements to complex radiative transfer modeling. Approaches include thermal imaging, multi- and hyperspectral thermal infrared, polarimetry at optical wavelengths, active and passive radar, acoustics, Vis-SWIR spectroscopy, multi-angle look angles, and [LiDAR](#).

Subsurface moisture

Subsurface moisture can be directly detected by ground-penetrating radar or inferred through observations of the surface. Multiwavelength active interrogation at radar wavelengths offers a proven method for discriminating soil moisture from effects such as volume scattering to develop a vertical profile of moisture to ~1 m depth. These approaches enable the discrimination of moisture from surface roughness. Passive long-wavelength infrared observations can detect relative warming and cooling rates to potentially discriminate areas of near-surface water from dry areas (they warm and cool at different rates). In the future, it may also be possible to employ sound for the interrogation of subsurface moisture. The acoustical response of a soil depends directly upon its strength and thus potentially offers a direct method for measuring the trafficability of a surface.

Soil grain size

Specific soil grain size can be robustly determined for well-sorted soils only because of a strong qualitative relationship between grain size and brightness in the near and shortwave infrared given a uniform composition. Additional effects due to subpixel surface roughness also need to be considered. The presence of clay-sized particles can be inferred more reliably due to compositional signatures, and clay minerals can be identified via specific optical characteristics. However, because clay minerals also exist as coatings on larger grains, the presence of these minerals does not necessarily indicate a significant abundance or a traffic hazard. Landforms known to contain fine-grained materials – desert pavements and dry lakes – can

themselves be detected by compositional signatures and morphology. Dry lake beds contain significant hydrated salts that have unique optical signatures in the infrared. The closely packed stones composing the surface of a desert pavement, under which several centimeters of fine-grained dust often accumulates, also have unique optical and radar reflectance and polarization properties.

Surface roughness

Several techniques exist to quantify the roughness of a surface. Direct imaging with active techniques such as microwave radar and LiDAR can provide absolute measurements, although resource intensive. However, passive microwave methods provide too coarse spatial resolution to provide useful trafficability information. Surface roughness can also be estimated via passive nadir and multi-angle optical measurements at visible and infrared wavelengths, though less precisely, with a large number of measurements potentially enabling a full reflectance function characterization to infer absolute grain size and with relative grain size information possible from the measurement of as few as two angles.

Summary

The trafficability of desert terrain is controlled by soil strength, surface roughness, and the propensity for a surface to generate dust (dust loading) that would obscure vision or impair engine performance. It is the combination of soil strength and vehicle footprint (the area over which the weight of the vehicle is distributed) that dominates a surface's trafficability. Perhaps the most difficult to recognize, and likely the most important factor for trafficability in desert terrains, is soil strength, which itself is dependent upon several factors that can be measured or estimated: soil moisture, grain (or clast) size, and composition. Subsurface moisture is particularly hazardous because dry surfaces in many terrains (e.g., playas, sabkhas, desert pavements) often disguise wet subsurfaces.

TROPOSPHERIC WINDS

Chris Velden
 University of Wisconsin, CIMSS, Madison, WI, USA

Synonyms

Atmospheric motion vectors; Cloud drift winds; Cloud motion winds; Satellite-derived winds; Water vapor motion winds

Definition

Troposphere. The lowest layer of the atmosphere between the Earth's surface and extending up to ~10–15 km, characterized by decreasing temperature with increasing altitude, and where most weather exists.

Tropospheric winds. Tropospheric winds can be estimated from atmospheric motion vectors, which are derived by tracking the displacement of clouds or water vapor in a sequence of images taken from meteorological satellites.

Introduction

Meteorological satellites perform a variety of functions. One of the primary derived products from the imagery they provide is atmospheric motion vectors (AMVs). These vectors are obtained by tracking the displacement of cloud or water vapor features in sequential images in order to deduce an estimate of the horizontal wind at that location. AMV extraction methods have evolved to the point of becoming fully automated and precise, and data sets are routinely produced by several national operational data providers around the globe. AMVs derived from meteorological satellite imagery have become an important source of tropospheric wind information, especially over the oceans where routine observations from other sources are scarce.

AMV extraction methods have been under development since the late 1960s (Menzel, 2001). Initial efforts

required human interaction to target and track cloud features in satellite imagery displayed with the Man computer Interactive Data Access System (McIDAS), developed by the Space Science and Engineering Center (SSEC) at the University of Wisconsin. These methods were very labor intensive and subjective, thus preventing the data from being used operationally. Since the late 1980s, automated techniques have been developed and advanced to the level where operational production was possible, and significant impact on global forecast models has been achieved. Tropospheric winds derived from operational algorithms are now being utilized quantitatively in global numerical models worldwide.

AMV extraction methods have consistently improved through collaborative research efforts which have positively impacted the processing strategies and algorithm functionality. The International Winds Working Group (IWWG) sanctioned by the World Meteorological Organization was established in 1991 and has facilitated the exchange of AMV research and improved algorithms. These upgraded algorithms have been implemented operationally by collaborating international meteorological agencies over the years. This has resulted in global availability and application of “state-of-the-art” satellite-derived AMV algorithms that have impacted many different areas of operational and research meteorology (Velden et al., 2005).

Data processing overview

The basic AMV derivation process involves the execution of a sequence of steps: image navigation/registration, target selection, target height assignment, vector displacement determination, and quality control. Prior to execution of the AMV derivation process, two input data sets must be collected and staged. The first is a sequence of three or more satellite images. The optimal time resolution between images is dependent on the spatial and spectral resolution of the imagery and the domain of the application. In practice, for most applications, this is ~15 min. The second data set required is a set of numerical model forecast fields valid for the image times being processed. These fields help guide the altitude placement of the derived vectors.

Once the input data are properly staged, AMV processing can begin. Potential tracking targets can be well-defined cloud features or sharp gradients in water vapor imagery. Target height assignment values are calculated using a number of different methods depending upon the spectral nature of the imagery being utilized. Targets (features) are then tracked between successive image pairs, looking for high correlations. If found, displacements are calculated to determine AMVs (estimated tropospheric winds at those locations). At this point, each AMV is quality controlled using a series of tests that check for consistency and fit of the vector with its neighboring data. Various quality flag values are assigned from this analysis to each wind vector examined and passed on to the user community.

Applications

Numerical weather prediction

Perhaps the most important application of AMVs is their assimilation as tropospheric winds into numerical forecast models. Proper analysis of atmospheric conditions at the model initialization time is paramount to subsequent accurate forecasts. The AMVs provide critical data over regions normally void of observations from other sources. The positive impact of the AMV data on numerical model forecasts has been proven in many studies, over many meteorological scales (Velden, 1996; Goerss et al., 1998; Soden et al., 2001; Rohn et al., 2001; LeMarshall et al., 2002; Kelly, 2004). Tropospheric winds derived from operational AMV algorithms are now being utilized quantitatively in global numerical models worldwide.

Tropical cyclones

The proper specification of the environmental flow field in the vicinity of tropical cyclones (TCs) can determine the storm motion, forecast track, and intensity. Since TCs are primarily oceanic events, satellite observations are critical to monitor the evolving environmental wind conditions. Fields of AMVs can be utilized to determine TC steering flows (Velden et al., 1992, 1998; Bosart et al., 1999; Dunion et al., 2002) and also to deduce the local vertical wind shear which is crucial to TC intensity modulation.

Polar regions

Geostationary satellites do not generally provide useful AMV information poleward of about 65° latitude due to their equatorial orbit. Polar-orbiting satellites have orbital periods of approximately 100 min and, therefore, provide consecutive scans over nearly the same polar regions at these intervals. Imagers on polar orbiters have scanning swath widths of 2,300 km or more, providing significant geographic overlap by consecutive orbits at high latitudes. These temporal and spatial characteristics provide the opportunity for deriving AMVs from successive orbits (single or multiple satellites) over the polar regions. The AMV processing methodology employed is based on the automated tracking algorithms used with geostationary satellites, modified for use with the Moderate Resolution Imaging Spectroradiometer (MODIS) on board the National Aeronautics and Space Administration's (NASA's) polar-orbiting *Terra* and *Aqua* satellites. Cloud and water vapor tracking with MODIS data is described further in Key et al. (2003). Numerical model impact studies have shown that the MODIS AMV data can have a positive impact on high-latitude forecasts. The AMVs are now routinely assimilated operationally at most global modeling centers.

Mesoscale and rapid scanning

Weather forecasters can utilize the additional detail that can be captured from more frequent imaging in events associated with rapidly changing cloud structures.

Successful tracking of features such as cumulus clouds over land, which have lifetimes that can be considerably less than 15–30 min, demands the use of imagery with time intervals in the 5 min range. Results from a study by Velden et al. (2000) showed that more frequent image sampling improved the AMV field density and quality, and the optimal tracking time interval was dependent on the spectral band employed. Fortunately, the global satellite providers and AMV producers are realizing the gains that are possible from rapid scans. So, the outlook is good for more frequent scanning cycles on near-term future geostationary satellite systems worldwide. As rapid scan imaging becomes a routine part of observing system strategies, quantities such as operational AMVs will greatly benefit. This, in turn, will directly benefit numerical model predictions and the operational forecast community.

Summary and outlook

The scientific community working on the retrieval of tropospheric winds from meteorological satellites recognizes the importance of steadily improving AMV observational quality so that the data continue to make a positive contribution to advancing data assimilation and forecast systems. In order to keep pace with these demands, innovative research toward improving ways of deriving winds from satellites has been a focus of the World Meteorological Organization and Coordination Group for Meteorological Satellites cosponsored International Winds Workshops. These workshops are held every 2 years and bring together AMV researchers from around the world to present new, innovative ideas on AMV extraction techniques, interpretation, and applications (Velden et al., 2005). The NWP community is always well represented at these workshops and provides an important exchange of information on the latest in data assimilation issues. The AMV applications briefly described here represent just a small sample of the new innovations in satellite-produced wind technologies, derivation methodologies, and products that have recently become available. The AMV data processing community is continuing to progress in all of these areas and is looking forward to pending new opportunities with emerging advanced sensor technologies.

UV

Definitions

Ultraviolet spectral region: Wavelengths less than 400 nm, the short wavelength limit of human vision, and longer than 10 nm, where the x-ray spectrum begins.

UV remote sensing goals: The Earth's ozone layer, volcanic eruptions, and airglow and auroral emissions.

UV spectral divisions: Regions based on properties of atmospheric gases and optical materials:

- Near UV (NUV) 400–300 nm
- Middle UV (MUV) 300–200 nm
- Far UV (FUV) 200–100 nm
- Extreme UV (EUV) 100–10 nm

Introduction

Near and middle UV wavelengths have information about ozone, sulfur dioxide, and trace gases in the troposphere and stratosphere (0–50 km) of interest to the atmospheric and volcanic sciences. Far and extreme UV wavelengths have information about airglow and auroral emissions from the thermosphere (>100 km) of interest in aeronomy and space weather. These studies have developed independently because the first deals with reflected sunlight, while the second deals with emissions from atoms or molecules in excited states. Excellent books on UV remote sensing science and technology are Green (1966) and Huffman (1992).

Near and middle UV remote sensing

The greatest public impact of satellite UV remote sensing of the atmosphere comes from measurements of *ozone*, the constituent that blocks UV sunlight from reaching the biosphere. Early rocket and satellite experiments used UV light to measure ozone. Rocket techniques measure the extinction of MUV sunlight versus height to derive the ozone distribution. Satellite techniques measure backscattered NUV and MUV sunlight to infer the vertical ozone distribution and total amounts. Remote sensing of an atmospheric constituent requires forward model calculations of the scattering and absorption processes for the given observing conditions, coupled with inverse calculations to retrieve the distribution of the constituent from the observed spectrum of light. Three physical processes control the transfer of near and middle UV radiation in the atmosphere: absorption by gases, scattering by molecules and aerosols, and reflection from clouds or the Earth's surface.

Atmospheric UV absorbers

The dominant atmospheric optical process in the NUV and MUV is *absorption* by oxygen and ozone. The absorption bands of ozone begin weakly near 360 nm and then increase exponentially from about 340 nm to a broad peak near 250 nm. Ozone is an unusual atmospheric constituent with an inverted distribution with altitude due to its formation from photodissociation of oxygen at MUV wavelengths. Ozone production is balanced by destruction by radicals in the H, N, O, and halogen families. The ozone density is low in the troposphere, increases in the stratosphere to a maximum around 25 hPa (~25 km height), and then decreases exponentially with height up to 60 km. This unusual distribution influences methods for remote sensing of ozone from space. NUV sunlight reaches the biosphere where two components, UVA and UVB, are recognized for their biologic action. Another

MUV absorber is sulfur dioxide, which has a short lifetime in the troposphere and is normally found only near sources, such as volcanoes, smelters, and fossil fuel power plants. However, large amounts are found in volcanic eruption plumes in the stratosphere where the SO₂ lifetime is about a month. Volcanic plumes can travel global distances before conversion to sulfate molecules.

Atmospheric scattering

The second major optical process at ultraviolet wavelengths is Rayleigh *scattering* by air molecules. This strong, inverse fourth-power wavelength-dependent scattering produces the blue sky. From space, Rayleigh backscattered UV sunlight is utilized to derive the vertical distribution of ozone and the total ozone amount. In addition to Rayleigh scattering, inelastic rotational Raman scattering shifts the wavelength of the light. This has an important effect on scattered sunlight due to Fraunhofer structure in the solar spectrum. Thus, spectral dips in Earth radiance are filled and peaks are diminished.

Reflection from the surface and clouds

NUV light that reaches the Earth's surface is reflected from the ground, vegetation, and water. The reflectivity of all terrestrial surfaces is small (<10 %), but clouds are very reflective (80–100 % for thick clouds) and can make a large contribution at the top of the atmosphere. Total column ozone amounts are derived using a radiative transfer model to account for the absorption, scattering, and reflections.

Radiative transfer models

Calculation of the radiance of the atmosphere is a major component of UV remote sensing. Numerical models of the radiance of the Earth's atmosphere were developed by Dave (1965) who computed tables of radiance versus geometry, wavelength, ozone profile, and surface reflectivity for use in satellite retrieval of total ozone. Other RT codes, such as LOTRAN and HITRAN, are available for general use.

UV remote sensing from the surface, balloons, and rockets

Total column ozone amounts have been measured since the 1920s through differential absorption of sunlight at NUV wavelengths using a double quartz prism spectrophotometer developed by G.M.B. Dobson (1968) at Oxford University. Dobson spectrophotometers are still in use for monitoring ozone trends at stations across the world. Later, Paetzold and colleagues in Germany developed balloon-borne UV filter photometers to measure the vertical distribution of ozone. Ozone densities are computed from the change in NUV solar irradiance with altitude. Ozone measurements in the photochemical production region above 30 km required rockets. Johnson et al. (1952) launched photographic spectrographs on Aerobee rockets for the first definitive data on

photochemical ozone densities up to 70 km. Krueger (1973) later developed MUV filter photometers for meteorological sounding rockets to measure latitudinal and seasonal changes and for calibration of satellite ozone profile data. The US Standard Atmosphere 1976 midlatitude ozone distribution is based on many of the early rocket soundings (Krueger and Minzner, 1976).

UV remote sensing from satellites

Early space experiments used UV filter photometers for measurements of the backscattered radiance of the sunlit Earth (e.g., Friedman et al., 1963). The first spectrum of backscattered MUV sunlight was measured with a spectrometer (e.g., Iozenas et al., 1969). These early experiments produced data to evaluate *forward* calculations from radiative transfer models. However, to remotely sense the ozone distribution that produced the observed radiance requires an *inversion* algorithm and a radiative transfer model to derive the *path* of the photons into and out of the atmosphere.

Vertical ozone distribution

The first ozone profile experiment measured the extinction of 260 nm sunlight with a filter photometer as rays from the Sun passed through the limb of the Earth to the satellite (Rawcliffe et al., 1963). The photon path in this case is simply the geometry of rays passing through the limb as a function of minimum ray altitude accounting for refraction and the finite size of the solar disc. This method is limited to one sunrise and sunset ozone profile during each orbit, but, similar to rocket soundings, can accurately be calibrated from rays taken above the ozone layer.

A more general method for remote sensing of ozone profiles from space involves measuring scattered sunlight from the nadir at strongly absorbed wavelengths between 250 and 300 nm where sunlight is totally absorbed by **stratospheric ozone** if it is not scattered back to space. The backscattered light originates only from altitudes above the depth for total absorption at each wavelength. As the ozone absorption coefficient increases, the penetration depth decreases. Thus, a nadir viewing instrument can determine the ozone profile by measuring the albedo (ratio of Earth radiance to solar irradiance) at several wavelengths. The path traveled by photons is no longer geometric, so a radiative transfer model is required to derive the ozone distribution. At upper stratospheric altitudes (25–50 km), the air densities are low enough that a solar photon is likely to be scattered only once in its path back to space. Under these conditions, an analytic algorithm was devised (Twomey, 1961) to retrieve the upper level ozone distribution from albedos at a few MUV wavelengths. The first upper level ozone profiles were obtained using MUV spectra from the OGO-4 satellite in 1967 (Anderson et al., 1969) using the Twomey algorithm and a coincident rocket ozone sounding for calibration. At altitudes below the ozone maximum near 25 km, multiple

scattering becomes important and only statistically constrained profile solutions are possible.

Global ozone monitoring

Fundamental problems for satellite spectrometers are the high dynamic range of signals across the UV spectrum, stray light control, and a solar calibration. The first satellite instrument built specifically to deal with these problems was the NASA Backscatter Ultraviolet (BUV) double monochromator proposed by J. V. Dave and C. L. Mateer of the National Center for Atmospheric Research and developed by D. F. Heath of the Goddard Space Flight Center (GSFC) for flight on the Nimbus 4 satellite in 1970. Twelve optimally selected wavelengths were used for MUV ozone profile retrieval and to test a new NUV total ozone algorithm (Dave and Mateer, 1967). This flight produced global upper level ozone data (Heath et al., 1973) and demonstrated that BUV total ozone retrievals were accurate (Mateer et al., 1971) using a multiple-scattering radiative transfer model (Dave, 1965) to determine the path for multiply scattered NUV photons.

Ozone profiles

BUV ozone profiles provided the first daily global information in the photochemical regime as a function of latitude and season. In the 4 year BUV record, the most significant scientific finding was that stratospheric ozone was kept in steady state by the catalytic cycles found in laboratory experiments. In August 1972, ozone losses appeared in the BUV data in the auroral zone when a solar proton event produced large quantities of nitric oxide in the only locations where the Earth's magnetic field permitted protons to reach the stratosphere (Heath et al., 1977). The success led to an advanced Solar Backscatter Ultraviolet (SBUV) instrument on the Nimbus 7 satellite in 1978 (Heath et al., 1975) and later to operational use on NOAA satellites. GSFC scientists undertook a major algorithm development effort to extend the profile retrieval below the single-scattering domain by accounting for multiple scattering and constraining the solution using maximum likelihood theory (Bhartia et al., 1996).

Total ozone

A new Total Ozone Mapping Spectrometer (TOMS) instrument was proposed by A. J. Krueger and flown with the SBUV on Nimbus 7 to ascertain the cause of high variability (Krueger, 1989). The instrument field of view (50×50 km at nadir) was scanned across track as the satellite moved in its orbit to generate full daily global maps of ozone. Total ozone retrievals use NUV wavelengths where sunlight penetrates to the Earth's surface, so that the entire column can be measured. The solution depends on accurate radiative transfer calculations for a simulated atmosphere containing climatological ozone profiles, observing geometry and reflections from the surface and

clouds (Dave, 1965). The instrument and algorithms are documented in <http://ozoneaq.gsfc.nasa.gov/n7sat.md>.

The TOMS total ozone images showed wave structure that matched planetary waves, demonstrating the control of atmospheric dynamics on total ozone through vertical displacement of air in the lower stratosphere. Figure 1 is an example of planetary waves in the total ozone field on April 16, 1984. This dynamic control of total ozone structure prevailed until chemistry was shown to produce major ozone features at a time when environmental concerns were expressed about chlorine in the atmosphere. A hole in the ozone over the Antarctic was found each October in TOMS data (e.g., Stolarski et al., 1986). This polar ozone depression began deepening in the 1980s in response to growth of chlorine from chlorofluorocarbons (CFC) released in the atmosphere. Chlorine is an ozone catalyst that is normally sequestered in stable compounds. However, surface reactions on aerosols in the wintertime Antarctic lower stratosphere produce chlorine molecules that are released as chlorine atoms when the Sun rises in spring, decreasing total ozone to one third of pre-CFC levels. Dramatic images of the Antarctic Ozone Hole (Figure 2) contributed to an international agreement to phase out production of CFC compounds: the Montreal Protocol on Substances that Deplete the Ozone Layer. Systematic TOMS global coverage is ideal for monitoring total ozone trends to validate models of global ozone change. Stabilizing the calibration of TOMS to detect trends of 1 %/decade is challenging (McPeters et al., 1996).

Sulfur dioxide and volcanic eruptions

A geophysical bonus is volcanic sulfur dioxide found in TOMS data when very large amounts appeared in the 1982 eruption of the Mexican El Chichon volcano. Discrimination between ozone and sulfur dioxide required a new algorithm (Krueger et al., 1995). The TOMS spatial mapping design proved to be excellent for measurement of transient phenomena. The size of all volcanic eruptions in the 25 year TOMS data record was determined (Carn et al., 2003) for climate research.

Absorbing aerosols

A third geophysical product from the TOMS UV radiances is an aerosol index (AI), a measure of dust, smoke, volcanic ash, and other absorbing aerosols (Torres et al., 1998). Aerosols change the spectral dependence of backscattered light at nonabsorbed wavelengths. TOMS AI is of particular value over land because of the low UV reflectivity of all terrestrial surfaces. Saharan dust is tracked from its desert origin to the Caribbean islands, while smoke can be tracked from forest fires in Canada to the Atlantic Ocean.

Early satellite ozone experiments are summarized in Krueger et al. (1980). Reviews of TOMS ozone and sulfur dioxide findings are in Krueger (1995) and Krueger et al. (2000). Three additional TOMS missions on research satellites and a series of operational SBUV flights on NOAA satellites continued the ozone and volcano eruption record for over 25 years.

Ultraviolet Remote Sensing, Figure 1 The horizontal distribution of total ozone on April 16, 1984, from TOMS data. Total ozone is measured in Dobson Units (DU) or milli-atm.-cm, the thickness of a layer of pure ozone at NTP conditions equal to all the overhead ozone. Tropical total ozone is always low, near 250 DU (2.5 atm.-mm), but higher latitude ozone varies seasonally, reaching 500 DU (5 atm.-mm) in springtime. The large waves are produced by upper troposphere meteorological troughs which bring stratospheric air down and create total ozone and ridges which lift and destroy total ozone. The jet streams follow the ozone contours.

Second-generation satellite UV remote sensing instruments

In 1990, with the concern about ozone depletion, the European Space Agency accepted a proposal from J. Burrows of the Max Planck Institute/Mainz for a new UV/visible remote sensing instrument for flight on the ERS-2 spacecraft. By this time, spacecraft telemetry had advanced so that far more information could be collected. The Global Ozone Monitoring Instrument (GOME) was developed to measure the full spectrum from 240 to 790 nm (Burrows et al., 1999). This allows absorbing species to be positively identified and wavelength errors and rotational Raman scattering to be corrected. The extended spectral coverage allows detection of other trace gases such as NO_2 , BrO, OClO, and formaldehyde (HCHO) in addition to ozone, sulfur dioxide, and aerosols. The first measurements of these trace gases from space were made with GOME data.

GOME algorithms use the Differential Optical Absorption Spectroscopy (DOAS) method that is less dependent on absolute radiance calibrations than are the BUV algorithms. DOAS uses a high-pass filter to isolate spectral band features in the radiance data due

to the absorption spectrum of the absorber, using a spectral interval broad enough to encompass band structure. The slant-path absorber amount is derived by a least squares minimization of the difference between observations and lab spectral data. An effective optical path for the selected band is computed using a radiative transfer model, similar to the BUV model. This path depends on wavelength, absorption coefficients, geometry, reflectivity of the ground or clouds, and the vertical distribution of all absorbers in the selected wavelength band.

GOME was followed in 2002 by the Scanning Imaging Absorption Spectrometer for Atmospheric Chartography (SCIAMACHY) research instrument launched on ENVISAT. SCIAMACHY added limb scattered light observations for profiles of stratospheric constituents. Nadir spatial resolution was improved over GOME with a ground resolution of 60×30 km and a swath width of 960 km. An online book, SCIAMACHY: Monitoring the Changing Earth's Atmosphere, is available: http://atmos.caf.dlr.de/projects/scops/sciamachy_book/sciamachy_book.html. Many of the scientific products are available through <http://www.iup.uni-bremen.de/sciamachy/index.html>.

Ultraviolet Remote Sensing, Figure 2 The Antarctic Ozone Hole on October 22, 1989, viewed in TOMS total ozone data. The deep oval region over Antarctica is produced by destruction of ozone in the lower stratosphere by chlorine in the polar vortex beginning in September and lasting until breakup of the vortex in November. Within the vortex, total ozone has decreased significantly since 1980 due to the growth of chlorofluorocarbons. Unprecedented low amounts less than 100 DU have been found. The midlatitude air surrounding the vortex remains unaffected with values above 400 DU because it is isolated from the polar air.

The Dutch-Finnish Ozone Measuring Instrument (OMI) (Levelt et al., 2006) launched in 2004 on the NASA EOS Aura platform (<http://aura.gsfc.nasa.gov/instruments/omi/index.html>; <http://www.knmi.nl/omi/research/science/>) returned to the TOMS concept of contiguous daily global coverage but with an eightfold increase in ground resolution (13×24 km at nadir) and with full spectral coverage from 270 to 500 nm. The contiguous coverage resulted in exceptional daily images of NO_2 and SO_2 sources. Figure 3 illustrates the SO_2 from an eruption of Nyamuragira volcano on November 30, 2006 (<http://so2.gsfc.nasa.gov/>). A 20-fold improvement in SO_2 sensitivity over TOMS allows monitoring of volcanic degassing and pollution from smelters and fossil fuel burning.

A second-generation GOME instrument, GOME-2, was launched on the first European polar-orbiting operational meteorological satellite, MetOp-A, in 2006. This was followed in 2012 with a second GOME-2 instrument on the MetOp-B satellite. GOME-2 adds a spatial scanner with ground resolution similar to TOMS. The series of MetOp flights will provide a continuation of the long-term record of ozone trends. The GOME-2 instrument and missions are described in http://www.esa.int/esaLP/SEMTEG23IE_LPmetop_0.html.

The USA launched its first hyperspectral UV instrument, Ozone Mapping and Profiler Suite (OMPS) (<http://npp.gsfc.nasa.gov/omps.html>), on the Suomi National Polar-orbiting Partnership (NPP) satellite in 2011 (<http://npp.gsfc.nasa.gov/index.html>). The NPP OMPS is the first of a series planned for Joint Polar Satellite System (JPSS) operational missions (<http://www.jpss.noaa.gov/>). OMPS continues ozone trend monitoring that began with the Nimbus 7 SBUV/TOMS mission in 1978 with the same observing requirements except that limb observations are added for improved vertical resolution of ozone profiles.

Far and extreme UV remote sensing

Remote sensing at FUV and EUV wavelengths views emissions from the upper atmosphere that result from radiative decay of molecules and atoms in excited states. Chemical reactions and solar photons produce airglow, while energetic particles produce the aurora. Models are then used to infer air densities in the thermosphere and the energy input from solar photons and energetic particles. UV observations are part of Global Space Weather Systems, in development to predict communication

Ultraviolet Remote Sensing, Figure 3 The plume of sulfur dioxide from an eruption of Niyamuragira volcano on November 30, 2006, from OMI data. Sulfur dioxide is distinguished from ozone because the absorption spectra differ in detail. The mass of SO₂ in the plume is determined by integrating across the cloud (e.g., 0.67 Tg, in this plume). This is an example of hundreds of volcanic eruptions that have been analyzed from TOMS and OMI data since 1978.

conditions and radiation environments for space travel. Many experiments have been flown on rockets and satellites since 1965 to measure the spectra and spatial distribution of the emissions. The aeronomy experiments and physical processes are discussed in detail in Huffman (1992).

Airglow

At wavelengths less than 200 nm, few solar photons are backscattered to space due to absorption by oxygen.

However, other processes produce emissions, known as *airglow*, both in day and at night, at the low air densities of the upper atmosphere. Molecules may *fluoresce* when stimulated by solar photons and atoms may undergo resonance reradiation. Absorption of UV sunlight can lead to photodissociation of molecules. Photoionization from UV sunlight produces energetic electrons that collide with molecules. These processes and reactions produce excited molecular and atomic states that radiate light at discrete wavelengths. The lowest altitude for airglow emissions is set by the air density where energy is

removed by collisional deexcitation rather than by radiation. Dayglow emissions produce information about N_2 , N, and O densities. Nightglow emissions are primarily from O_2 and NO. Visible nightglow emissions have been monitored from the ground for many years, but ultraviolet lines can only be observed from space. Excellent reviews of airglow and remote sensing are provided by Barth (1966), Meier (1991), and Huffman (1992).

Aurora

Aurorae are spectacular displays of curtains and filaments of green or red light visible from polar latitudes during periods of enhanced solar activity (see, e.g., Akasofu, 1989). They are produced when energetic electrons and protons impact the atmosphere to generate excited states in oxygen and nitrogen atoms and molecules that decay with characteristic spectral lines. Charged particles can only reach the atmosphere in polar regions where the Earth's magnetic field lines become vertical in the auroral ovals. The rich UV spectra viewed from space contain information about solar activity and air densities.

Global space weather systems

In the twenty-first century, FUV images of the Earth are becoming more important as space travel develops and we become more dependent for communications and navigation on space systems. Programs designed to understand the behavior of the thermosphere/ionosphere are maturing. The NASA POLAR mission (<http://pwg.gsfc.nasa.gov/polar/>), launched in 1996, includes an Ultraviolet Imager to detect auroral emissions in the 130–190 nm region as part of the International Solar Terrestrial Physics Program. The TIMED mission, launched in 2001, includes a Global Ultraviolet Imager (115–180 nm) in a group of instruments to investigate the mesosphere and lower thermosphere (<http://www.timed.jhuapl.edu/WWW/index.php>).

Outlook

UV remote sensing provides robust measurements of atmospheric ozone and sulfur dioxide and is an important component of a global space weather monitoring system. Ozone is produced and held in a steady state in the stratosphere by UV sunlight. The strong absorption limits the biologically damaging, shorter UV solar wavelengths from reaching the surface. The same wavelengths provide the means for measuring the ozone content and vertical distribution from the surface, balloons, rockets, and satellites. Data from the Nimbus 4 Backscatter Ultraviolet (BUV) instrument show conclusively that catalytic processes regulate ozone in the stratosphere. Images from the Total Ozone Mapping Spectrometer (TOMS) instrument on the Nimbus 7 satellite initially provided evidence for meteorological control of total ozone through vertical motions in the lower stratosphere. Later, TOMS images of the Antarctic Ozone Hole provided compelling evidence for large-scale destruction of ozone by chlorine

from industrially produced chlorofluorocarbons and led to international controls of ozone destroying pollutants. Monitoring of ozone trends from UV instruments will be continued for at least 50 more years to verify that destruction by halogens has been mitigated.

Sulfur dioxide is an important climate gas that is produced by volcanoes, smelters, and fossil fuel combustion. Quantitative data on all eruption SO_2 masses is available from the 25 year TOMS dataset. Improved sensitivity from GOME, SCIAMACHY, OMI, and succeeding hyperspectral instruments continues this eruption time series and adds noneruptive degassing from volcanoes, as well as emissions from smelters and in air pollution.

Far UV monitoring of airglow and auroral activity has provided comprehensive information about solar storm effects on the ionosphere and the near-Earth radiation environment. Interruption of communications, navigation, and power transmission has increasingly greater economic consequences in the twenty-first century. As human space travel to the Moon and beyond becomes a reality, this monitoring will be a necessary component of the Global Space Weather System.

Synonyms

Photometers; Spectrometers; UV

Definition

Ultraviolet spectral region. Wavelengths less than 400 nm, the short wavelength limit of human vision, and longer than 10 nm, the limit of X-rays.

UV instrumentation. Differ from “optical” instruments by UV transmitting materials.

UV spectral albedo. The ratio of Earth radiance to solar irradiance as a function of wavelength, comparable to reflectivity.

Introduction

Two classes of sensors are used for ground, balloon, rocket, and satellite UV remote sensing of the Earth: *filter photometers* and *spectrometers*. Two factors that distinguish UV instruments from visible light instruments are the need for UV transmitting optical components and the need to avoid stray light from the visible solar spectrum. Ordinary glass absorbs light at wavelengths less than 400 nm, so materials like quartz are required for transmitting optical components. The UV tail of the solar spectrum contains less than 10 % of the energy, and absorption by ozone can reduce radiances by three orders of magnitude lower than the solar irradiance. Care must be taken to insure that no visible light is transmitted or scattered in the optical system to be detected along with the desired UV wavelength. This becomes increasingly important as the band pass decreases or as the selected wavelengths are absorbed by the atmosphere. Stray light rejection is usually accomplished by use of filters, such as NiSO₄ crystals, or dichroic mirrors or by use of double monochromators. UV instruments are described in books by Huffman (1992) and Webb (1998).

Ground-based remote sensing

Atmospheric ozone absorbs ultraviolet sunlight at wavelengths less than 330 nm, increasing to a maximum near 250 nm. Dobson and Harrison (1926) developed a spectrometer to measure the total column amount of ozone in one of the first UV remote sensing experiments. They used a double-beam, double-prism spectrometer to measure the wavelength differential absorption by ozone in direct sunlight while removing visible light from the detector. Three pairs of wavelengths were needed for measurements over the full range of ozone amounts and solar zenith angles. A wedge neutral density filter is moved across the brighter beam until the intensities are matched as detected by a photomultiplier. An extraterrestrial calibration is derived from a Langley plot of measurements at each wavelength pair over a wide range of solar zenith angles on a day with constant total ozone. The changing path is extrapolated to zero to simulate the extraterrestrial reading. Dobson spectrophotometers are still widely used for monitoring of total ozone (Dobson, 1968). Vertical ozone profile information was also derived from zenith sky observations during twilight using an Umkehr (reversal) technique. Later, Brewer (1973) produced a grating spectrometer to measure total ozone. This instrument and a double grating version are also in wide use around the world.

Rockets

The first successful measurement of the vertical ozone distribution above 30 km used a rocket-borne photographic UV spectrograph to measure the extinction of sunlight as a function of altitude (Johnson et al., 1952). The ozone density decreases exponentially with altitude and a set of wavelengths with successively higher ozone absorption coefficients was needed to maintain precision with altitude. Following this pioneering measurement, a low-cost UV filter photometer ozonesonde was developed for launch from many global stations on meteorological sounding rockets (Krueger, 1973). This instrument used three interference filters and a nickel sulfate – Corning glass filter combination to block visible light. The data were taken during descent on a parachute from 60 km, where the extraterrestrial solar intensity was measured for computation of overhead ozone at lower altitudes. Sunlight was incident on a flat diffuser plate and a beam splitter corrected signal variations due to angle changes. The US Standard Atmosphere (1976) ozone distribution was constructed from rocket sounding data.

Satellite UV instruments

When satellites were developed, ultraviolet instruments were an early priority because the atmosphere absorbs these wavelengths. Initially, filter photometers using the same components as rocketsondes were flown. A nadir-viewing instrument (Friedman et al., 1963), launched in 1962, measured radiances at 255 nm for comparison with early radiative transfer calculations (Green, 1966). A 260 nm filter UV radiometer was also

flown in 1962 to measure the vertical ozone profile from the extinction of sunlight during sunrise and sunset (Rawcliffe et al., 1963). Flights of UV spectrometers began 3 years later.

Spectrometers

Iozenas et al. (1969) used a double monochromator with a spectral resolution of 1.4 nm on satellite flights in April 1965 and June 1966 to measure nadir radiance and solar irradiance from which the atmospheric spectral albedo was computed. The solar spectra were determined using a matte quartz diffuser plate to fill the instrument field of view (FOV). Limb spectra were also measured using a mirror to point the instrument axis slightly above the visible limb. In 1967, C. A. Barth launched a single Ebert-Fastie monochromator on the NASA OGO-4 satellite. Anderson et al. (1969) used a single-scattering ozone retrieval algorithm (Twomey, 1961) and calibrated the albedos using a coincident rocket sounding (Krueger, 1969).

BUV/SBUV

The first satellite instrument optimally designed for global ozone measurements was the NASA Backscatter Ultraviolet (BUV) instrument that was proposed by C.L. Mateer and J.V. Dave of NCAR and developed by D.F. Heath of Goddard Space Flight Center. Mateer's retrieval algorithm and Dave's radiative transfer calculations were used for vertical profile retrievals and also to test an algorithm for total ozone retrievals (Dave and Mateer, 1967). The BUV and its successor, the Solar Backscatter Ultraviolet (SBUV) instrument on Nimbus-7, used eight selected wavelengths between 255 and 308 nm for profile retrievals and four wavelengths between 312.5 and 339.8 nm for total ozone retrievals. Major design issues were the three orders of magnitude change in the albedo between 250 and 340 nm due to ozone absorption and stray light rejection requirement of six orders of magnitude. The BUV/SBUV is a cam-driven, wavelength step scan, double Ebert-Fastie monochromator (Figure 1) with very high stray light rejection and a large dynamic range (Heath et al., 1973). The wavelength scanning was slow (32 s/frame) for good signal/noise ratio at the short wavelengths, and a co-aligned 380 nm filter photometer channel measured radiance changes due to underlying clouds in the nadir-pointed FOV as the spacecraft moved in its orbit. The instrument response to solar irradiance was measured using a diffuser plate that was moved into the FOV at the terminator. Degradation of the reflectivity of the diffuser plate affected the albedo calibration. This became a significant issue when ozone trends were sought to confirm predictions of ozone depletion. New, redundant diffuser designs were incorporated in later flights.

TOMS

The total ozone retrieval scheme of Dave and Mateer (1967), tested on the Nimbus-4 BUV, delivered results in

Ultraviolet Sensors, Figure 1 Optics diagram of the BUV and SBUV instruments. BUV-class instruments are double Ebert-Fastie monochromators that accept backscattered sunlight from an 11° nadir field of view at 12 selected 1 nm wavelength channels between 255 and 340 nm. A depolarizer negates any polarization sensitivity. The wavelengths are selected serially over a 32 s cycle using cam-driven holographic gratings. The radiance is measured with a photomultiplier detector. The Earth albedo calibration is obtained from direct solar irradiance data taken via a diffuser plate that is rotated into the field of view when the Sun is near the horizon at sunset. Fluctuations in radiance due to changing cloud fields are compensated using a parallel filter photometer channel that is frequently sampled.

excellent agreement with coincident Dobson spectrometer data. However, the high variability suggested structure in the total ozone field. A. J. Krueger of Goddard Space Flight Center proposed a new instrument, the Total Ozone Mapping Spectrometer (TOMS), to map this structure by scanning the FOV cross track while measuring the high-radiance, total ozone wavelengths to permit short sampling times. The TOMS instrument (Figure 2) uses a single Ebert-Fastie polychromator with six, fixed exit slits corresponding to the BUV total ozone wavelengths and two longer wavelengths to measure surface spectral reflectivity. A chopper wheel sequentially passes the wavelengths to a photomultiplier. A scan mirror synchronously directs the FOV to 35 cross-track positions. A wavelength scrambling depolarizer avoids biases due to monochromator polarization. Scanning is designed for complete global coverage each day with 50×50 km nadir resolution that is adequate to resolve suspected jet stream modulations on the total ozone field yet did not overload the Nimbus telemetry. The TOMS instrument was mated with an advanced BUV, the Solar Backscatter Ultraviolet (SBUV) instrument, for flight on the Nimbus-7 satellite in 1978 (Heath et al., 1975).

GOME

European interest in satellite-based UV remote sensing rose in the 1990s as ozone became an environmental issue. John Burrows of the Max Planck Institute/Mainz proposed a new instrument for the ERS-2 satellite that took advantage of many improvements in satellite technology since 1970. In addition, new solid-state UV detector arrays were available. The Global Ozone Monitoring Instrument (GOME) measures the full spectrum from 240 to 790 nm rather than discrete wavelengths as used in the BUV class of instruments. The spectrum is first split into four channels using quartz pre-disperser prisms (Figure 3). Each channel then is dispersed by a holographic grating to a Reticon linear array silicon detector. To correct for the polarization sensitivity of the instrument, a device is added to measure the degree of polarization in three broadband channels. The instrument field of view (40×320 km) is directed to three cross-track positions as the spacecraft flies in a polar orbit.

The GOME instrument design is tailored for use of the Differential Optical Absorption Spectroscopy (DOAS) algorithm for retrieval of total ozone and other NUV absorbing species. This differs from the SBUV and TOMS

Ultraviolet Sensors, Figure 2 Optics diagram of TOMS instruments. TOMS instruments consist of single Ebert-Fastie polychromators that accept backscattered sunlight from a 3° field of view that is directed in 35 cross-track positions with a scanning mirror. The swath width of 2,700 km provides contiguous global coverage each day with 50 km nadir ground resolution. Total ozone and sulfur dioxide and aerosol index are derived from the radiance at six selected 1 nm wavelength channels between 312.5 and 380 nm on the Nimbus-7 and Meteor-3/TOMS missions. The wavelengths are sampled using a rotating aperture plate that opens the six exit slits sequentially. A depolarizer after the scan mirror avoids polarization sensitivity biases. The Nimbus TOMS used the SBUV diffuser plate for solar calibration, while later instruments used a carousel to rotate three diffuser plates into the field of view using different exposure rates to correct for degradation.

that were designed to use strongly absorbing wavelength bands and radiative transfer tables to retrieve ozone amounts. The DOAS method makes use of spectral band fine structure at weakly absorbed, longer wavelengths and is less dependent on absolute radiance calibrations than is the BUW method. With the continuous spectral coverage of GOME, trace gases including formaldehyde and BrO, in addition to NO_2 which absorbs at violet wavelengths, were measured for the first time (Burrows et al., 1999).

SCIAMACHY

A new Scanning Imaging Absorption Spectrometer for Atmospheric Chartography (SCIAMACHY) research instrument was launched on the European environmental satellite ENVISAT in 2002. SCIAMACHY alternated nadir and limb observations for more information on the profiles of stratospheric constituents using scattered light at the horizon. Nadir spatial resolution was improved over GOME by scanning the FOV across the flight track with a ground resolution of 60×30 km and a swath width of 960 km. An online book, SCIAMACHY: Monitoring the Changing Earth's Atmosphere, is available at: <http://atmos.caf.dlr.de/projects/scops/>

sciamachy_book/sciamachy_book.html. Many of the scientific products are available through <http://www.iup.uni-bremen.de/sciamachy/index.html>.

OMI

The next advancement in UV Earth observations was the Ozone Monitoring Instrument (OMI) built by the Netherlands and Finland for flight on the NASA EOS Aura Platform in 2004 (Levelt et al., 2006). OMI is a complex hyperspectral grating spectrometer (Figure 4) using a thin (1°) along-track but wide (114°) cross-track field of view in a push broom configuration to obtain full contiguous daily global observations at UV (264–380 nm) and visible (349–504 nm) wavelengths (<http://www.knmi.nl/omi/research/instrument/index.php>). A depolarizer avoids radiometric biases due to polarization sensitivity in the spectrometer. A dichroic mirror directs visible and UV wavelengths into separate optical channels for stray light control. The UV light then is divided into short (264–311 nm) and long (307–383 nm) wavelength regions again to minimize stray light at the short, highly absorbed wavelengths used for ozone profile retrievals. The dispersed light is imaged on a frame-transfer back-thinned CCD with cross-track and spectral information

Ultraviolet Sensors, Figure 3 Optics diagram of the GOME instrument. GOME is a double UV/visible spectrometer with continuous spectral coverage from 240 to 790 nm with moderate resolution. The full spectrum is split into four channels by a group of prisms and a beam splitter. Each channel is then dispersed with a grating and detected with a silicon linear array with 1,024 pixels. A portion of the light is sent to a polarization-measuring device (PMD) for correction of the radiance measurements. Radiance data are collected over three large (40×320 km) ground pixels.

as orthogonal components. Thus, as the spacecraft moves along its orbit, the spatial-spectral data are serially read out for telemetry to the ground. An eightfold improvement in ground resolution over TOMS enhances detection of small sources of SO_2 and absorbing aerosols. This instrument returned to the TOMS concept of contiguous daily global coverage but with an eightfold increase in ground resolution (13×24 km at nadir) and with full spectral coverage. The contiguous coverage has resulted in exceptional daily images of NO_2 and SO_2 sources. The availability of optimum wavelengths results in a 20-fold improvement in SO_2 sensitivity over TOMS, allowing monitoring of volcanic degassing, smelter pollution, and pollution from fossil fuel burning.

GOME-2

A second-generation GOME instrument, GOME-2, was launched on the first European polar-orbiting operational meteorological satellite, Metop-A, in 2006 (<http://www.eumetsat.int/Home/Main/Satellites/Metop/index.htm>). This was followed in 2012 with a second GOME-2 instrument on the Metop-B satellite. GOME-2 adds a spatial scanner with ground resolution similar to TOMS. The series of Metop flights will provide a continuation of the long-term record of ozone trends.

The GOME-2 instrument and mission are described in http://www.esa.int/esaLP/SEMTEG23IE_LPmetop_0.html.

OMPS

The first American hyperspectral UV remote ozone sensing instrument, Ozone Mapping and Profiler Suite (OMPS), was launched in 2011 on the Suomi National Polar-orbiting Partnership (NPP) satellite (<http://npp.gsfc.nasa.gov/omps.html>). OMPS consists of a nadir sensor with requirements similar to TOMS and SBUV and a limb imaging spectrometer for ozone profiling with higher vertical resolution than is possible with nadir sounding. The NPP OMPS is the first of a series planned for Joint Polar Satellite System (JPSS) operational missions. OMPS continues ozone trend monitoring that began with the Nimbus-7 SBUV/TOMS mission in 1978.

The OMPS Nadir Sensor (Dittman et al., 2002a) consists of total column and profile ozone spectrometer modules with a common telescope operated in a wide field-of-view (FOV) push broom configuration. A dichroic beam splitter divides the 250–380 nm Earth radiance spectrum near 305 nm into the longer, total ozone and the shorter, ozone profile wavelengths. A blocking filter reduces visible wavelength radiances for stray light control. For total ozone retrievals the 300–380 nm

Ultraviolet Sensors, Figure 4 Optics diagram of the OMI instrument. OMI uses a dichroic mirror to separate the spectrum into visible and UV components. This diagram shows the UV section where NUV and MUV wavelengths are dispersed by a grating after collimation by a silica lens. The dispersed light is focused near a field mirror that splits the spectrum into NUV and MUV components for stray light control. Both UV spectra are imaged on a frame-transfer CCD detector. The instrument field of view is a $114^\circ \times 1^\circ$ fan produced by an entrance telescope. The cross-track information is focused in one CCD dimension, while spectral information is in the other dimension. A depolarizer corrects any polarization sensitivity. The ground resolution is 13×24 km and the swath width produces full contiguous daily global resolution.

Ultraviolet Sensors, Figure 5 Optical configuration of the OMPS Nadir Sensor – a depolarized push broom hyperspectral UV imaging instrument with contiguous global coverage. A total column ozone module uses a single grating spectrometer for the longer, higher radiance total ozone wavelengths (300–380 nm); an ozone profile module uses double gratings for the shorter, low-radiance wavelengths (250–310 nm). Both spectrometers share a push broom telescope with a 110° cross-track field of view for contiguous global total ozone coverage.

backscattered radiance across a 110° FOV is dispersed by a convex grating spectrometer and imaged on a split frame-transfer, cooled CCD. For the 250–310 nm ozone profile wavelengths, the radiance from a 16.7° central part of the FOV is dispersed in a Monk-Gillieson double spectrometer and imaged on a second CCD. Spectral resolution is 1 nm. Solar irradiance is measured with working and reference diffusers for degradation assessment (Figure 5).

The OMPS Limb Imaging Spectrometer (Dittman et al., 2002b; Leitch et al., 2003) measures the radiance

distribution in vertical traces across the Earth's daytime limb to retrieve vertical ozone and aerosol distributions with 3 km vertical resolution. Upper stratospheric ozone distributions to 60 km are derived from 10 selected UV wavelengths; aerosol profiles and lower stratospheric ozone distributions above 8 km are derived from 11 visible and near-infrared wavelengths. A prism spectrometer is fed by 3 telescopes with horizontally displaced views of the limb to estimate horizontal gradients in ozone. Height versus wavelength radiances from three limb scans are simultaneously imaged on a split frame-transfer CCD.

Ultraviolet Sensors, Figure 6 Principal components of the OMPS Limb Imaging Spectrometer. Each of three telescopes utilizes confocal pairs of off-axis parabolas (M1 and M2). Dual entrance apertures (for dynamic range) are followed by a polarization compensator, entrance slits, and aperture stops. The secondary mirrors M2 feed a quartz prism spectrometer. A two-mirror camera focuses the images on a CCD.

The five order-of-magnitude change of radiances across the limb and the spectrum is addressed by careful stray light control, dual aperture stops, and multiple gain ranges. Pixel gain on orbit is monitored using solar-illuminated working and reference diffuser plates (Figure 6).

Far and extreme UV sensors

A long series of experiments have been flown to measure UV airglow and auroral emissions from space. The first FUV image of the Earth was taken from the Moon during the Apollo program (Carruthers and Page, 1972), and Gérard and Barth (1976) measured auroral spectra from OGO-4. Auroral images at H Lyman alpha (121.6 nm) were taken with a modified TV camera on the Japanese EXOS – K satellite and University of Iowa spin scan filter photometers on Dynamics Explorer satellites produced images of the aurora in the 1980s (Frank and Craven, 1988). Several satellite programs followed, including High LATitude (HILAT) and (Polar Beacon experiment and Auroral Research) Polar BEAR, carrying photometers and Ebert-Fastie spectrometers. Most of the geophysical information is in the 100–200 nm FUV spectral region. The NASA POLAR mission (<http://pwg.gsfc.nasa.gov/polar/>), launched in 1996, includes an Ultraviolet Imager to detect auroral emissions in the 130–190 nm region as part of the International Solar Terrestrial Physics Program. The TIMED mission, launched in 2001, includes a Global Ultraviolet Imager (115–180 nm) in a group of instruments to investigate the mesosphere and lower thermosphere (<http://www.timed.jhuapl.edu/WWW/index.php>). The cited web sites are excellent sources of information

on these missions, which are designed to support Space Weather research.

Summary

UV remote sensing instruments are used to measure atmospheric ozone at near and middle UV wavelengths and to measure airglow and auroral emissions at far UV wavelengths. Ozone measurements made from the ground, from balloons and rockets, and from space use the absorption of sunlight in Hartley and Huggins bands of ozone. Total column amounts are measured from the ground using monochromators. The vertical distribution of ozone is measured with interference filter photometers on rockets and balloons. Both total column and vertical ozone distributions are remotely measured from satellites using filter photometers and spectrometers that view the sunlit nadir atmosphere or the limb.

In the USA, the Backscatter Ultraviolet (BUV) instrument was launched on the Nimbus-4 satellite in 1970. SBUV and Total Ozone Mapping Spectrometer (TOMS) instruments flown on Nimbus-7 in 1978 and on later satellites have collected the longest satellite record of ozone changes. Both instruments use Ebert-Fastie monochromators. The BUV and successor, Solar Backscatter Ultraviolet (SBUV), instruments require double monochromators to reject stray light from visible wavelengths that dominate the solar spectrum. These instruments measure the Earth radiance at selected wavelengths and use depolarizers to avoid sensitivity to polarization in Rayleigh-scattered sunlight. They are calibrated by viewing a diffuser plate exposed to extraterrestrial sunlight.

Filter photometers and Ebert-Fastie monochromators are also used at far UV wavelengths to measure spectral line emissions from the thermosphere and ionosphere.

New generations of European ozone monitoring instruments make use of composite optical benches for full spectrum data at UV and visible wavelengths. The first instrument, Global Ozone Monitoring Instrument (GOME), launched on ERS-2 in 1995, uses a pre-disperser prism and gratings to break the spectrum into four bands that individually measure the nadir spectral radiance with linear detector arrays. A successor, the Scanning Imaging Absorption Spectrometer for Atmospheric Chartography (SCIAMACHY), launched on ENVISAT in 2002, adds limb data and better ground resolution. Full daily global coverage, similar to TOMS, was obtained with the Dutch-Finnish Ozone Measuring Instrument (OMI), launched on the EOS Aura satellite in 2004. This instrument avoids a mechanical scanner by using a fan-shaped field of view operated in a push broom fashion. OMI uses a dichroic mirror to separate the spectrum into bands that are then dispersed with gratings for detection with a CCD containing orthogonal spatial and spectral information. European operational ozone monitoring is carried out with a new generation series of GOME instruments, GOME-2, first launched on the Metop-A satellite in 2006, next on the Metop-B satellite in 2012. This instrument adds spatial scanning similar to TOMS. In the USA, operational ozone monitoring is being continued using the Ozone Mapping and Profile Suite (OMPS) series of hyperspectral instruments, initially launched on the Suomi – NPP satellite – in 2011, to be followed by flights on JPSS satellites.

Definition and key parameters

Remote sensing data are used together with demographic parameters to characterize and monitor **urban environments**. For urban remote sensing, key measurements include night-light (NL) from visible-near infrared sensors, multispectral signatures having different spectral mixing (SM) for different land cover categories, and high-resolution radar backscatter (σ_0) obtained from scatterometer data with the Dense Sampling Method (DSM). NL is defined as the light occurred in areas lit by anthropogenic sources at nighttimes. SM is a composition of signatures from multiple channels with different electromagnetic wavelengths corresponding to blue, green, and red in the visible light range and also to parts of the near infrared. DSM σ_0 in an urban area represents the radar cross section from ensembles of targets such as houses, buildings, factories, and other man-made infrastructures on land surface. Associated with σ_0 for each target ensemble, an index of variability (IV) is defined as $(1 + \delta/\sigma_0)$ in decibel, where δ is the standard deviation. Among the critical datasets to describe social and economic patterns are population and road network. The residential population (P_r) is defined as the population counted in each administrative unit. The ambient population (P_a) represents the number of daily averaged people located in each gridded pixel. Road network data are available in many formats from various sources that are routinely updated. These parameters will be further described in detail in the sections below. In this entry, Beijing in China is used to illustrate the general points.

Urban landscape

Remote sensing technology offers some unique images and data of the urban landscape. Much of this entry explains the contributions that remotely sensed data make independent of other data sets. In this section, we also describe the contribution of such data when used in combination with demographic and socioeconomic data. Particularly where the latter types of data are lacking, the combination of data sources may be especially powerful for identifying and monitoring the physical and human urban landscape.

Cities exist largely because people and capital become more productive when they cluster close together. Yet, for urban growth to be beneficial, urban policy making must reconcile three main objectives: economic growth, equity among the population, and environmental sustainability. Additionally, to achieve these objectives, policy makers must facilitate mobility which requires setting aside sufficient land for public and private forms of transport. Maintaining environmental sustainability also requires good institutions and enforcement for making smart land-use decisions that encourage efficient transport and a safe built environment. Moreover, climate change and potential exacerbation of disasters such as flood, drought, and fire extremes are major factors in long-term sustainable urban planning.

Designing the right policy instruments to help make urban growth productive and sustainable requires up-to-date information. However, most cities do not have the capacity to maintain up-to-date land registries and land-use maps at a fine scale. Population and housing censuses provide some information about who lives where and the characteristics of the dwellings and residents, but are typically collected only once per decade. Information on individual parcels of land (e.g., through tax records) is even sparser in most countries. Even where such statistical systems are introduced, they lack a retrospective perspective. Remote sensing data can help fill these data gaps and improve urban management, planning, and monitoring.

Here, Beijing is considered as a case study. This city represents an example of rapid urban growth in an emerging economy. Since the 1980s, China implemented containment strategies to guide urban growth. In the face of double-digit economic growth concentrated in the urban areas in Eastern China, Beijing and other cities have nevertheless struggled to address the needs for economic growth, rapid motorization driven by rapid income growth, huge demand for housing from migrants, and wealth-driven demand for larger floor space. Between 1990 and 2008 its population grew from 10.8 to 17 million on a land area of 16,410 km². Population is coarsely allocated into administrative units (Figure 1), which are arbitrarily defined with boundaries determined by obscure political processes. Further compounding the uncertainty, these are official figures and do not include the “floating” population – migrants who do not hold official, *Hukou*, registration cards (Chengrong et al., 2008; Yeh and Xu, 2009). Because the

Beijing Administrative Units and Urban Allocation

Urban Environments, Beijing Case Study, Figure 1 Beijing administrative unit and urban allocation. NL9495 extent is denoted by the hatched areas. Blue, brown, and green areas indicate the administrative areas for Beijing city proper, city district, and county, respectively. Depending on how one defines the urban contours of Beijing, using administrative data alone produces more than one estimate of population within urban Beijing. The dots in the figure represent settlement points, i.e., aspatial representations of urban areas. The United Nations' World Urbanization Prospects and associated database identifies two settlements (green dots inside red dots at Beijing Shi and Langfang) in the Beijing region. GRUMP identifies 11 settlements (red dots) in the same area. The overlay of the NL9495 extent with administrative and point data help to reveal locations missing possible point representation; those places (purple dots) were identified ex post facto after GRUMP. For many GRUMP settlements, it is possible to generate a series of possible comparative population estimates, as noted in the call out boxes. In GRUMP, NL9495 data give an urban space to the point that the UN identifies as Beijing and further combine space between administrative areas. In Beijing county, the NL data identify urban areas that would otherwise be undefined spatially within the county.

floating population is hard to capture through the official census, it is important to consider alternative means for identifying areas of urban change.

Remote sensing can help generate relevant information for policy analysis and research (Liu et al., 2002; Angel et al., 2007). By coupling population data with remote sensing data, it is possible to gain another view of the urban form. The combination of remote sensing and demographic data is a powerful tool for detecting changes that may occur between censuses. In countries with restrictive data-use policies on finely resolved census-type

data, remote sensing data may also provide a means to fill in where a census cannot; such is the case of Beijing. Uninhibited by administrative or political constraints, remote sensing data provide useful urban information where other data sources are restricted.

Remote sensing approaches

Satellite remote sensors, useful for observations of urban environments, operate at frequencies across the electromagnetic spectrum from visible to microwave.

In particular, this entry presents results derived from Optical Linescan System, Landsat, and QuikSCAT satellite data. These datasets have been successfully applied to urban studies.

Night-light

Global NL data, acquired by the Defense Meteorological Satellite Program (DMSP) Operational Linescan System (OLS), have been used as a proxy indicator of urban areas (Elvidge et al., 1997, 2001, 2004; Sutton et al., 1997, 2001; Owen et al., 1998; Balk et al., 2006). The DMSP-OLS was designed to collect global cloud imagery using a pair of broad spectral bands placed in the visible and thermal. The DMSP satellites are flown in polar orbits and each collects 14 orbits per day. With a 3,000 km swath width, each OLS is capable of collecting a complete set of images of the Earth twice a day. At night, the visible band signal is intensified with a photomultiplier tube (PMT) to enable the detection of moonlit clouds. The boost in gain enables the detection of lights present at the Earth's surface. Most of the lights are from human settlements (cities and towns) and ephemeral fires. Gas flares are also detected and can easily be identified when they are offshore or in isolated areas not impacted by urban lighting.

The National Oceanic and Atmospheric Administration (NOAA) National Geophysical Data Center (NGDC) serves as the long-term archive for DMSP measurements, with data extending from 1992 to the present. The archive is organized as individual orbits which are labeled to indicate the year, month, date, and start time. For this study, individual orbits were processed with automatic algorithms that identify image features (such as lights and clouds) and the quality of the nighttime data. The following criteria were used to identify the best nighttime lights data for compositing:

1. Center half of orbital swath (best geolocation, reduced noise, and sharpest features)
2. No sunlight present
3. No moonlight present
4. No solar glare contamination
5. Cloud free (based on thermal detection of clouds)
6. No contamination from auroral emissions

Nighttime image data from individual orbits that meet the above criteria are added into a global latitude–longitude grid (Plate Carrée projection) having a resolution of 30 arc sec. This grid cell size is approximately a square kilometer at the equator. The average visible band digital number (DN) is calculated by dividing the sum of DN values by the number of valid observations. Lights from fires are removed based on their high DN values and low frequency of occurrence. A background mask covering areas devoid of lights is used to define the background noise level, which defines a locally variable threshold for zeroing the digital values in grid cells that do not contain light detections. By overlaying data from two or more years and applying a contrast stretch, it is possible to see changes in lighting over time.

The 2009 NL result for Beijing is presented in Figure 2. NL measurements are acquired globally over several decades with a series of DMSP-OLS. In this study, intercalibrated stable NL data in version 4 are used. For reference, the NL extent contour derived from 1994 to 1995 NL data (called NL9495 hereafter) is overlaid on the 2009 NL image in Figure 2. Including low NL values to sufficiently capture small populated communities, NL9495 is used as a proxy indicator of urban and suburban extent in the Global Rural Urban Mapping Project database (CIESIN et al., 2004; Balk, 2009). Although NL9495 is known to be more expansive than the true extent of a given urban or suburban area due to the

Urban Environments, Beijing Case Study, Figure 2 Intercalibrated stable NL of Beijing from F16 DMSP-OLS satellite measurements in 2009. The color scale is for NL values from 0 (no light) to 63 (maximum saturated intensity).

blooming effects (Elvidge et al., 2004; Small et al., 2005), it is useful as the first demarcation within which a city is amply enclosed. The Beijing change is evident in that the strong NL has expanded even beyond the NL9495 contour limit, especially in the south and in the east of Beijing. While sprawling settlement in Beijing is obvious, the NL in the Beijing center is saturated and consequently the central change is not observable. This limitation can be addressed by multispectral low-light imaging capability of future advanced satellite sensors (Elvidge et al., 2007).

Spectral mixing

Landsat provides the basis for spectral mapping of urban and suburban environments, which are characterized by diversity. A diversity of land uses results in a diversity of land cover types and thus a diversity of spectral characteristics. Analysis of laboratory and field spectra of building materials and impervious surfaces confirms both unique spectral absorptions associated with specific, generally synthetic, materials (Herold et al., 2004; Small, 2009) and the presence of numerous impervious materials that are spectrally indistinguishable from naturally occurring substrates (Small, 2009). In addition to substrates and impervious surfaces, there is also a fundamental ambiguity in the spectral similarity between indigenous and urban vegetation types.

The spectral nonuniqueness of much urban land cover makes it very difficult to accurately delimit urban areas at pixel scales with broadband sensors. Spectral mixing at subpixel scales further complicates the problem. Spatial analysis of high-resolution (1 m) panchromatic imagery from a diversity of urban areas worldwide indicates that the characteristic scale of most urban land cover is in the range of 10–20 m (Small, 2003, 2009). Consequently, almost all pixels imaged by decameter resolution sensors like Landsat are spectrally mixed pixels. Comparative spectral mixture analysis of Landsat 7 multispectral imagery for 30 cities worldwide indicates that there is no unique spectral signature (or range of signatures) that consistently distinguish urban land cover from a wide variety of nonurban land cover types at pixel scales. However, the spectral heterogeneity of urban land cover can often be used to distinguish it from many nonanthropogenic land cover types that are more spectrally homogeneous at pixel scales.

The accuracy of urban land cover classification depends as much on the surrounding nonurban land cover as it does on the urban area itself. In many temperate and tropical environments, urban areas are surrounded by densely vegetated land cover – either indigenous or agriculture. In these cases the urban land cover can often be distinguished by the comparatively low-vegetation densities as many urban environments are characterized by little or no vegetation (Small, 2005, 2009). In arid and semiarid environments, where undeveloped land covers tend to have a variety of exposed rock and soil substrates similar or identical to local building materials,

this distinction is absent, and it becomes much more difficult to accurately map urban land cover with decameter scale multispectral imagery (Small, 2005).

Despite the pervasive spectral ambiguities, it is often possible to derive bounding estimates of urban extent from multispectral imagery. Because many urban areas are characterized by some consistency in building materials, and the pervasive presence of deep shadow, spectral mixtures of substrate and shadow often distinguish urban environments from vegetated surroundings. Starting with training spectra from unambiguously urban core areas, it is possible to incrementally increase the spectral heterogeneity along a mixing trajectory between shadow and substrate to derive bounding estimates of urban extent. Urban extent can often be bounded by deriving conservative and liberal estimates of urban land cover and comparison to higher resolution imagery. The difference in location and spatial extent of these estimates is generally small compared to the average size (Small et al., 2005). Figure 3 shows an example of such bounding estimates for Beijing and how they compare to night-light intensity in 2008. The utility of bounding maps like this is in their ability to characterize the location, size, and approximate extent of urban land cover relative to surrounding land covers which might be classified with greater accuracy. The limitation is the potential for considerable spectral ambiguity and pixel-scale classification errors of both commission and omission.

Scatterometer

Ku-band backscatter data were obtained globally by the SeaWinds scatterometer on the QuikSCAT (QSCAT) satellite since July 1999 (Jet Propulsion Laboratory, 2006). The scatterometer footprint (two-way, half-power, full beamwidth) has an elongated or “egg” shape of about 25 km in azimuth by 37 km in range. Such coarse footprint renders the standard QSCAT data inapplicable to observations of urban areas that require a much higher resolution.

Earlier approaches to increase resolution involve matrix inversion, which is in essence the traditional deconvolution method (DCM). Álvarez-Pérez et al. (2000) assume azimuthally independent radar echo so that DCM can be used; however, the alignment of buildings and man-made structures in cities results in azimuthally dependent backscatter, which violate the validity condition for DCM. DCM further requires that backscatter of the targeted area remains unchanged during the time period of data acquisition for the resolution enhancement (Early and Long, 2001). This additional requirement further invalidates the DCM whenever backscatter changes (e.g., by snowmelt, precipitation, flood, diurnal effects, temperature change, etc.).

To account for the DCM shortfall, DSM (Nghiem et al., 2009) is developed to derive backscatter at a resolution much higher than the 25 km by 37 km footprint. In DSM, the Rosette Transform is applied to both the mean and the

Urban Environments, Beijing Case Study, Figure 3 Urban–rural land cover gradients in reflected and emitted light. Landsat 5 false-color composite (left) in 2008 shows developed, agricultural, and undeveloped land cover. Homogeneous green areas are agriculture while the dark pink, purple, and gray areas are generally associated with mixtures of SWIR-bright building materials and deep-shadow characteristic of more intensive development. Stable night-light brightness (center) for 2008 ranges from dim-low DN values (purple to cyan) to brighter (green to red) and saturated (white). Unlighted areas (black) are undeveloped. Day-night composites (right) combine Landsat and night-lights to illustrate consistencies in land cover and night-light brightness. Superimposed night-light brightness (red) on upper (green) and lower (blue) bounding estimates of built-up extent shows high-density built environments (white) associated with bright night-lights while agriculture and low-density rural land cover are associated with lower light levels (DN < ~20).

fluctuating part of backscatter data collocated at each location within each 1 km² area. The major advantage is that DSM allows the target to change in azimuth and in time to achieve the high resolution using a composition of data over a long period to minimize speckle in the resultant image (the longer the time period the better). All 10 years of QSCAT data can be used together to obtain DSM σ_0 and IV for decadal observations of urban and suburban environment. Moreover, QSCAT data can be partitioned seasonal, annually, or interannually to monitor urban change at different timescales.

DSM is applied to investigate Beijing urban characteristics in this study. The DSM σ_0 (Figure 4), derived from QSCAT data acquired in 2009, shows the extensive Beijing sprawl especially in the southeast side well beyond the NL9495 limit. Compared to the NL 2009 (Figure 2), DSM σ_0 detects more sprawling in the southeast extending into Daxing Xian and Tongzhou. Both DSM σ_0 and NL agree that there is less expansion in the north and the west of Beijing where complex mountains hinder the urban growth.

There are small isolated areas identifiable by brighter NL compared to the surroundings (e.g., reddish areas in Daxing Xian and Tongzhou outside the NL9495 limit in the NL image in Figure 2); however, such areas are not distinguished in the DSM σ_0 image (Figure 4). This result suggests that buildings, houses, or other man-made infrastructures, which should have high backscatter, are not substantial in those small communities. This is a limitation of the QSCAT DSM data, and future satellite scatterometers should have a smaller footprint or data should be processed into thinner slices for a higher

resolution so that small human settlements can be identified.

More than just the city extent, the DSM σ_0 image in Figure 4 reveals the core of Beijing (orange to red) with a transition (yellow) into the greater Beijing (green). This urban typology is observable by DSM σ_0 because the mean backscatter has a large dynamic range that can account for radar signatures of different urban areas in Beijing without the saturation problem. The Beijing core identified by DSM σ_0 corresponds to the area of high density of roads (Figure 4). Multiple rings of roads in the Beijing road network encircle the city center with the larger rings closer to the outer part of the Beijing core (orange to red area in Figure 4), which characterize the distinct concentric sprawl, a serious violation of the General Plan of Beijing (Shenghe et al., 2002).

Combining remote sensing and demography

Each satellite sensor has certain capabilities and limitations. To achieve an optimal set of information characterizing urban environments, a combination of multisatellite data together with census data is necessary. The integration of remote sensing data from different satellite sensors in a Geographic Information System (GIS) environment represents a well-established approach being widely recognized as powerful and efficient in monitoring and evaluating urban sprawl and urban land use and land cover change over a specific period of time (Mesev, 1997; Wu et al., 2006; Jat et al., 2008; Feng, 2009). Rindfuss et al. (2003), in particular, highlighted the importance of combining remote sensing data with

Urban Environments, Beijing Case Study, Figure 4 DSM σ_0 of Beijing from QSCAT satellite measurements in 2009. The color scale is for backscatter from low value (magenta) to high value (white). Beijing road network (thin gray lines) is overlaid on the DSM map with road data from CloudMade.com at <http://downloads.cloudmade.com> (accessed on July 1, 2010). The road data are updated weekly (<http://www.openstreetmap.org>).

demographic data, primarily from surveys, and identified it as one of the key aspects in urban land use and land cover change studies (also see Liverman et al., 1998).

DSM-processed QSCAT data provide results evenly gridded at 30 arc sec in latitude and in longitude as a rectangular array of points in a Geographic Coordinate System (GCS) – World Geodetic System (WGS) 84 datum. The reference point is at 0° latitude and 0° longitude, and the rectangular array ranges from 0° to $[360-(1/120)]^\circ$ eastward and from 0° to 88° and -88° northward and southward, respectively. With each point storing its own geographic coordinates, each DSM σ_0 and the associated IV value can be referred to the area (approximately a square kilometer at the equator) it represents. Thus, the rectangular array of points can be used to create a raster grid, with a pixel size of 30 arc sec, in which each cell is identified by the values stored in the point located at its southwest corner (Nghiem et al., 2009).

Each QSCAT raster grid from 2000 to 2009 is coregistered (i.e., spatially aligned so that all pixels representing the same area and location in different rasters are exactly coincidental) with the DMSP-OLS NL raster dataset and with two different population raster datasets modeling the global residential (P_r) and ambient (P_a) population distribution, in order to run a pixel-by-pixel analysis in a GIS environment. Both the Global Rural Urban Mapping Project (GRUMP) dataset representing P_r (CIESIN et al., 2004) and the LandScanTM (LandScan

2008TM/UT-Battelle, LLC) dataset representing P_a (Dobson et al., 2000) depict the distribution of human population across the globe at a resolution of 30 arc sec. These datasets result from methods that transform population data from their native irregularly shaped spatial units (vector format), which are usually administrative and of varying shape, size, and resolution, to a regular raster grid of quadrilateral latitude–longitude cells at a fixed resolution (Tobler et al., 1997; Deichmann et al., 2001; Dobson et al., 2003; Balk and Yetman, 2005). In particular, the allocation mechanism for GRUMP P_r explicitly takes into account population and extent of urban areas (see Balk et al., 2006; Balk, 2009, for a detailed description of the methodology), whereas the allocation mechanism for LS P_a is based on likelihood coefficients calculated considering multiple key indicators of population distribution (see Oak Ridge National Laboratory, 2010, for a description of the general methodology).

In this study, GIS technology is used to process and combine different remote sensing products in order to characterize the Beijing environment in the decade of 2000s (2000–2009) and to highlight the relationship between the remote-sensed “urban sprawl indicators” (NL and QSCAT DSM datasets) and the distribution of the population (as represented both in the GRUMP and in the LS datasets) in the Beijing urban and suburban area. We present the linear correlation results, between the two population raster datasets and both DSM and NL values (Table 1), for Beijing urban and suburban area within the

Urban Environments, Beijing Case Study, Table 1 Correlation analysis between population data (GRUMP 2000 and LS 2004–2008) and remote sensing signatures (DSM backscatter and NL brightness)

	<i>n</i> (5 % cases)	GRUMP 2000		LS 2004–2008	
		DSM 00-09	NL 00-09	DSM 00-09	NL 00-09
Urban area					
Beijing	248	−0.046	−0.12	0.724	0.475

common NL9495 extent. Both the DSM and the NL values used in the analysis were averaged between 2000 and 2009 while the GRUMP and the LS datasets depict, respectively, P_r in the 2000 and P_a averaged over 2004, 2006, 2007, and 2008. Due to the large number of raster grid cells, and because a relatively high number of observations would render even very weak relationships as significant, we use a 5 % random sample of those cells to obtain an appropriate representation of the relationships.

Results from the correlation analysis in Table 1 show a very small correlation coefficient between either DSM σ_0 or NL and P_r from GRUMP 2000. Since infrastructures represented by DSM σ_0 and anthropogenic lights represented by NL must be both physically related to human settlements, the weak negative correlation suggests that P_r is not colocated in the dense built-up areas. In contrast, a strong association is found between DSM σ_0 and P_a from LandScan™ (LS) because houses, offices, factories, or other infrastructures are where people are most likely to be located physically at any time. Similarly, there is an association between NL and P_a . The strong σ_0 – P_a relationship supports the use of radar data in demography and other social sciences.

Figure 5 illustrates the composite approach combining both remote sensing and demographic data to observe urban characteristics of Beijing. The DSM σ_0 , averaged over all data collected in 2000–2009, represents the urban extent and typology in the decade of 2000s. In Figure 5, the spatial pattern of DSM time-average backscatter and that of the LS P_a are similar and thus explain the high correlation between the scatterometer remote sensing data and the ambient population census, whereas the residential population P_r , which is partitioned into each administrative unit, has a spatial distribution different from the scatterometer observation. Larger values (green-yellow, top right panel in Figure 5) of the DSM IV indicate that large changes have occurred in the central core and also in the transition areas of Beijing. The NL image, from data averaged over 2000–2009, has less spatial distinction compared to that of the DSM backscatter within the NL9495; however, NL can detect many more small

settlements outside the NL9495 contour. In contrast to both DSM and NL results, Landsat data reveal a much higher resolution containing more spatial details.

Summary

Various remote sensing methods and demographic datasets are used in the Beijing case study to illustrate their capability to observed physical and demographic characteristics of the urban environment. NL data serve well to identify the outer limit of not only large urban areas but also small settlements. For each large urban contour limit from NL, DSM scatterometer data can detect urban extent and typology. Within each urban type classified by DSM data, Landsat spectral signatures can provide high-resolution details of the urban land cover. It is found that DSM σ_0 has the highest correlation with ambient population of Beijing. To monitor urban change, data can be partitioned into different timescales. The combination of multiple remote sensing methods together with demographic measures is necessary to effectively observe urban environments, rather than each dataset standing alone – both by adding shape and contour to urban population estimates as well as to describe patterns of association between population models and those detecting the rapidly changing built environment. Although Beijing may have local characteristics in detail, it shares many issues of a megacity common to other megacities across the world, where methods and results in this Beijing study can be applicable.

While several important remote sensing approaches applicable to global urban observations are presented here, this Beijing case study is by no means exhaustive. Global synthetic aperture radar (SAR) data such as from the Space Shuttle Radar Mission (STRM) has a great potential to obtain a uniform database of global infrastructure representing the state of global urban environments in the specific period of data collection (Nghiem et al., 2001). With the interferometric SAR capability, the recent TanDEM-X Mission (Krieger et al., 2010) and the future DESDynI Mission (National Research Council, 2007) can provide three-dimensional data to measure building height, while a future class of optical sensors such as that proposed for the Nightsat Mission (Elvidge et al., 2007) can significantly improve the urban remote sensing capability. These advances are critical for developing a consistent global urban infrastructure dataset to meet the need of the social and physical scientific communities as well as policy and decision makers.

Definition

Urban heat island (UHI): Urban materials such as asphalt, concrete, and bricks predominate in the urban landscape and are most associated with residential, commercial, and industrial land use types. These materials can increase the temperatures of an urban area in comparison to the surrounding rural land, generating an urban heat island (Oke, 2011). Urban materials contribute heat to their surroundings through the way they store and release heat energy from the sun. This effect is especially noticeable at night when streets and buildings continue to radiate heat, elevating minimum temperatures (Goward, 1981) (Figure 1).

Introduction

The typical city on a summer afternoon has been found to be 2.5 °C hotter than its surroundings (Akbari et al., 1990). Different urban materials grouped together by land use type, such as commercial or residential, create patterns of higher and lower temperatures across a city.

The urban heat island (UHI) effect can cause chronic heat stress on people in the urban environment and can lead to higher morbidity and mortality, particularly among vulnerable populations such as the poor and the elderly (Conti et al., 2005; Harlan et al., 2008). The size of an urban area directly impacts the scale of its UHI effect (Oke, 1973).

Although, heat island temperatures generally peak 3–5 h after sunset, elevated urban temperatures also occur in the daytime (Oke, 1982). The most severe heat islands occur during the summer, in cities with little relief, and where there are generally clear skies with little wind. There is also a positive correlation between city size and

the magnitude of an UHI (Oke, 1973). Overall, urban areas with populations of more than 100,000 can be 8–12 °C warmer than rural areas (Bonan, 2002).

Urban researchers and decision makers can utilize remote sensing technology to determine the impact of current land use on the UHI and use future projections of land use plans to mitigate the UHI effect (Voogt and Oke, 2003).

Thermal inertia and surface temperature

When one thinks of an urban area, one usually pictures tall buildings, streets, highways, living spaces, vegetated yards, and parks laid out in a pattern across the landscape. A city may not seem connected to a natural landscape of rocks and soils but at the molecular level, where thermal properties are defined, there is a strong relationship. Urban materials have similar thermal properties to natural materials and can be studied in the same way through remote sensing.

All materials on the surface of the Earth emit absorbed solar energy, and this emissivity can be recorded by a remote sensor and converted to surface temperature. An urban material's surface temperature is dependent on its physical properties of thermal inertia, albedo (reflectivity), and roughness (Casanova et al., 2007). Urban materials with high emissivities, such as concrete, can absorb high amounts of solar energy. The opposite is true of materials with low emissivities, such as aluminum. Thermal inertia is essentially the ability of a material to conduct and store heat. This means that materials with high thermal inertia such as metal or sand, heat up and cool off quickly, whereas materials with low thermal inertias, such as granite or concrete, heat up slowly and then release their heat slowly, overnight. Roughness, or the three-dimensional structure of an urban area, also plays a role in temperature as tall, densely set buildings create urban canyons that increase the number of surfaces available to absorb heat and block cooling wind currents (Oke, 1987).

Albedo also plays a role in the UHI effect, particularly in relation to the temperature of roofs. Materials with high albedos reflect high levels of solar radiation, while low albedo materials absorb high levels of incoming solar radiation, therefore emitting high amounts of thermal energy. The difference between the surrounding air and low albedo roof coverings can be as high as 50 °C as opposed to 10 °C for high albedo roof coverings (Berdahl and Bretz, 1997). The thermal inertia and albedo of urban materials, in addition to the city structure, work together to generate the UHI effect (Hoyano, 1984; Oke, 1987).

Remote sensing of urban materials

In order to accurately determine emissivity and temperature, a remote sensor must have sufficient spectral resolution in the thermal wavelengths. Instruments such as ASTER, Landsat ETM+, and AVHRR have this capability (Stefanov et al., 2007). ASTER, for example, has five bands in the 8.12–11.65 µm range and can be used to

Urban Heat Island, Figure 1 Temperatures fluctuate over different urban land use types, peaking over the urban core and dipping over water and vegetated areas. This figure shows that while surface temperatures fluctuate widely during the day, they are more constant and match the air temperatures more closely overnight. The urban heat island effect is strongest at night, when minimum nighttime temperatures are elevated compared to those in the surrounding rural area (Voogt, 2000; EPA, 2008).

determine the composition of urban and geologic materials. In addition to emitted energy, reflectance is also necessary to characterize the albedo, vegetation density, and many land cover/land use parameters, such as impervious surfaces.

Choosing the appropriate sensor for a study of urban materials requires an analysis of the spatial, spectral, and temporal resolutions available, as well as cost. For example, airborne instruments often offer very high spatial and spectral resolution (such as the airborne sensor MASTER) but may have low temporal resolution; sometimes only one image is available for a given area. Satellites often have higher temporal resolution (sometimes multiple scenes are available for a single day) and offer global coverage but have lower spatial and spectral resolution than airborne instruments.

Land use and the urban heat Island

Urban areas densely covered by concrete and buildings have higher temperatures than areas with lower building density and abundant vegetation (Hoyano, 1984; Akbari

et al., 1990; Aniello et al., 1995; Voogt, 2000; Dousset and Gourmelon, 2003). Different land use types, such as commercial, residential, or industrial, each contain common urban materials, and these major land use types each have a unique thermal signature (Hoyano, 1984; Voogt, 2000).

Urban materials with high thermal inertias, such as concrete and asphalt, slowly emit heat throughout the night, raising minimum temperatures. For example, in Phoenix, Arizona, USA, summertime lows have increased from 22.7 °C to 26.7 °C over the last 25 years, and overall temperatures are projected to increase by approximately 10° over the next few decades (Balling and Brazel, 1987). This increasing intensity of the UHI can be attributed to population growth and increasing development of land (Cayan and Douglas, 1984; Balling and Brazel, 1986). The downtown and industrial areas of Paris and Los Angeles have seen increased temperatures of greater than 7 °C over the last 10 years. Residential urban areas with high concrete to open land ratios are significantly warmer than areas with less buildings and more vegetation (Hoyano, 1984).

Land use types that have high levels of vegetation, such as parks and open spaces, cool the more densely

developed areas around them through evapotranspiration and can significantly mitigate the UHI effect (Akbari et al., 1990; Dousset and Gourmelon, 2003; Yu and Hien, 2006; Akbari and Shea Rose, 2008; Cao et al., 2010).

Evapotranspiration is a measure of water loss over time from soil and water body evaporation and plant transpiration. Plants and wet soil use a portion of the energy they have absorbed from the sun to convert liquid water into water vapor. This subtracts from the energy that would be radiated from the ground if the ground were bare dirt (Avissar, 1996). The rate of evapotranspiration a plant produces is dependent on how much water the plant requires, the moisture of the soil, and the weather, particularly solar radiation and wind.

Park Cool Island (PCI) effects have been observed to mitigate UHI effects in urban areas. In Sacramento, vegetated parks cooled their surroundings by 5–7 °C through shading and evapotranspiration (Spronken-Smith and Oke, 1998), and parks in Los Angeles and Paris significantly cooled their surroundings (Dousset and Gourmelon, 2003). A study of micro-UHIs in Dallas, Texas, found that areas lacking tree cover were 5–11 °C hotter than those with trees (Aniello et al., 1995).

Heat stress and health

Extreme heat event, exacerbated by the UHI effect, in urban areas has been known to cause chronic heat stress and to affect morbidity and mortality rates (McGeehin and Mirabelli, 2001; Curriero et al., 2002).

Heat stress on a human being can be measured through a human energy budget model which generates a quantitative description of a person's thermal comfort given a certain environment and activity level (Brown and Gillespie, 1995; Heisler and Wang, 2002). People absorb and reflect energy from the sun, just as urban and natural materials do. A person is cooled by sweat evaporated from the skin and wind convection, similar to the evapotranspiration process of a plant.

People of differing socioeconomic groups in urban environments often experience different levels of heat stress due to the different land use and urban materials they are exposed to in their daily lives. Those who are less affluent tend to be exposed to microclimates that have a higher UHI effect (Stefanov et al., 2004; Harlan et al., 2006, 2008). In Phoenix, Arizona, for example, a \$10,000 increase in annual median household income was associated with a 0.28 °C decrease in surface temperature (Jenerette et al., 2007). The elderly are also particularly vulnerable to heat stress exacerbated by the UHI effect. In the summer 2003 heat wave in Italy, for example, there was an increase of 3,134 deaths attributed to heat, 92 % of which were elderly individuals (Conti et al., 2005).

Conclusion

The UHI effect will be a continuing challenge as the world continues to urbanize, cities grow in size and density, and

are increasingly also impacted by global climate change. Satellite remote sensing can play a significant role in monitoring the land use and material properties that contribute to the UHI effect and can provide a common platform to compare UHI effects across cities. Both urban researchers and decision makers currently have access to free and low-cost remote sensing data they can use to quantify the impact of the UHI on their cities, such as Landsat, MODIS, and ASTER. Future global satellite remote sensing instruments higher thermal infrared spectral resolution, with the ability to acquire nighttime data, and finer spatial and temporal resolutions will be needed to further quantify and compare UHI effects globally.

Cities can currently take steps to mitigate their UHI effects through land use planning strategies, such as using high albedo (reflective) roofs and road surfaces, strategically locating parks and shade trees, and using concretes and building materials with lower heat capacities. Cities can now also receive guidance on the public health implications of the UHI effect and produce land use plans that take into account the heat stress on its citizens, particularly vulnerable populations such as the poor and the elderly.

Greenness

Definition

Greenness. The composite optical property of canopy chlorophyll content, leaf area, vegetation cover, and structure.

Soil line. A scatterplot of soil spectra in red and NIR space that forms a zero vegetation baseline from which vegetation can be more accurately measured.

Introduction

Vegetation indices are optical measures of vegetation canopy “greenness” used to quantify vegetation amounts and vigor. A VI measurement combines the chlorophyll-absorbing *red* spectral region (0.6–0.7 μm) with the nonabsorbing, leaf reflectance signal in the *near-infrared* (NIR; 0.7–1.3 μm) to provide a consistent and robust measure of area-averaged canopy photosynthetic capacity. The first vegetation indices were formed by spectral ratioing of the NIR with red band using field radiometers. The greater the amount or vigor of green vegetation present, the larger the contrast between NIR and red reflectances and the higher the resulting NIR/red ratio values, while a reduced spectral contrast would be attributed to lower vegetation amounts, senescing vegetation, or vegetation under stress.

Satellite-based vegetation indices (VIs) were developed in the 1970s for landscape monitoring and have

become indispensable tools in a wide range of applications and decision support systems for scientific and societal purposes. Example applications include natural resource monitoring, agricultural efficiency and famine early warning systems, carbon and water management, biodiversity and invasive species assessments, and environmental health. VIs were operationally implemented with the normalized difference vegetation index (NDVI) global data record computed from the NOAA Advanced Very High Resolution Radiometers (AVHRR) since 1981 (Brown et al., 2006). Many global scientific advancements, related to biogeochemical cycling, net primary production, and vegetation responses to climate variability, can be attributed to the development and consistency of the AVHRR–NDVI time series record (Cracknell, 1997).

Vegetation index equations

There are many ways in which the red, NIR, and other bands may be combined to measure vegetation, and this has resulted in a multitude of VI equations that include band ratios, normalized differences, linear band combinations, and optimized band combinations (Tucker, 1979). The NDVI is a functional variant of the NIR/red band ratio that provides greenness values between -1 and $+1$:

$$\text{NDVI} = (\rho_{\text{N}}/\rho_{\text{R}} - 1)/(\rho_{\text{N}}/\rho_{\text{R}} + 1) = (\rho_{\text{N}} - \rho_{\text{R}})/(\rho_{\text{N}} + \rho_{\text{R}}) \quad (1)$$

where $\rho_{\text{N,R}}$ are reflectances in the NIR and red bands, respectively. An important advantage of the NDVI, as a ratio, is its ability to produce stable values by normalizing many extraneous sources of noise. This was particularly useful in the early AVHRR era, in which data quality problems due to sensor instrument noise, illumination differences, and atmosphere contamination were particularly prevalent.

There are some disadvantages with NDVI in landscape studies, related to the nonlinear behavior of ratios, sensitivity to soil background, and saturation at moderate to high vegetation densities. As a result, optimized variants of the NDVI have been developed that capture essential biophysical phenomena with improved fidelity and with minimal external influences. For example, the soil-adjusted vegetation index (SAVI) was developed to minimize soil influences by incorporating an adjustment parameter (L) in the NDVI equation:

$$\text{SAVI} = (1 + L)(\rho_N - \rho_R) / (L + \rho_N + \rho_R) \quad (2)$$

Other variants of SAVI include the transformed SAVI (TSAVI), the generalized SAVI (GESAVI), and the modified SAVI (MSAVI) and are reviewed in Jiang et al. (2007).

VIs have also been optimized for resistance to atmosphere influences, as in the atmospherically resistant vegetation index (ARVI) and the enhanced vegetation index (EVI), which utilize a blue band to correct for aerosol effects in the red band (Huete et al., 2002). The global environment monitoring index (GEMI) was designed to be resistant to atmosphere effects in AVHRR–NDVI data sets (Pinty and Verstraete, 1992). The EVI minimizes soil background influences and reduces VI signal saturation problems encountered over densely vegetated forests and croplands. The wide dynamic range vegetation index (WDRVI) also enhances sensitivity over highly vegetated conditions (Gitelson, 2004). Increased sensitivity is achieved through optimized use of the NIR band, which exhibits greater optical penetration in high-biomass areas.

Quantitative measures of greenness may also be formulated through linear combinations of the red and NIR bands, as in the perpendicular vegetation index (PVI) (Richardson and Wiegand, 1977) that measures greenness as the orthogonal distance of a pixel to a “soil line” in red–NIR space. This concept is readily extended to multiple-band space whereby the spectral structure of vegetated pixels resembles a three-dimensional “tasseled cap” shape defined by a soil plane, a greenness axis, and either a yellowness axis (plant senescence) or a *wetness* axis, depending on the bands utilized (Crist and Kauth, 1986).

Biophysical properties and processes

VIs are not *intrinsic* physical quantities themselves, but are widely used as proxies in estimating canopy state variables, including leaf area index (LAI), fraction of absorbed photosynthetically active radiation (f_{APAR}), chlorophyll content, and vegetation fraction (F_v). VI relationships with these biophysical quantities have been extensively studied through field measurements and with canopy radiative transfer models (Huemmrich, 2001) and found to vary greatly over the variable structural assemblages of foliage cover, leaf area, and chlorophyll typically found across different land cover types and phenology stages. As a consequence, satellite studies

show VIs are often only moderately correlated with specific canopy variables, are land cover dependent, and not easily extended to regional and global scales that involve multiple vegetation types and canopy structures. The numerous applications of satellite VIs in ecological studies are extensively reviewed in Glenn et al. (2008), Kerr and Ostrovsky (2003), and Pettorelli et al. (2005).

VIs are found to be strongly related to green vegetation fraction (F_v), although both linear and nonlinear relationships are reported (Carlson and Ripley, 1997). Green vegetation fraction can also be derived through simple linear combinations of high (vegetation) and low (soil) VI values within a scene or biome type. In the case of LAI, there is a general positive association with VIs at low LAI values between 0 and 2 and increasingly weak sensitivity at LAI beyond 2 or 3 (Baret and Guyot, 1991), although increased sensitivity in higher LAI canopies has been reported with the EVI in dense (LAI > 5) Amazon forests (Huete et al., 2006). Canopy chlorophyll content is an important plant community property in studies of ecosystem productivity, CO_2 fluxes, and vegetation stress. VI relationships with total canopy chlorophyll content tend to be curvilinear related because surface leaves intercept more light than leaves deeper in the canopy. However, the direct retrieval of chlorophyll content from satellites is confounded by other factors, such as canopy architecture, chlorophyll distribution within the canopy, LAI, and soil background. Vegetation canopy f_{APAR} measurements are widely used in radiation dynamics and light-use efficiency studies to relate satellite VIs with primary productivity and biomass accumulation. The NDVI has been shown to be linearly correlated with f_{APAR} in field and modeling studies, and its integral over the growing season has been correlated with ecosystem net primary production (Baret and Guyot, 1991). In a multi-biome study across North America, Sims et al. (2006) empirically derived a linear f_{APAR} –NDVI relationship across 16 different species as $f_{\text{APAR}} = 1.24 * \text{NDVI} - 0.168$.

Ecosystem processes

Recent applications of VIs have demonstrated their utility in studies of ecosystem functioning and in deriving estimates of the rates of ecosystem processes, such as photosynthesis and transpiration that depend on PAR light absorbed by leaves (Glenn et al., 2008). Vegetation gross primary productivity (GPP) is related to the amount of canopy absorbed PAR, or APAR, through a light-use efficiency (LUE) term, specific to vegetation type, with which the absorbed light is used in carbon fixation, or photosynthesis. This is depicted as $\text{LUE} = \text{GPP}/\text{APAR}$ (Monteith and Unsworth, 1990).

Satellite VI data have been shown useful in providing repetitive observations of seasonal and interannual variations in vegetation activity in response to climate and land use forcings. VIs are widely used in characterizing various vegetation phenophases, such as the onset of greening,

leaf development, length of the growing season, and subsequent browning and dormancy, which are critical to understanding ecosystem functioning and associated seasonal patterns of carbon, water, and energy fluxes (Zhang et al., 2003).

Moderate and coarse resolution vegetation index products

There now exist multiple satellite VI products, generated from the AVHRR instruments and from newer sensor systems, including the Moderate Resolution Imaging Spectroradiometer (MODIS) sensors onboard the Terra and Aqua Earth Observing System platforms, the Sea-viewing Wide Field-of-view Sensor (SeaWiFS), and SPOT-VEGETATION instruments. Vegetation indices are seamless data products that are computed the same across all pixels in time and space, without prior assumptions of biome type, land cover condition, or soil type, and thus represent actual, long-term measurements of the land surface. They are readily fused and intercalibrated across multiple sensor systems to maintain critical long-term time series data needed for climate-related process studies. Satellite VI products work optimally with cloud filtering, radiometric calibration, precise geolocation, and a snow mask. In addition, the VI product performs best using atmosphere-corrected surface reflectance inputs that are further *composited* over set time intervals for removal of cloud and cloud shadow contamination and to constrain sensor view angles and minimize the presence of bad quality pixels (Figure 1). VI data sets are available at varying spatial (250 m to 8 km) and temporal (daily to monthly) resolutions to capture essential vegetation biophysical dynamics and to meet the needs of the user community.

The accuracy of these VI products will vary in space and time as a result of spatial and seasonal variations in cloud persistence, unresolved clouds, and quality of upstream surface reflectance retrievals. Validation and accuracy assessments of satellite VI products are quite challenging and require periodic samplings of vegetation states at scales on the order of a kilometer. Large-scale field campaigns, such as HAPEX, BOREAS, and LBA, provide valuable ground validation data over specific biome types and climates. Regional and global tower networks equipped with NDVI-like hemispherical sensors and eddy covariance flux measures of CO₂ and H₂O offer more validation opportunities over a more complete sampling of land cover types. Phenology networks also provide budbreak, greening, and browning information that will improve performance assessments of VI satellite products.

Direct broadcast and readout technologies also provide near real-time access to satellite imagery and VI products for a variety of rapid response applications, including fire detection and disaster mitigation (<http://directreadout.sci.gsfc.nasa.gov/>). A quick turnaround time between data acquisition and VI product delivery greatly enhances the

Vegetation Indices, Figure 1 Example of the enhanced vegetation index (EVI) computed from 16 day composited (April 7–22, 2003) Terra-MODIS reflectances in bands 1 (red), 2 (NIR), and 3 (blue) for a portion of North America (the darker green colors indicate highest vegetation densities).

benefit for many user groups that need to respond quickly to observed changes in vegetation activity due to drought, fire, and extreme weather events.

Conclusion

As a result of their simplicity, vegetation indices are among the most robust techniques in remote sensing, yielding consistent spatial and seasonal to long-term comparisons of green vegetation at local to global scales. VIs are invaluable tools in monitoring vegetation biophysical conditions related to green foliage density and ecosystem processes related to light absorbed by green vegetation, specifically canopy photosynthesis and plant transpiration. There exist many VIs and all have been related to some extent with various biophysical quantities; however, there remain significant differences in how they depict “greenness,” rendering multiple VIs potentially useful and complementary.

VEGETATION PHENOLOGY

John Kimball

Flathead Lake Biological Station, University of Montana,
 Polson, MT, USA

Definition

Vegetation phenology is the timing of seasonal developmental stages in plant life cycles including bud burst, canopy growth, flowering, and senescence, which are closely coupled to seasonally varying weather patterns. Land surface phenology (LSP) is a related term describing vegetation changes observed from satellite remote sensing, recognizing that satellite observations constitute an aggregate signal from heterogeneous surface conditions that may not be representative of any single plant species response. Thus, the satellite LSP measurement is an appropriate indicator of broadscale vegetation-climate interactions and associated landscape changes in ecosystem condition.

Introduction

Vegetation phenology strongly influences land-atmosphere energy, water, and trace gas exchanges. Canopy growth and senescence affect surface albedo and sensible and latent energy partitioning, with direct impacts to weather and climate. Vegetation phenology both influences and is responsive to environmental conditions including temperature, moisture supply, humidity, and photoperiod. Phenology events are spatially complex and temporally dynamic, influenced by vegetation morphology, species, and microclimate variability. Plant phenology in temperate and extratropical latitudes coincides with seasonal changes in day length and temperature, whereas tropical forest, savanna, and grassland phenology varies with seasonal wet/dry events and can display multiple periods of growth and senescence during a single annual cycle.

Satellite remote sensing provides for systematic, repeat global observations that are sensitive to vegetation conditions. Potential uses of land surface phenology (LSP) information include defining vegetation canopy status in large-scale climate and biogeochemical models, and analyses of climate-biosphere interactions. Numerous phenology measures have been derived from satellite remote sensing time series (e.g., Reed et al., 2003), including the following: time of growing season onset (initiation of sustained photosynthesis), offset (canopy senescence, leaf drop, and dormancy), and duration; date of maximum greenness or canopy development; seasonal amplitude of vegetation greenness (magnitude of vegetation canopy growth); and rates of greenup (photosynthetic increase) and senescence (photosynthetic decrease). The most appropriate satellite measurements for global LSP monitoring provide nearly complete coverage of the terrestrial biosphere and frequent (~weekly) sampling to resolve rapid changes in vegetation life cycles. Appropriate spatial

Vegetation Phenology, Figure 1 Mean annual maximum vegetation greenness onset from the MODIS (MOD12Q2) phenology product. *Gray* areas represent frequent cloud cover, open water, ice, and other nonvegetated land masked from further processing; *dark blue* areas represent vegetation with low seasonal EVI range.

scales for LSP assessment approach 30 m resolution for characterizing individual vegetation patches, while coarser scale (>1 km resolution) observations are sufficient to characterize climate-biosphere interactions. Finer scale mapping is constrained by the need for high temporal fidelity and global coverage. Most satellite remote sensing studies utilize optical or microwave regions of the electromagnetic spectrum for LSP assessment, each with associated trade-offs in resolution and sensitivity to vegetation and atmospheric parameters.

Optical remote sensing

Most optical remote sensing LSP studies exploit the sensitivity of red and near-infrared wavelengths to photosynthetic biomass, including presence, abundance, and distribution of green leaves. The potential for LSP monitoring from space was recognized with the initiation of Landsat in the 1970s, though the 16–18 day repeat cycle of these measurements was generally too coarse to resolve rapid vegetation changes. Initiation of the NOAA Advanced Very High Resolution Radiometer (AVHRR) series in the early 1980s made LSP monitoring practical on a global basis. Many subsequent satellite studies of global vegetation dynamics have used the AVHRR record. However, the NASA Moderate Resolution Imaging Spectroradiometer (MODIS) record has rapidly become a sensor of choice for vegetation studies due to improved calibration, advanced cloud detection and aerosol screening capabilities, and heightened spectral sensitivity to photosynthetic biomass. The MODIS record includes an operational (MOD12Q2) LSP product (https://lpdaac.usgs.gov/products/modis_products_table) derived using enhanced vegetation index (EVI) time series from the

EOS Terra satellite; the MOD12Q2 product is produced twice annually at 1 km resolution and includes multiple variables for each grid cell, including timing of maximum vegetation greenness onset (Figure 1). A closely related MYD12Q2 LSP product is derived using MODIS EVI data from both Terra and Aqua satellites and is produced annually at finer (500 m) resolution. These data provide a continuous (from 2000) global record of seasonal to decadal variability in vegetation greenness and associated LSP dynamics suitable for climate change studies.

Green vegetation shows preferential absorption and reflection in respective red and near-infrared portions of the visible spectrum, which forms the basis of the LSP measurement from optical remote sensing. A common vegetation index (VI) for phenology studies is the Normalized Difference Vegetation Index (NDVI), which is the ratio of the difference between red and near-infrared bands over their sum. The NDVI is sensitive to changes in vegetation greenness, while minimizing variable atmosphere, illumination, and soil background effects. Other VIs include the EVI which provides improved vegetation discrimination and reduced signal saturation over dense vegetation; a VI derivative is the Leaf Area Index (LAI) which provides a measure of photosynthetic leaf area that accounts for variable canopy structure.

Optical remote sensing of vegetation has several limitations including atmosphere cloud/aerosol contamination, varying soil/surface background reflectivity, and seasonal reductions in solar illumination at higher latitudes. Efforts to mitigate atmospheric effects include spatial/temporal maximum value compositing (MVC) of the VI time series; commonly used satellite data records employing the MVC approach include AVHRR NDVI Global Inventory Modeling and Mapping Studies (GIMMS) 15 day (<http://glcf>.

umiacs.umd.edu/data/gimms/) composites. The lack of precise calibration and cloud screening promote higher noise levels in the AVHRR record, though the GIMMS NDVI product is derived using extensive post processing of the data to mitigate sensor calibration, view geometry, volcanic aerosols, and other known effects not related to vegetation. The MODIS VI and LAI 8- and 16 day global products are derived using higher-quality daily retrievals and variable (including MVC) compositing techniques depending on the number and quality of observations. MODIS incorporates advanced cloud screening and atmospheric aerosol corrections and provides an improved basis for LSP monitoring. However, the resulting VI time series can be too infrequent to resolve temporally dynamic phenology events. Other limitations include signal degradation from reduced solar illumination and shadowing at high latitudes. The presence of snow can decrease the VI independent of changes in photosynthetic biomass. Missing or degraded satellite observations during critical vegetation phases also reduce LSP accuracy.

Microwave remote sensing

Satellite active (radar) and passive microwave sensors can detect LSP-related changes in vegetation canopy structure and biomass, independent of many environmental constraints on optical remote sensing. Satellite microwave sensors used for LSP studies include the NASA SeaWinds scatterometer and Advanced Microwave Scanning Radiometer for EOS (AMSR-E), which are capable of near daily global monitoring and have relatively long data records. Satellite observations at lower ($\sim \leq 37$ GHz) microwave frequencies are insensitive to solar illumination, clouds, and other atmosphere effects; these attributes enable potential global monitoring day or night and under virtually all weather conditions, dependent upon on sensor design and orbital geometry.

Satellite microwave LSP assessments include temporal change classifications of radar backscatter or brightness temperature (T_b) series to determine landscape freeze/thaw status and associated frozen temperature constraints to canopy gas exchange and vegetation growing seasons (Kimball et al., 2004). SeaWinds Ku-band radar backscatter data was used to estimate canopy LAI and associated LSP changes over a range of global vegetation types (Frolking et al., 2006), while a daily emissivity difference index of 19 and 37 GHz channels from the Special Sensor Microwave/Imager (SSM/I) was used to detect spring onset and canopy development over broadleaf deciduous forest (Min and Lin, 2006). The vegetation optical depth (VOD) retrieval from passive microwave remote sensing is a frequency-dependent measure of canopy extinction of land surface microwave emissions; AMSR-E 10.7 GHz frequency VOD retrievals were used to map the LSP start of season over North America and document relations between MODIS VI greenup and VOD-derived canopy biomass changes for different ecoregions (Jones et al., 2012).

Vegetation absorbs, scatters, and emits microwave energy; the resulting LSP signal is strongly dependent on sensing frequency and polarization, and vegetation canopy structure and biomass (Ulaby et al., 1986). The vegetation canopy signal is significant at Ku-, X-, and C-band frequencies (4–18 GHz) with wavelengths similar to the characteristic (1.7–7.5 cm) size of individual leaves. The signal contribution from deeper canopy layers, including photosynthetic and non-photosynthetic components, is larger at lower microwave frequencies, while sensitivity to land surface conditions is inversely proportional to overlying vegetation biomass density.

A limitation of passive microwave remote sensing for LSP monitoring is a relatively coarse sensor footprint compared to radar and optical sensors. Spatial resolution of microwave radiometers is frequency dependent and varies from approximately 30 km (37 GHz) to 60 km (19 GHz) for the SSM/I (Special Sensor Microwave/Imager). Terrestrial emissions of microwave energy are naturally low and require coarser resolution observations to enhance sensor signal to noise. Alternatively, radars illuminate the land surface directly and spatial resolution is driven by a desire to resolve individual landscape elements while maintaining frequent sampling and global coverage. Synthetic aperture radars (SARs) provide relatively fine-scale mapping of vegetation properties, though few provide both global coverage and frequent (<weekly) temporal sampling. Global data archives from other radars including SeaWinds and ASCAT (Advanced SCATterometer) meet these criteria but have relatively coarse (~ 25 –50 km) footprints. Post processing of overlapping image swaths from multiple satellite observations has produced enhanced resolution products at pixel scales from 4.5 km (SeaWinds) to 12.5 km (AMSR-E, SSM/I) (Early and Long, 2001). While resolution enhancement sacrifices some temporal fidelity, effective global coverage and temporal repeat of observations are generally sufficient for LSP monitoring.

Methods for LSP assessment

Methods for LSP assessment generally involve analyzing the shape of the VI seasonal curve to classify the timing of key thresholds or inflection points associated with vegetation life cycle events. Similar shape analysis or change detection methods are applicable to land parameter retrievals from both optical (VI, LAI) and microwave (e.g., VOD) remote sensing, while the majority of previous LSP studies and the following discussion focus on VI time series analysis. Analytical change detection approaches are susceptible to noise and associated high-frequency variability present in nearly all VI series. Methods for noise reduction include VI spatial compositing and temporal smoothing to reduce atmosphere cloud/aerosol contamination or other effects. Relatively simple classification approaches apply smoothed VI series with prescribed thresholds and backward-looking, moving window averages to distinguish LSP

events. An advantage of these methods is their relative simplicity. These methods work well for local scales and specific vegetation types but are difficult to implement globally because they do not account for heterogeneous surface or vegetation conditions, including multiple growth cycles. Efforts to circumvent these limitations include the use of globally variable, phenoregion-specific VI thresholds for assessing major LSP events and classifying phenotypic populations to reduce sensitivity to noise in individual pixels (White and Nemani, 2006).

Other classification techniques analyze VI series using mathematical models to identify life cycle thresholds. The MOD12Q2 algorithm analyzes smoothed EVI series using piecewise logistic functions to identify major LSP events coinciding with local extremes in temporal change rates of the VI seasonal cycle (Zhang et al., 2003). This methodology treats each pixel individually without the use of thresholds or empirical constants and is globally applicable. It is also capable of identifying multiple vegetation growth and senescence periods within a given year. A major assumption of these methods is that phenology can be characterized by a set of mathematical functions, which may not hold for areas that do not exhibit large seasonal changes in canopy biomass (e.g., evergreen forests) or where drought or defoliation events result in multiple VI curves with sharp peaks or broad plateaus. Also, the resulting LSP metrics can vary strongly depending on the particular data processing and classification methods used, even when based on the same satellite inputs (White et al., 2009).

Validation

LSP validation has involved comparisons against finer scale field measurements from native and cultivated indicator plants. These data predominantly represent species-specific events including timing of bud burst, flowering, and leaf drop from sparse in situ observation networks. Global phenology observations are expanding to include coordinated regional programs such as the USA National Phenology network (<http://www.usanpn.org/>). Direct comparisons between these data and LSP metrics are challenging because most field-based phenology observations involve individual species or local observations that may not be representative of landscape conditions within the surrounding satellite footprint.

Finer resolution satellite measurements from Landsat have been fit to sigmoid logistic growth models for spatial extrapolation of phenology observations to regional scales commensurate with global satellite remote sensing (Fisher et al., 2006). Tower eddy covariance measurements of land-atmosphere CO₂ exchange are more consistent with the scale of satellite remote sensing, facilitating more direct comparisons of field and satellite-based phenology metrics (Jones et al., 2012). Other approaches include the development of climate data-driven phenology models that incorporate information on individual plant species but provide a means for spatial extrapolation of sparse

field observations to the scale of satellite observations. An extension of this approach involves the integrated use of satellite observations, field measurements, and indicator clone models (Kathuroju et al., 2007). These methods provide the means for spatial scaling, prognostic modeling of future phenology events, and attribution of underlying processes influencing LSP patterns (White and Nemani, 2006).

Conclusion

Global operational LSP records have been generated from MODIS since 2000, with planned data continuity under the Visible Infrared Imaging Radiometer Suite (VIIRS) program. The AVHRR record continues to grow, enabling multi-decadal LSP studies that can distinguish impacts from weather variability, periodic climate oscillations (e.g., ENSO), and longer-term climate trends. Alternative global satellite data from ASCAT, AMSR-E, and other microwave sensors offer synergistic information on vegetation freeze/thaw status and canopy biomass structure that are insensitive to many of the environmental constraints on optical remote sensing. A wide array of algorithms exists for processing these data into LSP information (e.g., Zhang et al., 2003; Jönsson and Eklundh, 2004; White and Nemani, 2006). These various sensors and algorithms provide different perspectives, resolutions, and accuracies across the globe. Optical remote sensing delivers greater LSP precision where microwave data are too coarse to resolve subgrid-scale land cover dynamics. Alternatively, microwave remote sensing may deliver greater LSP accuracy where persistent clouds or reduced solar illumination limit optical retrievals. Together these data provide complimentary LSP information on vegetation greenness and biomass structure and insight regarding underlying environmental processes (Jones et al., 2012).

Future advancement of remote sensing science for LSP will likely incorporate data reduction and optimization techniques including empirical clustering and data assimilation for merging complimentary information from multiple sensors, land models, and observation networks to maximize LSP accuracy and understanding (e.g., Stöckli et al., 2011). These methods may vary for different applications, as agriculture may have different resolution and accuracy requirements than biosphere-climate monitoring. The development and extension of long-term global LSP datasets from reprocessing and reanalysis of long-lived sensor records will also allow more precise detection, analysis, and prediction of climate and land cover change effects. Improved capabilities for near-term phenology forecasting will involve the integration of satellite data with surface observations, weather prediction, and ecological models (White and Nemani, 2006) and benefit diverse applications including fire risk (Roads et al., 2005), human health (Lash et al., 2008), and crop yield predictions (Mkhabela et al., 2005).

Volcanic eruptions

Definition

Volcanism: the set of geologic processes that result in the expulsion of lava, pyroclastics, and gases at the Earth's surface. The process by which magma and gases are transferred from Earth's interior to the surface.

Introduction

It is estimated that more than 500 million people live on or near active volcanoes around the world. The very eruptive products that present clear and frequent danger to the inhabitants are the primary reason for their presence: fertile volcanic soils. Currently, there are of the order of 1,000 volcanoes worldwide that are considered active, having erupted in the last 10,000 years (Simkin and Siebert, 1994). That is more than the number of active volcanologists, suggesting that remote sensing technology can substitute for human observers or ground-based instruments to keep an eye on active volcanoes over time. There are several volcanic phenomena that lend themselves to remote detection and monitoring: eruption plumes, laden with ash, SO₂, and water; low-temperature anomalies such as crater lakes and fumaroles; high-temperature anomalies, such as lava flows, pyroclastic flows, and lava domes; and deformation of the volcanic edifice.

Eruption cloud detection

The earliest reports of successful observations of volcanic eruptions showed eruption plumes captured by weather satellites, such as GOES (Geostationary Operational Environmental Satellite), GMS (Geostationary Meteorological Satellite), or AVHRR (Advanced Very High Resolution Radiometer). These instruments typically have spatial resolution of 1–15 km and repeat observation periods as short as 15 min. These satellites are currently used routinely by the Alaska Volcano Observatory (AVO) and the National Weather Service to detect and monitor elevated ground temperatures and eruption clouds at volcanoes in the North Pacific Region (Dean et al., 2002). Volcanoes in this region include those in Alaska, Kamchatka Peninsula, and the northern Kuril Islands. These data provide observations multiple times per day of over 100 active volcanoes in this region. Visible and infrared band data are automatically processed to generate images that optimize the detection of eruptions, including geometric and radiometric correction, and subsectioning to nine preassigned sectors. Each sector includes multiple

Volcanism, Figure 1 MODIS visible image of Chaiten volcano, Chile, captured May 31, 2008. The small red square is a thermal anomaly at the volcano's summit. The image covers about 500 km east–west.

volcanoes. Data are then processed to optimize detection of eruptions including single-band contrast, multiple-band combinations, and coastline overlays. JPEG and GIF images are generated for access from remote computers via the World Wide Web. The data are also automatically scanned to generate time-temperature graphs at specific volcanoes to detect thermal changes. Analysts routinely review the data and submit observation reports twice daily. During heightened alerts, the data are analyzed and observation reports are submitted at least four times per day. AVO reports eruptions through its communication network to government officials and the general public via voice, fax, and e-mail. All volcano-related observations are entered into a Web-accessible database.

Another satellite instrument that is used operationally to detect and monitor eruptions is MODIS (Moderate Resolution Imaging Spectroradiometer) on NASA's Terra and Aqua platforms. The MODIS Thermal Alert Web site was created as a real-time tool to monitor volcanic eruptions (Flynn et al., 2002). A review of some of the thermal anomalies associated with volcanic activity that have been discovered includes large-scale effusive eruptions like those at Nyamuragira, Africa and Kilauea, Hawaii, providing examples of the utility of monitoring hazards on a daily basis. Additional activity detected at Howard Island and Erta 'Ale may have otherwise gone unreported because of their inaccessibility. During a recent series of eruptions of Chaiten in Chile, MODIS captured many images, including one on May 31, 2008, shown in Figure 1. Monthly MODIS alert composites are used to summarize global volcanic activity. Currently, the MODIS Thermal Alert covers the globe four times per day from two satellites, each with a MODIS instrument.

Thermal phenomena

Detecting and monitoring thermal phenomena associated with volcanoes, from space, requires sufficient spatial resolution to resolve the features, adequate wavelength regions to detect the thermal energy, and temporal coverage to be at "the right place at the right time." Volcanoes display precursory phenomena, as well as thermal features associated with eruptions. Included in the former are changes in temperature of lava lakes, growth of lava domes, and development or changes of temperature of fumaroles. Included in the latter are high-temperature or cooling lava flows, pyroclastic flows, debris flows, and dome growth.

Early work by Francis and Rothery (1987), Rothery et al. (1988), and Glaze et al. (1989) showed the potential use of Landsat Thematic Mapper data to estimate the temperature of volcanic phenomena, based on the presence of spectral bands in the visible, shortwave infrared, and thermal infrared wavelength regions, and spatial resolution of 30–120 m. A nice example of assembling a time history of thermal behavior as detected and measured by remote sensing, compared to eruptive history, was described by Oppenheimer et al. (1993). They assembled 15 Landsat images for 9 years from Lascar volcano, Chile, and documented the evolution of a lava dome within the summit crater. The thermal data indicated that Lascar experienced two cycles of lava dome activity. The first one culminated in an explosive eruption in 1986 that completely destroyed the dome.

Moderate resolution (<100 m) thermal infrared data are continuing to be used for monitoring volcanoes. A large experiment is ongoing over the North Pacific using low-resolution satellite data (MODIS, AVHRR) as triggers to schedule acquisitions of ASTER thermal data (90 m resolution) over erupting volcanoes (Ramsey and Dehn, 2005). A long time sequence has been acquired for Kliuchevskoi volcano in Kamchatka. Because of its location at high latitudes, polar-orbiting satellites have almost daily opportunities to obtain data there. From January 2005 to May 2005, 15 cloud-free images were acquired and are shown in Figure 2. The bright areas are hottest. Clearly evident is the early development of a summit crater thermal anomaly, either a lava dome or lava lake. In early February, the first of several pyroclastic flows were emplaced. Also quite evident are "cold" plumes coming out of the summit. They are colder than the ground because they have risen from the vent and cooled as they rose.

Wilson et al. (2007) reported on using satellite data to measure lava effusion rates. Kliuchevskoi volcano is the largest and one of the most active volcanoes on the Kamchatka Peninsula. The most recent eruption from January to August 2007 produced several strombolian eruptions, lava flows, mudflows, and ash plumes. To monitor the progress of the eruption, effusion rates were calculated from thermal infrared imagery. A volume of lava at a given temperature emits a fixed amount of thermal

Volcanism, Figure 2 ASTER thermal infrared images over Klyuchevskoi volcano, Kamchatka, Russia. Hot areas (lave dome, lava lake, and recently emplaced flows) are bright (hot). The eruption plumes are dark and cold. The time series was acquired from January to May 2005.

radiation measured at the satellite. By constraining temperature, volume with time (effusion rate) can be calculated. Effusion rates can give an indication of changes during an eruption, rather than after the activity has decreased or ceased. Effusion rates were consistently greater than $3.0 \text{ m}^3/\text{s}$ and reaching to $15.1 \text{ m}^3/\text{s}$. Calculations of effusion rates of Klyuchevskoi were conducted using a two-component analysis from the Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) and compared to those made with coarser spatial resolution sensors: Advanced Very High Resolution Radiometer (AVHRR) and Moderate Resolution Imaging Spectroradiometer (MODIS). By constraining effusion rates in near real time, the potential hazards from the volcano can be effectively mitigated.

Deformation detection

Interferometric synthetic aperture radar, also abbreviated InSAR, is a radar technique that uses two or more SAR

images to generate maps of surface deformation, using differences in the phase of waves returning to the satellite. The technique can potentially measure centimeter-scale changes in deformation over time spans of days to years. InSAR can be used in a variety of volcanic settings, including deformation associated with eruptions, inter-eruption strain caused by changes in magma distribution at depth, gravitational spreading of volcanic edifices, and volcano-tectonic deformation signals. Early work on volcanic InSAR included studies on Mount Etna (Lundgren and Rosen, 2003) and Kilauea, with many more volcanoes being studied as the field developed (Amelung and Day, 2002; Pritchard and Simons, 2004). The technique is now widely used for academic research into volcanic deformation (Yun et al., 2007), although its use as an operational monitoring technique for volcano observatories has been limited by issues such as orbital repeat times, lack of archived data, coherence, and atmospheric errors.

Conclusion

The goal of remote sensing science is to contribute to predicting volcanic eruptions. As such, remote sensing provides several unique tools to the geophysicist's arsenal of observational capabilities. Presently, only very short-term predictions can be made, mainly based on in situ seismic data. But by increasing the number of volcanoes observed, building up time histories of thermal changes, and relating those to eruption behavior, it is hoped that one day potential eruptions can be successfully predicted, and damage to people and property mitigated.

Definition

The global hydrological cycle can be described by the following physical processes which form a continuum of water movement. Complex pathways include the passage of water from the gaseous envelope around the planet called the atmosphere through the bodies of water on the surface of Earth such as the oceans, glaciers, and lakes and at the same time (or more slowly) passing through the soil and rock layers underground. Later, the water is returned to the atmosphere. A fundamental characteristic of the hydrological cycle is that it has no beginning and it has no end.

Introduction

The role of hydrological cycles in the Earth system, the amount of water on the Earth's surface, and its distribution in various reserves are first introduced together with the water cycles on the Earth. The concept of mean residence time, water stored in various parts over the Earth's surface as various phases, such as glacier, soil moisture, water vapor, and water flux among these reserves, such as precipitation, evaporation, transpiration, and runoff, is briefly explained with their roles in global climate system, and their quantitative estimates are presented. The zonally

averaged net transport of freshwater and the role of rivers in the global hydrological cycle are quantitatively shown. Finally, the measurements of certain fluxes and storages in the global hydrological cycle by using satellite remote sensing are reviewed.

Earth system and water

The Earth system is unique in that water exists in all three phases, that is, water vapor, liquid water, and solid ice, compared to the situations in other planets. The transport of water vapor is regarded as energy transport because of its large amount of latent heat exchange during phase change to liquid water (approximately 2.5×10^6 J kg⁻¹); therefore, water cycle is closely linked to energy cycle. Even though the energy cycle on the Earth is an "open system" driven by solar radiation, the amount of water on the Earth does not change on shorter than geological timescales (Oki, 1999; Oki et al., 2004), and the water cycle itself is a "closed system."

On the global scale, the hydrological cycles are associated with atmospheric circulation, which is driven by the unequal heating of the Earth's surface and atmosphere in latitude (Peixoto and Oort, 1992).

Annual mean absorbed solar energy at the top of the atmosphere is maximum near equator with approximately 300 W m⁻², decreases suddenly at higher latitudes, and is approximately 60 W m⁻² at Arctic and Antarctic regions. Emitted terrestrial radiative energy from the Earth at the top of the atmosphere is approximately 250 W m⁻² for $\pm 20^\circ$ north and south, gradually decreases at higher latitudes, and is approximately 175 W m⁻² at Arctic and 150 W m⁻² at Antarctic region. As a consequence, the net annual energy balance is positive (absorbing) for tropical and subtropical regions in $\pm 30^\circ$ north and south and negative in higher latitudes (Dingman, 2002).

If there are no atmospheric and oceanic circulation on the Earth, temperature difference on the Earth should have

Water and Energy Cycles, Table 1 World water reserves (simplified from Table 9 of “World water balance and water resources of the Earth” by UNESCO Korzun (1978). The last column, mean residence time, is from Table 34 of the report)

Form of water	Covering area (km ²)	Total volume (km ³)	Mean depth (m)	Share (%)	Mean residence time
World ocean	361,300,000	1,338,000,000	3,700	96.539	2,500 years
Glaciers and permanent snow cover	16,227,500	24,064,100	1,463	1.736	1,600 years
Groundwater	134,800,000	23,400,000	174	1.688	1,400 years
Ground ice in zones of permafrost strata	21,000,000	300,000	14	0.0216	10,000 years
Water in lakes	2,058,700	176,400	85.7	0.0127	17 years
Soil moisture	82,000,000	16,500	0.2	0.0012	1 years
Atmospheric water	510,000,000	12,900	0.025	0.0009	8 days
Marsh water	2,682,600	11,470	4.28	0.0008	5 years
Water in rivers	148,800,000	2,120	0.014	0.0002	16 days
Biological water	510,000,000	1,120	0.002	0.0001	A few hours
Artificial reservoirs		8,000			72 days
Total water reserves	510,000,000	1,385,984,610	2,718	100.00	

been more drastic; temperature in the equatorial zone should have been high enough that the outgoing terrestrial radiation balances the absorbed solar energy, and temperature in the polar regions, which should have been low enough, as well. In reality, there are atmospheric and oceanic circulations that lessen this expected temperature gradation in the absence of circulations.

Both atmosphere and ocean carry energy from the equatorial region toward both polar regions. In the case of atmosphere, the energy transport consists of sensible heat and latent heat fluxes (Masuda, 1988). The global water circulation is this latent heat transport itself, and water plays an active role in the atmospheric circulation; it is not a passive compound of the atmosphere, but it affects atmospheric circulation by both radiative transfer and latent heat release of phase change.

Water reserves, fluxes, and residence time

The total volume of water on the Earth is estimated as approximately $1.4 \times 10^{18} \text{ m}^3$, and it corresponds to a mass of $1.4 \times 10^{21} \text{ kg}$. Compared with the total mass of the Earth ($5.974 \times 10^{24} \text{ kg}$), the mass of water constitutes only 0.02 % of the planet, but it is critical for the survival of life on the Earth, and the Earth is called *Blue Planet* and *Living Planet*.

There are various forms of water on the Earth's surface. Approximately 70 % of its surface is covered with salt water, the oceans. Some of the remaining areas (continents) are covered by freshwater (lakes and rivers), solid water (ice and snow), and vegetation (which implies the existence of water). Even though the water content of the atmosphere is comparatively small (approximately 0.3 % by mass and 0.5 % by volume), approximately 60 % of the Earth is always covered by clouds (Rossow et al., 1993). The Earth is the planet whose surface is dominated by various phases of water.

Water on the Earth is stored in various reserves, and various water flows transport water from one to another. Water flow (mass or volume) per unit time is also called *water flux*.

The mean residence time in each reserve can be simply estimated from the total storage volume in the reserve and the mean flux rate to and from the reserve; there is even a distribution of flux rate coming in and going out from the storage (Chapman, 1972). The last column of Table 1 presents the values of the global mean residence time of water. Evidently, the water cycle on the Earth is a “stiff” differential system with the variability on many timescales, from a few weeks to thousands of years.

$$T_{\text{mean}} = \frac{\text{Total storage volume}}{\text{Mean flux rate}} \quad (1)$$

The mean residence time is also important to consider when water quality deterioration and restoration are discussed, since the mean residence time can be an index of how much water is turned over. Apparently, river water or surface water is more vulnerable than groundwater to be polluted; however, any measure to recover better water quality works faster for river water than groundwater. Since the major interests of hydrologists have been the assessment of volume, inflow, outflow, and chemical and isotopic composition of water, the estimation of the mean residence time of certain domains has been one of the major targets of hydrology.

Existence of water on the earth

Table 1 (simplified from a table in Korzun, 1978) introduces how much water is stored in which reserves on the Earth:

- The proportion in the ocean is large (96.5 %). Even though the classical hydrology has traditionally excluded ocean processes, the global hydrological cycle is never closed without including them. The ocean circulation carries huge amounts of energy and water. The surface ocean currents are driven by surface wind stress, and the atmosphere itself is sensitive to the [sea surface temperature](#). Temperature and salinity

determine the density of ocean water, and both factors contribute to the overturning and deep ocean general circulation.

- Other major reserves are solid water on the continent (glaciers and permanent snow cover) and groundwater. *Glacier* is the accumulation of ice of atmospheric origin generally moving slowly on land over a long period. Glacier forms discriminative U-shaped valley over land and remains moraine when it retreats. If a glacier “flows” into an ocean, the terminated end of the glacier often forms an iceberg. Glaciers react in comparatively longer timescale against climatic change, and they also induce isostatic responses of continental scale upheavals or subsidence in even longer timescale. Even though it is predicted that the thermal expansion of oceanic water dominates the anticipated *sea level rise* due to global warming, glaciers over land are also a major concern as the cause of sea level rise associated with global warming.
- *Groundwater* is the subsurface water occupying the saturated zone. It contributes to runoff in its low-flow regime, between floods. Deep groundwater may also reflect the long-term climatological situation. Groundwater in [Table 1](#) includes both gravitational and capillary water. Gravitational water is the water in the unsaturated zone (vadose zone), which moves under the influence of gravity. Capillary water is the water found in the soil above the water table by capillary action, a phenomenon associated with the surface tension of water in soils acting as porous media. Groundwater in Antarctica (roughly estimated as $2 \times 10^6 \text{ km}^3$) is excluded from [Table 1](#).
- *Soil moisture* is the water being held above the water table. It influences the energy balance at the land surface as a lack of available water suppresses evapotranspiration and as it changes surface albedo. Soil moisture also alters the fraction of precipitation partitioned into direct runoff and percolation. The water accounted for in the runoff cannot be evaporated from the same place, but the water infiltrated into soil may be uptaken by the capillary suction and evaporated again.
- The atmosphere carries *water vapor*, which influences the heat budget as latent heat. Condensation of water releases latent heat, heats up the atmosphere, and affects the atmospheric general circulation. *Liquid water in the atmosphere* is another result of condensation. *Clouds* significantly change the radiation in the atmosphere and at the Earth’s surface. However, as a volume, liquid (and solid) water contained in the atmosphere is quite little, and most of the water in the atmosphere exists as water vapor. *Precipitable water* is the total water vapor in the atmospheric column from land surface to the top of the atmosphere. Water vapor is also the major absorber in the atmosphere of both short-wave and longwave radiation.
- *Water in rivers* is very tiny as stored water all the time however, the recycling speed, which can be estimated as the inverse of the mean residence time, of river water

(river discharge) is relatively high, and it is important because most social applications ultimately depend on water as a renewable and sustainable resource.

Overall, the amount of water stored transiently in a soil layer, in the atmosphere, and in river channels is relatively minute, and the time spent through these subsystems is short, but, of course, they play dominant roles in the global hydrological cycle.

Water cycle on the earth

The water cycle plays many important roles in the climate system, and [Figure 1](#), revised from Oki and Kanae (2006), schematically illustrates various flow paths of water (Oki, 1999). Values are taken from [Table 1](#) and also calculated from the precipitation estimates by Xie and Arkin (1996). Precipitable water, water vapor transport, and its convergence are estimated using ECMWF objective analyses, obtained as 4 year mean from 1989 to 1992. The roles of these water fluxes in the global hydrological system are now briefly introduced:

- *Precipitation* is the water flux from atmosphere to land or *ocean* surface. It drives the hydrological cycle over land surface and changes surface salinity (and temperature) over the ocean and affects its thermohaline circulation. *Rainfall* refers to the liquid phase of precipitation. Part of it is intercepted by canopy over vegetated areas, and the remaining part reaches the Earth’s surface as throughfall. Highly variable, intermittent, and concentrated behavior of precipitation in time and space domain compared to other major hydrological fluxes mentioned below makes the observation of this quantity and the aggregation of the process complex and difficult.
- *Snow* has special characteristics compared with rainfall. Snow may be accumulated, the albedo of snow is quite high (as high as clouds), and the surface temperature will not rise above 0°C until the completion of snowmelt. Consequently, the existence of snow changes the surface energy and water budget enormously. A snow surface typically reduces the aerodynamic roughness, so that it may also have a dynamical effect on the atmospheric circulation and hydrological cycle.
- *Evaporation* is the return flow of water from the surface to the atmosphere and takes the latent heat flux from the surface. The amount of evaporation is determined by both atmospheric and hydrological conditions. From the atmospheric point of view, the fraction of incoming solar energy to the surface leading to latent and sensible heat flux is important. Wetness at the surface influences this fraction because the ratio of actual evapotranspiration to the potential evaporation is reduced due to drying stress. The stress is sometimes formulated as a resistance, and such a condition of evaporation is classified as hydrology driven. If the land surface is wet enough compared to the available energy for evaporation, the condition is classified as atmosphere driven.

- Transpiration is the evaporation of water through *stomata* of leaves. It has two special characteristics different from evaporation from soil surfaces. One is that the resistance of stomata is related not only to the dryness of soil moisture but also to the physiological conditions of the vegetation through the opening and closing of stomata. Another is that roots can transfer water from deeper soil than in the case of evaporation from bare soil.

Vegetation also modifies surface energy and water balance by altering surface albedo and by intercepting precipitation and evaporating this rainwater.

- Runoff at the hillslope scale is nonlinear and a complex process. Surface runoff could be generated when rainfall or snowmelt intensity exceeds the infiltration rate of the soil or precipitation falls over saturated land surface. Saturation at land surface can be formed mostly by topographic concentration mechanism along hillslopes. Infiltrated water in the upper part of the hillslope flows down the slope and discharges at the bottom of the hillslope. Because of the highly variable heterogeneity of topography, soil properties such as conductivity and porosity, and precipitation, basic equations such as Richards' equation, which can express the runoff process fairly well at a point scale or hillslope scale, cannot be directly applied to the macroscale because of its nonlinearity.

Runoff returns water to the ocean which may have been transported inland in vapor phase by atmospheric advection. The runoff into oceans is also important for the freshwater balance and the salinity of the oceans. Rivers carry not only water mass but also sediments, chemicals, and various nutritional matters from continents to seas. Without rivers, the global hydrological cycles on the Earth will never close.

The global water cycle unifies these components consisting of the state variables (precipitable water, soil moisture, etc.) and the fluxes (precipitation, evaporation, etc.).

Zonally averaged net transport of freshwater

The meridional (north–south direction) distribution of the zonally averaged annual *energy* transports by the atmosphere and the oceans has been evaluated, even though there are quantitative problems in estimating such values (Trenberth and Solomon, 1994). However, the corresponding distribution of water transport has not often been studied although the cycles of energy and water are closely related. Wijnffels et al. (1992) used values of the convergence of water vapor flux in the atmosphere (Q) from Bryan and Oort (1984) and discharge data from Baumgartner and Reichel (1975) to estimate the freshwater transport by oceans and atmosphere, but their results seem to have large uncertainties, and they did not present the freshwater transport by rivers.

The annual freshwater transport in the meridional (north–south) direction can be estimated from Q and river discharge with the geographical information such as the location of river mouths and basin boundaries (Oki et al., 1995). Results are introduced in the next section.

Rivers in global hydrological cycle

The freshwater supply to the ocean has an important effect on the thermohaline circulation because it changes the salinity and thus the density. The impacts of freshwater supply to ocean are enhanced in the case of large river basins because they concentrate freshwater from large

Water and Energy Cycles, Figure 2 The annual freshwater transport in the meridional (north–south) direction by atmosphere, ocean, and rivers (land) (Oki et al., 1995). Water vapor flux transport of $20 \times 10^{12} \text{ m}^3/\text{year}$ corresponds to approximately $1.6 \times 10^{15} \text{ W}$ of latent heat transport. Shaded bars behind the lines indicate the fraction of land at each latitudinal belt.

areas to their river mouths. It also controls the formation of sea ice and its temporal and spatial variations. Annual freshwater transport by rivers and the atmosphere to each ocean is summarized in Table 2 based on the atmospheric water balance (Oki, 1999). Some part of the water vapor flux convergence remains in the inland basins. There are a few negative values in Table 2, suggesting that net freshwater transport occurs from the ocean to the continents. This is physically impossible and is caused by errors in the source data. Although detailed discussion of the values in Table 2 may not be meaningful, it is nevertheless interesting that such an analysis does make at least qualitative sense using the atmospheric water balance method with the geographical information on basin boundaries and the location of river mouths. In this analysis, it should be noted that the total amount of freshwater transport into the oceans from the surrounding continents has the same order of magnitude as the freshwater supply that comes directly from the atmosphere, expressed by Q .

The annual freshwater transport in the meridional direction has also been estimated based on the atmospheric water balance with the results shown in Figure 2. The estimates in Figure 2 are the net transport, that is, in the case of oceans, it is the residual of northward and southward freshwater fluxes by all ocean currents globally, and it cannot be compared directly with individual ocean currents such as the Kuroshio and the Gulf Stream. It should be noted that the directions of river flows are mostly steady unlike the ocean or atmospheric circulations and concentrate the freshwater in one direction throughout the year.

Transports by the atmosphere and by the ocean have almost the same absolute values at each latitude but with different signs. The transport by rivers is about 10 % of these other fluxes globally (this may be an underestimation because Q tends to be smaller than the river discharge observed at a land surface). The negative (southward) peak by rivers at 30°S is mainly due to the Paraná River in South America, and the peaks at the equator and 10 °N are due to rivers in South America, such as the Magdalena and Orinoco. Large Russian rivers, such as the Ob, Yenisey, and Lena, carry freshwater toward the north between 50 °N and 70 °N.

These results suggest that the hydrological processes over land play nonnegligible roles in the climate system, not only by the exchange of energy and water at the land surface but also through the transport of freshwater by rivers, which affects the water balance of the oceans and forms a part of the hydrological circulation on the Earth among the atmosphere, continents, and oceans.

Remote sensing in global hydrological cycle

Over the past 20 years, significant progress has been made toward routine monitoring of certain fluxes and storages in the global hydrological cycle by satellite remote sensing, while continued progress is anticipated from upcoming missions. Table 3 gives an overview on the past, current, and planned future hydrological remote sensing

capabilities. Some of these important achievements in measuring global water cycle components are discussed below:

- *Precipitation* – The remote sensing precipitation observation systems were originated about three decades ago (Griffith et al., 1978). Most rainfall products measured from spaceborne platforms, for example, NEXRAD (Next-Generation Radar) and TRMM (Tropical Rainfall Measuring Mission) Precipitation Radar rainfall measurements, are typically provided at large space–time scales suitable for coarse-scale meteorological applications, such as climatologic analysis and water balance studies. Satellite rainfall retrieval is subject to errors caused by various factors ranging from infrequent sampling to the high complexity and variability in the relationship of the measurement to precipitation parameters. Therefore, advanced retrieval algorithm and spatial downscaling techniques (e.g., PERSSIAN, Precipitation Estimation from Remotely Sensed Information Using Artificial Neural Networks; Sorooshian et al., 2000) are necessary to be applied to the satellite rainfall data for the purpose of the study of global water cycle. The planned Global Precipitation Measurement (GPM; <http://gpm.gsfc.nasa.gov/>), which is an international satellite mission scheduled to launch in 2014, envisions a large constellation of passive microwave sensors to provide global rainfall products at the temporal resolution of ~3 h and spatial resolution

Water and Energy Cycles, Table 3 Summary of past, current, and planned future hydrological satellite remote sensing capabilities

Satellite sensors/missions	Hydrological variables measured	Time period of observation
Geostationary Operational Environmental Satellite (GOES)	Precipitation	1978–present
Special Sensor Microwave/Imager (SSM/I)	Precipitation, snow water equivalent, snow extent	1987–present
Scanning Multichannel Microwave Radiometer (SMMR)	Snow water equivalent, snow extent	1978–1987
European Remote Sensing-1 (ERS-1) Radar Altimeter and SAR	Surface water height, soil moisture	1991–2000
TOPEX/Poseidon	Surface water height	1993–2005
European Remote Sensing-2 (ERS-2) Radar Altimeter and SAR	Surface water height, soil moisture	1996–present
Tropical Rainfall Measuring Mission (TRMM)	Precipitation	1998–present
Advanced Microwave Sounding Unit (AMSU)	Precipitation	1998–present
Moderate Resolution Imaging Spectroradiometer (MODIS)/Terra	Snow extent, evapotranspiration ^a	2000–present
Geosat Follow-On Mission	Surface water height	2000–present
Atmospheric Infrared Sounder (AIRS)/Aqua	Water vapor	2002–present
Advanced Microwave Scanning Radiometer – EOS (AMSR-E)/Aqua	Soil moisture, snow water equivalent	2002–present
Moderate Resolution Imaging Spectroradiometer (MODIS)/Aqua	Snow extent, evapotranspiration ^a	2002–present
ENVISAT Radar Altimeter-2 and ASAR	Surface water height, soil moisture	2002–present
Jason-1	Surface water height	2002–present
Gravity Recovery and Climate Experiment (GRACE)	Total water storage, soil moisture, ^a groundwater ^a	2002–present
Soil Moisture and Ocean Salinity (SMOS)	Soil moisture	2009 - present
Soil Moisture active Passive (SMAP)	Soil moisture	Scheduled in 2014
Global Precipitation Measurement (GPM)	Precipitation	Scheduled in 2014

^aNot directly measured; ancillary data required in the estimation

of $\sim 100 \text{ km}^2$ (Hossain and Lettenmaier, 2006; Smith et al., 2007). The GPM mission will provide almost real-time rainfall information at three hourly sampling interval on a global basis, thus allowing hydrologists an opportunity to improve flood prediction capability for medium to large river basins, especially in the underdeveloped world where in situ precipitation gauge networks are sparse. Another current community-wise agenda on the satellite precipitation missions is the “Program for Evaluation of High Resolution Precipitation Products (PEHRPP),” which is an effort led by the International Precipitation Working Group (IPWG) to evaluate the quality of currently available high-resolution satellite rainfall products (Ebert et al., 2007).

- *Terrestrial water storage* – Another contribution of remote sensing technologies to understand the global hydrological cycle has been the measurement of terrestrial water storage (TWS) and its components (Famiglietti, 2004). The major achievements in this aspect include (1) soil moisture retrieval (Jackson et al., 2002; Njoku et al., 2003) from the Soil Moisture and Ocean Salinity (SMOS; Pellarin et al., 2003) and Hydrosphere Satellite Mission (Hydros; Entekhabi et al., 2004), (2) surface water height measurement using the altimetry (Alsdorf and Lettenmaier, 2003; Alsdorf et al., 2007), and (3) integrated measurement of TWS from the Gravity Recovery and Climate Experiment (GRACE) mission (Tapley et al., 2004), among others. TWS is a fundamental component of the global water cycle and an integrated measure of surface and subsurface water availability (i.e., the sum of soil moisture, groundwater, snow and ice, waters in vegetation and biomass, and surface water in lakes, reservoirs, wetlands, and river channels snow). It has great importance for the management of water resources, agriculture, and ecosystem health. TWS controls the partitioning of precipitation into evaporation and runoff and the partitioning of net radiation into the sensible and latent heat fluxes, with significant implications for precipitation recycling, hydrological extremes (i.e., flood and drought), and land memory processes (Shukla and Mintz, 1982; Eltahir and Bras, 1996; Eltahir and Yeh, 1999; Koster et al., 2004), while TWS change is a basic quantity in closing the terrestrial water balance from local to regional and global scales (Ngo-Duc et al., 2005; Güntner et al., 2007; Yeh and Famiglietti, 2008). Despite its importance, its role in the global hydrological cycle has received little attention relative to other hydrological processes (Lettenmaier and Famiglietti, 2006), and there are no extensive networks currently in existence for monitoring TWS changes. Satellite observations of the Earth’s time-variable gravity field from the GRACE mission (Tapley et al., 2004) present a new opportunity to explore the feasibility of monitoring TWS variations from space. Short-term (monthly, seasonal, and interannual) temporal variations in gravity on land are largely due to corresponding changes in vertically

integrated terrestrial water storage (Wahr et al., 2004). This has allowed for the first time observations of variations in total TWS at large river basins (Swenson et al., 2003; Chen et al., 2005; Seo et al., 2006; Winsemius et al., 2006) to continental scales (Wahr et al., 2004; Ramillien et al., 2005; Schmidt et al., 2006; Klees et al., 2007; Syed et al., 2008); for new approaches to remote estimation of discharge (Syed et al., 2005) and evapotranspiration (Rodell et al., 2004); of groundwater variations (Rodell and Famiglietti, 2002; Yeh et al., 2006) and snow water storage (Frappart et al., 2005); and for validation and improvement of the terrestrial water balance in the global land surface hydrological models (Niu and Yang, 2006; Swenson and Milly, 2006).

- *Water vapor* – Another example of remote sensing measurements is the global water vapor distribution. Water vapor is one of the most important greenhouse gases; small amounts of water vapor in the form of clouds can strongly affect both shortwave and longwave radiations. Buoyancy created by changes in the phase of water largely drives the vertical motion of the atmosphere. The Atmospheric Infrared Sounder (AIRS) on board NASA’s Earth Observing System (EOS) *Aqua* spacecraft measures water vapor at $\sim 2 \text{ km}$ vertical resolution with 10–15 % accuracy in clear sky conditions (Moustafa et al., 2006). Such information is available only in a small percentage of the globe because most of the AIRS pixels are cloud contaminated. Success in applying AIRS data has been achieved via selectively choosing cloud-free pixels. Additionally, surface lidar can also provide useful information on water vapor, temperature, and winds in clear air below clouds although they are rather expensive and delicate instruments of limited deployment and coverage. Global Positioning System (GPS) also holds promise to be used as a water vapor sensor when combined with independent temperature analyses.

Summary

The global hydrological cycle consisting of oceans, water vapor in the atmosphere, and terrestrial water, is essential to the Earth system. The cycle is closed by the exchange of water and energy fluxes between these reservoirs. Although the amounts of water in the atmosphere and river channels are relatively small, their fluxes are large, and hence a critical role in society, which is dependent on water as a renewable resource. The ultimate goal of the hydrological science is to enhance the understanding of global water and energy cycles on various spatial and temporal scales through monitoring and modeling, and the outcomes should also be beneficial and accessible to other scientific disciplines, the general public, and the decision makers.

WATER RESOURCES

Taikan Oki¹ and Pat J.-F. Yeh²

¹Institute of Industrial Science, University of Tokyo, Tokyo, Japan

²Department of Civil and Environmental Engineering, National University of Singapore, Singapore, Singapore

Synonyms

Freshwater resources; Runoff

Definition

Water resources mainly correspond to freshwater which can be utilized by human beings for irrigation, industrial purposes, and domestic uses. Even though the stocks of water in natural and artificial reservoirs are helpful to increase the available water resources for human society, the flow of water should be mainly regarded as water resources since water is a naturally circulating resource that is constantly recharged. Maximum (potential) availability of renewable freshwater resources under given climatic condition has been traditionally regarded as precipitation minus evapotranspiration, which corresponds to runoff. However, transpiration from soil moisture through crops is contributing to human society and the flux is regarded as water resources as well. Therefore, evapotranspiration from soil moisture in croplands is called as green water nowadays, and conventional water resources withdrawn from rivers, surface water, and groundwater are called as blue water.

Introduction

All organisms, including humans, require water for their survival. Therefore, ensuring adequate and sufficient water supplies is essential for human well-being. Stored waters, such as deep groundwater and water in reservoirs, are often considered as water resources. However, they are a part of hydrological cycles, and groundwater is also circulating even though its speed could be rather slow. Some groundwater is called “fossil water,” which implies that the aquifer was recharged long term ago and that it will be depleted if being overly exploited just as fossil fuels. From this point of view, flows of water should be considered as water resources in the assessments, designing, and planning of sustainable water usage.

Global water balance and water resources

Conventionally, available freshwater resources are defined as annual runoff estimated by compiling observed river discharge data or by using water balance equation (i.e., the residual of annual precipitation minus evapotranspiration; see Baumgartner and Reichel, 1975; Korzun, 1978). Such an approach has and is continuing to provide information on the annual freshwater resources for many countries. Theoretically, available annual freshwater resources can be derived using annual

precipitation (P) and evapotranspiration (E) measurements; however, the residual term annual runoff (R), namely, annual available freshwater resources, is relatively small compared to P and E . P and E are approximately 1,100 and 1,200 mm/year, respectively, over the ocean and 800 and 500 mm/year over the land (Oki, 1999). Therefore, the estimation of R could contain certain amount of uncertainties due to even comparatively small errors in the estimation of P and E .

Atmospheric water balance computation using the information of water vapor flux convergence could be alternatively used to estimate global runoff distribution owing to the advent of four-dimensional data assimilation (4DDA) technique in atmospheric science (Oki et al., 1995). Even though the microwave remote sensing of precipitable water (vertically integrated water vapor) and temperature profiles is contributing to improve the quality of 4DDA data, this approach is suitable for global overview of the distribution of available freshwater resources (Trenberth et al., 2007).

Model-based estimation of available freshwater resources

Relatively simple water balance models have been used to estimate grid-based available freshwater resources in the world (Alcamo et al., 2000; Vörösmarty et al., 2000). Later, land surface models (LSMs) were applied for the estimation of global water cycles (Oki et al., 2001; Dirmeyer et al., 2006) and for the global water resources assessment by comparing the demand side for both the twentieth century and the future (Shen et al., 2008). Some of these estimates on global water balance were calibrated by multiplying an empirical factor inferred from available observed river discharge data. However, recent model developments are capable to estimate runoff with adequate accuracy without the need of calibration (Hanasaki et al., 2008a). Such estimates by using numerical models require external atmospheric forcing data such as precipitation and temperature, and the accuracy of estimated freshwater resources is highly dependent on the quality of the forcing data (Oki et al., 1999). Satellite remote sensing can provide reasonable estimates of the forcing data for the regions with low density of in situ observations, particularly with regard to the quantities such as precipitation and downward shortwave and longwave radiation. Additionally, 4DDA reanalysis products have been commonly used as the forcing data for air temperature, humidity, and wind speed. In order to assure the quality of the estimations, the results of land surface simulations have been validated, typically, by comparing with in situ discharge observations. However, recently, various satellite remote sensing observations have been used to validate hydrological variables other than discharge such as inundated area (Prigent et al., 2007) and total terrestrial water storage (Kim et al., 2009). Also, some remote sensing variables, such as top-soil moisture (Reichle and Koster, 2005) and snow cover

(Zaitchik and Rodell, 2009), have been assimilated into modeling system to reduce the simulation uncertainty.

Global distribution of available freshwater resources

Figure 1 illustrates the global distribution of annual runoff estimated by land surface models from the multi-model ensemble simulations under the Global Soil Wetness Project (Dirmeyer et al., 1999). Annual runoff (Figure 1) can be considered as the maximum available renewable freshwater resources (RFWR) if waters from upstream cannot be reused at downstream due to consumptive use or water pollution (Oki et al., 2001). Runoff is accumulated through river channels and realized as river discharge (Figure 1). River discharge can be considered as the potentially maximum available RFWR if all the water from upstream can be used. Both runoff and river discharge are concentrated in limited areas, and their amounts range from nearly zero in desert areas to more than 2,000 mm/year in the tropics and greater than 200,000 m³/s of discharge on average near the river mouth of the Amazon (Oki and Kanae, 2006).

Some macroscale hydrological models recently developed for water resources assessments have been equipped with a reservoir operation scheme (e.g., Haddeland et al., 2006; Hanasaki et al., 2006) in order to simulate the “real” hydrological cycles and provide information on actually available freshwater resources. These water resources have been significantly influenced by anthropogenic activities and modified from the “natural” hydrological cycles even on the global scale in “Anthropocene” (Crutzen, 2002).

Water resources for crop growth

An integrated water resources model can further be linked to a crop growth sub-model designed for inferring the timing and quantity of irrigation requirement and estimating environmental flow (Hanasaki et al., 2008a). Such an approach enables the assessment of the balances between demand and supply of water resources on a daily time scale. Using this approach (Hanasaki et al., 2008a), a gap in the sub-annual distribution of water availability and water use can be detected in the Sahel, the Asian monsoon region, and southern Africa, where the conventional water scarcity indices such as the ratio of annual water withdrawal to water availability or the available annual water resources per capita (Falkenmark and Rockström, 2004) cannot properly detect the stringent balance between water demand and supply (Hanasaki et al., 2008b).

Moreover, macroscale numerical models can be associated with a scheme tracing the origin of flow path as if tracing the isotopic ratio of water (Yoshimura et al., 2004). Such a water flow-tracing function, if incorporated into an integrated water resources model (e.g., Hanasaki et al., 2008a) with the consideration of multiple sources of water withdrawals including streamflow, medium-size

Water Resources, Figure 1 Global distribution of (a) mean annual runoff (mm/year), (b) mean annual discharge (million m^3/year), and (c) water scarcity index R_{ws} . Water stress is higher for regions with larger R_{ws} (Oki and Kanae, 2006).

Water Resources, Figure 2 (a) The ratio of blue water to the total evapotranspiration during a cropping period from irrigated cropland (the total of green and blue water). The ratios of (b) streamflow, (c) medium-size reservoirs, and (d) nonrenewable groundwater withdrawals to blue water (Hanasaki et al., 2010).

reservoirs, and nonrenewable groundwater in addition to precipitation on the croplands, is able to trace the origin of water used to produce the major crops (Hanasaki et al., 2010).

Figure 2a illustrates the ratio of blue water to the total evapotranspiration during the cropping period in irrigated croplands. Here the blue (green) water is defined as the amount of water evapotranspiration originated from irrigation (precipitation) (see Falkenmark and Rockström, 2004). Figure 2a shows distinctive geographical distribution of the pattern of the dependence on blue water. Total annual blue water consumption is estimated approximately as 1,500 km³/year, which is about 20 % of the total consumptive use of approximately 7,000 km³/year of water resources in croplands during the cropping period (Hanasaki et al., 2009). Further, the ratios of the source of blue water are shown for streamflow including the influence of large reservoirs, medium-size reservoirs, and nonrenewable groundwater in Figure 2b–d, respectively. Areas highly dependent on nonrenewable groundwater are detected in the Pakistan, Bangladesh, and in western part of India, north and western parts of China, some regions in the Arabian Peninsula, and the western

part of the United States and Mexico. Cumulative nonrenewable groundwater withdrawals estimated by the model correspond fairly well with the country statistics of total groundwater withdrawals, and such an integrated model has the ability to quantify global virtual water flow (Allan, 1998; Oki and Kanae, 2004) and “water footprint” (Hoekstra and Chapagain, 2007) through the major crop water consumption (Hanasaki et al., 2009).

Remote sensing applications in water resources

The last two decades have witnessed significant achievements toward routine monitoring of global hydrologic cycle components by using remote sensing techniques, while continued progress is anticipated from upcoming missions. Among these space efforts, the following missions are particularly relevant to water resources applications:

1. Integrated measurement of terrestrial water storage (TWS) from the Gravity Recovery and Climate Experiment (GRACE) mission (Tapley et al., 2004), launched in 2002
2. Soil moisture retrieval from the Soil Moisture and Ocean Salinity (SMOS; Kerr et al., 2000), launched

by the European Space Agency (ESA) in 2009, and the Soil Moisture Active and Passive (SMAP) mission (Entekhabi et al., 2004), planned to launch by NASA in 2014

3. Surface water height measurement using the altimetry from the Surface Water Ocean Topography (SWOT) mission (Alsdorf and Lettenmaier, 2003), planned to launch by NASA in 2014

TWS is a fundamental component of in closing the terrestrial water balance from local to regional and global scales. As an integrated measure of surface and subsurface water availability, TWS bears significant implications for water resources planning and management. Despite its importance, there are no extensive networks currently in existence for monitoring TWS changes. Satellite observations of Earth's time-variable gravity field from the GRACE mission present a new opportunity to explore the feasibility of monitoring TWS variations from space. Short-term (monthly, seasonal, and interannual) temporal variations in gravity on land are largely due to corresponding changes in vertically integrated terrestrial water storage (Wahr et al., 2004). This has allowed for the first time observations of variations in total TWS at large river basins (Swenson et al., 2003) to continental scales (Wahr et al., 2004). Also, application using GRACE data has been made in the estimation of discharge (Syed et al., 2005), evapotranspiration (Rodell et al., 2004), groundwater variations (Yeh et al., 2006), snow water storage (Frappart et al., 2005), surface water dynamics (Han et al., 2009), lateral redistribution of water storage through river networks (Kim et al., 2009), and validation and improvement of global land surface hydrological models (Niu and Yang, 2006).

The SMOS and upcoming SMAP missions are the first dedicated satellite missions to measure surface soil moisture levels globally. Soil moisture is an important factor which interfaces water and energy exchanges between the land surface/atmosphere and is the most important hydrological quantity for agriculture. Water management for irrigation is a critical issue for global crop production and food safety. Root zone soil moisture, which is strongly related with transpiration (green water), will be more reliably estimated by merging SMOS and SMAP observations with a land surface model in a data assimilation system, even though the enhanced technologies in those satellites are still limited to directly observe only topsoil moisture. It will enable meteorology and food agencies to forecast crop yield and enhance the capabilities of crop water stress decision support systems, monitor global climate change, detect droughts, and conduct flood forecasting and weather prediction.

The SWOT satellite mission and its wide-swath (20–120 km) altimetry technology for repeated elevation measurements can measure the water height variations of the global oceans and terrestrial surface waters accurately. For water resources applications, hydrological observations of the temporal and spatial variations in water

volumes stored in all wetlands, lakes, and reservoirs are extremely important. However, because of coarse spatial (>100 km) and temporal (>1 month) resolutions, previous researches using altimetry (e.g., Birkett et al., 2002) have been used in only limited conditions and objectives. By measuring water height and area variations in higher spatial (2 m × 10 m to 2 m × 60 m) and temporal (2 weeks) resolutions which allow accurate estimation of river discharges and lake/wetland storages in remote regions, SWOT will contribute to a fundamental understanding of the terrestrial branch of the global water cycle and hence benefit global water resource planning and management.

Conclusions

Current advancement of remote sensing technology has not proved to be well capable of observing global water fluxes; thus, it is not an easy task to accurately estimate available freshwater resources based on remotely sensed data. However, remote sensing technique can help in providing necessary information such as meteorological forcing data, land use and land cover, extent of surface water bodies, and topography for the modeling estimation of water resources. Remote sensing of cropland coverage, planting date, and harvesting date, and detection of irrigated areas are necessary for assessing the balances between demand and supply of water resources in addition to the social information, such as population distribution, urban area, industrial water use, and domestic water use. Remote sensing of hydrological quantities, such as snow cover, soil moisture, and temporal change of total terrestrial water storage, can provide great values to constrain and validate hydrological model simulations and thereby assure accurate estimates of freshwater resources from model simulations of water storages and fluxes.

 Technology, Pasadena, CA, USA

Synonyms

Atmospheric humidity; Atmospheric moisture

Definition

Water vapor. Water in gaseous form, usually mixed with dry air in the Earth's atmosphere.

Water vapor mixing ratio. The ratio of density of water vapor to the density of air. Typical values range from a few grams/kilogram in the tropical lower troposphere to a few micrograms/kilogram around the tropopause.

Relative humidity. The ratio of water vapor partial pressure to *saturation vapor pressure*. A common measure of water vapor amount, but not conserved as an air parcel changes temperature. *Mixing ratio* is conserved.

Saturation vapor pressure. Maximum partial pressure of water vapor adjacent to a plain surface of water or ice. Water vapor saturation vapor pressure follows the *Clausius-Clapeyron relation* for water and varies approximately exponentially with temperature.

Clausius-Clapeyron relation. Equation relating equilibrium pressure of a gaseous substance adjacent to a solid or liquid surface. The Clausius-Clapeyron relation varies exponentially with temperature at about 7 %/K near

freezing. In terrestrial atmospheric sciences, this term generally refers to water vapor with respect to liquid water or ice.

Latent heat of vaporization. Heat required to convert a unit mass of liquid water to water vapor. The same heat is released when water vapor condenses to liquid, as happens in clouds. Analogous latent heat of fusion refers to conversion between ice and liquid. Water vapor latent heats are very large: about 2.3×10^6 J/kg for conversion of liquid water to vapor compared to dry air heat capacity of 717 J/kg-K.

See American Meteorological Society (2010) and Wallace and Hobbs (2006) for additional terms, including dew point, *frost point*, and specific humidity.

Introduction

Water vapor varies significantly throughout the atmosphere. While a trace species in the middle atmosphere, it is the third most abundant gas in the Earth's lower troposphere. It has three important roles in weather and climate. First, water vapor is the dominant greenhouse gas so it has a significant effect on the planetary energy balance. Second, because the atmospheric capacity for water vapor varies exponentially with temperature, its radiative effects may act to amplify any surface warming; water vapor feedbacks are believed to roughly double anthropogenic warming (Intergovernmental Panel on Climate Change, 2007). Third, clouds and precipitation both begin as water vapor. Thus, water vapor acts indirectly on radiatively important clouds, while its condensation releases latent heat and affects precipitation. A major challenge in [weather forecasting](#) is improved precipitation forecasts, and water vapor is the atmospheric source for precipitation. Latent heat release represents about half the warming of the tropical atmosphere and makes a small but important contribution at higher latitudes, especially in storm systems (Hartmann, 1994). The importance of water vapor has made its observation a cornerstone of remote sounding techniques for decades.

Influence on weather

Thunderstorms and severe weather are significantly enhanced by the presence of water vapor, especially at low levels. Latent heat released by water vapor condensing onto cloud liquid droplets causes warming and reduced density, enhancing convective instability (Emanuel, 1994). This instability is most pronounced where cooler, dry air overlies warm, moist air, as is common in spring, summer, and fall in the American Midwest; high convective instability is a major factor in the formation of tornadoes. Latent heat release is also a major factor in organized tropical convective systems, including hurricanes.

Radiative effects and climate feedbacks

Water vapor is the dominant greenhouse gas in the atmosphere, with strongest absorption in the middle and upper

troposphere (400–100 hPa pressure) where many of its infrared spectral lines become saturated (Liou, 1992). Water vapor is not well mixed (unlike other greenhouse gases such as carbon dioxide or methane), so estimating its radiative effects has required direct observations of its distribution. This has presented a challenge, because only recently have high information content water vapor data sets become available from satellites (see below). The global upper tropospheric water vapor record prior to 2002 was based on regression models of local relative humidity versus satellite-observed brightness temperatures in the 6.3 μm infrared band from broadband radiometers (Soden et al., 2005). Other early studies addressed upper tropospheric water vapor variability using balloon-borne sensors, but only in the early twenty-first century did those sensors become sensitive enough to detect the very small water vapor amounts typical of the upper troposphere (Voemel et al., 2007).

Water vapor is also an important factor in climate feedbacks. Atmospheric water vapor has an enormous source at the ocean surface, depends strongly on temperature through the Clausius-Clapeyron relation, and acts as a greenhouse gas. Combined, these factors give water vapor a positive feedback (amplifying effect) on surface warming or cooling. Dessler et al. (2008) used satellite observations and El Niño-Southern Oscillation as a proxy for carbon dioxide-induced surface warming and examined radiative forcing kernel functions from climate models. They showed that climate models' water vapor feedback in response to warming roughly doubled surface warming, consistent with the observed atmospheric response (see also Dessler and Sherwood, 2009). In further confirmation of water vapor response to surface warming, Santer et al. (2007) attributed an increase in a 20 year record of total water vapor as a response to anthropogenic warming.

Direct confirmation of upper tropospheric water vapor response to surface warming – and verification of a positive water vapor feedback – remains a challenge (Boers and van Meijgaard, 2009; National Research Council, 2003). Also, the mechanisms whereby water vapor is mixed throughout the troposphere are not fully understood (Gambacorta et al., 2008). The vertical distribution of water vapor is important in feedback processes because lower tropospheric water vapor strongly couples surface changes to the atmosphere. Climate models are based on deep convective parameterizations, which can lead to biased water vapor distributions in models (Pierce et al., 2006) along with height-dependent temperature biases (John and Soden, 2007). Because water vapor and temperature are coupled by deep convection, these biases are related and their radiative contributions partly cancel (National Research Council, 2003; Bony et al., 2006). John and Soden (2007), following Held and Soden (2006), show evidence that climate model feedbacks are robust despite biases in mean fields. While the water vapor

feedback is well understood, parameterization of cloud physics in climate models (including the coupling between clouds and water vapor) is a major source of uncertainty in climate projection (Stephens, 2005; National Research Council, 2003).

Remote sensing of water vapor

The basis of all remote sensing or remote sounding systems is an instrument, or set of instruments, to observe electromagnetic radiation. (Remote sounding is the process of inferring vertical structure of temperature, clouds, and constituent gases like water vapor from observed spectral information.) In the case of water vapor, the observations are typically in the 6.3 μm infrared band or the 183 GHz microwave band. In addition to an instrument making observations, remote sensing systems usually include a numerical post-processing system to retrieve vertical distributions of geophysical parameters from the calibrated observed radiances. Therefore, remote sensing “observations” of water vapor (and many other atmospheric quantities) are in fact inferences about the state of the atmosphere. This makes the attribution of uncertainties an especially important and challenging component of remote sounding.

History of satellite remote sensing of water vapor

Satellite remote sensing of atmospheric water vapor extends back to the 1960s, when a variety of remote sensing instruments were launched into polar and geosynchronous orbits (Kidder and Vonder Haar, 1995). Many of these instruments included observations at wavelengths sensitive to water vapor. By the 1970s, basic methodologies for observing water vapor from space were established, and the United States began launching the TIROS Operational Vertical Sounder (TOVS) series of satellite instruments dedicated to tropospheric sounding. TOVS was first launched in 1978 and included the High-Resolution Infrared Sounder (HIRS) and the Microwave Sounding Unit. The highest-quality long-term satellite water vapor record is from Special Sensor Microwave Imager (SSM/I) instrument, though only as total water vapor. Other improvements in water vapor include the incorporation of four microwave water vapor channels with the Advanced Microwave Sounding Unit-B (AMSU-B) in 2000. AMSU-A, part of the Advanced TOVS sounders, included only a single water vapor channel. Technological advances have produced infrared instruments with higher spectral resolution than their microwave counterparts. This improved spectral resolution leads to greater information about water vapor vertical structure. The strength of microwave instruments is their greater coverage in the presence of clouds, though at the cost of vertical resolution. The Atmospheric Infrared Sounder (AIRS) instrument, launched in 2002 by the United States National Aeronautics and Space Administration (NASA) on the Aqua spacecraft into a 1:30 equator

crossing orbit, provides detailed information about water vapor (and a number of other quantities) from the surface to the upper troposphere with its 2000+ infrared channels and 20 microwave channels in a co-boresited AMSU-A instrument (Chahine et al., 2006). A similar instrument, the Infrared Atmospheric Sounding Interferometer (IASI), launched in 2006 by the European Space Agency provides similar information in a 9:30 local orbit on the first of three Meteorological Operational satellites (Centre National D'Etude Spatiales, 2010). IASI observations are collocated with microwave observations from the Microwave Humidity Sounder (Polar Orbiting Environmental Satellite, 2010) for additional constraints on the water vapor distribution. Other modern satellite instruments observing water vapor include the Microwave Limb Sounder (MLS), a limb-viewing instrument with sensitivity from the upper troposphere to the stratosphere and carried on the NASA Aura platform. This is a follow-on to an MLS instrument on the Upper Atmosphere Research Satellite (UARS) but with sensitivity to both temperature and water vapor (UARS MLS could detect variations in relative humidity only; see Fueglistaler for a review of instruments sensing the upper troposphere and stratosphere). Aura carries the Tropospheric Emission Spectrometer, with the unique ability to sense the water vapor isotopologue HDO in the troposphere (Worden et al., 2007).

Synonyms

Weather forecasting

Definition

Weather. State of the atmosphere and its day-to-day variation, mostly described by temperature, wind, cloudiness, and precipitation.

Weather Prediction. Prediction of weather at a given time and location using numerical models and observations.

Numerical atmospheric modeling

Numerical models are used to simulate the evolution of all those processes in the atmosphere and at surfaces that affect the atmospheric state. Increasingly, these models add complexity to the modeled components of atmosphere and surfaces that go beyond the basic formulation of mass, heat, and momentum transport. With increasing complexity of the models, a wider range of spatial and temporal process scales has to be accounted for and the diversity and nonlinearity of the modeled processes increases as well (Kalnay, 2003).

In many applications, numerical models or model output are combined, for example, by nesting smaller-scale models into larger-scale models; by coupling of models for the atmosphere and land surfaces (see “*Ocean-Atmosphere Water Flux and Evaporation*”; “*Land-Atmosphere Interactions, Evapotranspiration*”), hydrology, waves, and oceans; and by coupling of atmospheric dynamics with chemistry models.

Global numerical models usually employ a set of primitive equations to describe atmospheric dynamics under the assumption of momentum conservation, heat exchange through thermodynamics, and mass conservation (see “*Atmospheric General Circulation Models*”). Processes with scales well below the scales that the numerical model can resolve are described by physical parameterizations that approximate the effect of sub-grid processes on the resolved scales and vice versa. Among these are radiation processes (see “*Radiation, Electromagnetic*”), cloud condensation and convection, orographic drag, turbulent diffusion, and most surface processes (Kalnay, 2003).

Since most processes exhibit nonlinear behavior and are discretized in space and time, the corresponding equations are solved numerically. The choice of solution method depends on the model type. Some global models are spectral models, where the horizontal dimension is described by a set of waves and where the horizontal resolution is proportional to the highest defined wave number. Others solve the above equations on structured or unstructured horizontal grids. The vertical dimension is

usually defined by finite layers with varying choice of coordinate systems (e.g., sigma, eta, theta, hybrid coordinates; e.g., Warner, 2011).

At operational numerical weather prediction (NWP) centers, numerical models are run as part of the analysis system that estimates the state of the (global) atmosphere at a given time as well as for producing the forecast over the desired time range. The analyses are used to initialize the forecast model runs. These deterministic forecasts are often complemented by ensemble forecasts for which a set of forecasts are produced from perturbed initial conditions, possibly using further stochastic input. The perturbations are supposed to represent the uncertainty of the initial state estimate as well as the model, so that the ensemble of forecasts provides an estimate of forecast uncertainty. To reduce computational cost, the ensemble forecasts are run at lower spatial resolutions than the deterministic model. With increasing forecast range (monthly/seasonal), ensemble-type modeling becomes more important because the nonlinear response to small differences in the initial conditions and model errors become large and the knowledge of ensemble forecast spread is crucial for interpreting forecast skill.

Atmospheric data assimilation

Data assimilation systems (see “*Data Assimilation*”) in NWP provide the mathematical framework for performing atmospheric analyses that represent the best estimate of the state of the atmosphere at a certain time. The quality of the forecast depends on both the accuracy of the numerical model and the accuracy of the initial state estimate. The initial state estimate is called the analysis and represents an inversion problem. In general, this inversion problem is underdetermined so that the analysis must employ information from a priori data (in NWP usually short-range forecasts initialized with previous analyses) and observations using a mathematical framework to optimally combine the two.

The complexity of the data assimilation system to be used depends on the application and the affordable computational cost and can range from simple interpolation techniques to four-dimensional variational and ensemble Kalman filter schemes or even nonlinear methods (Daley, 1991; Ide et al., 1997; Rabier, 2005). Global analysis systems are solving the above inversion problem with state vector dimensions of the order of 10^8 (the product of the number of grid points, number of levels, and dimension of state vector) and observation vector dimensions of the order of 10^7 (product of number of observation points, number of levels, or satellite instrument channels/range gates).

Today, most global operational NWP centers are operating 4D-Var (Lewis and Derber, 1985) data assimilation systems that are capable of combining sparse and heterogeneously distributed data with a dynamical model. A computationally efficient derivative is the incremental 4D-Var method that is based on the assumption that model behavior is nearly linear in the vicinity of a good

short-range forecast of the model state (first guess) so that the analysis is produced from incrementally updating the first-guess estimate (Bouttier and Courtier, 2002; Rawlins et al., 2007). The advantage of 4D-Var methods lies in the fact that (1) they produce meteorological fields that are dynamically consistent because the optimization is performed over a time window through which the model is integrated and (2) that computationally efficient adjoint models can be used with incremental methods (Courtier et al., 1993). Systems like this are currently in use at ECMWF, the UK Met Office, Météo-France, the Meteorological Service of Canada (MSC), the Japan Meteorological Agency (JMA) (for the regional model), and in the USA at the Naval Research Laboratory (NRL).

At regional scales, ensemble-based methods (Andersen, 2001; Houtekamer and Mitchell, 2001) become increasingly implemented because they do not require the development of adjoint models and are capable of explicitly calculating analysis error statistics than can be used for estimating model errors and for initializing ensembles of forecasts (Lorenc, 2003). Due to the necessity of running ensembles, the computational effort is considerable and currently not affordable at global scales with the same horizontal resolutions as obtained with variational assimilation methods.

However, increasingly hybrid systems composed of high-resolution variational and low-resolution ensemble data assimilation are implemented in which the ensemble system provides background error statistics for the high-resolution analysis.

Satellite data in weather prediction

Satellite data products

Satellite data can be assimilated as level 1 (e.g., calibrated and geo-located electromagnetic radiances) or level 2 (e.g., derived geophysical products such as temperature and humidity; see “*Geophysical Retrieval, Overview*”) data. The choice depends on various factors, most prominently on the amount of maintenance required in an operational system. Level 2 product retrieval often employs a similar inversion framework as NWP data assimilation system to derive the desired parameters, namely, a priori information from NWP models or climatologies, radiative transfer, error, and bias models. Most level 2 products, however, employ different models and a priori constraints than used in NWP modeling, and their error characteristics are often not well defined or difficult to account for in data assimilations systems (Joiner and Dee, 2000). Further, when retrieval algorithms or instrument characteristics (e.g., loss of channels, increase of noise, and instrument recalibration) change, the NWP data assimilation system must be tuned to the performance of the new product, which is often cumbersome in an operational framework.

On the other hand, level 1 satellite data assimilation requires running radiative transfer models (see “*Radiative Transfer, Solution Techniques*”; “*Radiative Transfer, Theory*”) that simulate observation-equivalent radiances

from the model state. For the most important application of satellite data in NWP, that is, the observation of temperature and moisture structures in the atmosphere, radiative transfer models are very fast and accurate (Saunders et al., 1999; Han et al., 2006), and they allow the flexible use of radiometer channels as a function of situation-dependent sensitivity and potential channel corruption. They also greatly simplify observation error and bias estimation.

The same approach of level 1 data assimilation is increasingly used for observations sensitive to clouds, precipitation, aerosols, surface characteristics and trace gases and observables from active sensors.

History of satellite data usage

Derived wind vectors obtained from geostationary cloud (later also water vapor) feature tracking were among the first products used in the early days of satellite data assimilation. The associated cloud feature heights are retrieved from infrared window channels (Nieman et al., 1993), and the data produced good impact on analysis and forecast quality, mainly in the Southern Hemisphere where little conventional observations were available. With the launch of infrared and microwave sounders onboard polar orbiting satellites, more information on vertical temperature structures became available. At that time, the assimilation of retrieved geophysical products was preferred over radiances due to less efficient radiative transfer models, more simple observation operators, and the uncertain impact of satellite data in general. Initial experiments with sounder data produced even negative impact due to unknown bias characteristics of the retrieved profiles and model error statistics that were not tuned to deal with profile data obtained from observations other than radiosondes.

An intermediate step between the assimilation of retrieved products and radiance assimilation is based on 1D-Var techniques. Here, a single-column (one-dimensional variational or 1D-Var) retrieval is performed with radiance observations, and the retrieval product is assimilated globally by the corresponding global analysis scheme (optimum interpolation, 3D/4D-Var). The advantage of such an approach is that the constraints and assumptions used in the 1D-Var retrieval are very similar to those used in the global scheme because they are performed within the same analysis system. One of the earliest protagonists of this approach were Eyre et al. (1993) in Europe, producing retrieved temperature profiles from TOVS data that comprises observations from the HIRS, MSU, and SSU instruments. This approach has greatly facilitated the promotion of satellite data usage in NWP and was later extended to the use of moisture-sensitive channels and instruments such as the AMSU-B and the SSM/I (Phalippou, 1996). Most of these systems were later replaced by direct radiance assimilation, that is, excluding the intermediate retrieval step, for the abovementioned reasons (Andersson et al., 1994; Derber and Wu, 1998).

The initial concerns over general satellite data impact were mostly overcome by the time 4D-Var data assimilation systems were established, mainly because of the improved treatment of spatial and temporal collocation between data and model simulations, better forecast model error formulations, and the improved interaction of temperature and moisture with model dynamics (Andersson and Thépaut, 2008). In the 1990s and early years of the twenty-first century, the dominant impact of satellite data on numerical weather forecast skill was contributed by ATOVS data that combines HIRS AMSU-A and AMSU-B observations. The first ATOVS sensor package was launched with NOAA-15 in 1998 and has been continued until NOAA-19 (launched in 2009). For both NOAA-18 and NOAA-19, the AMSU-B has been replaced with MHS. Since 2006, the same package is also available on the EPS series METOP.

The microwave sounder system is complemented by, so-called, microwave imagers (e.g., SSM/I, and the follow-on instrument SSMIS, AMSR-E onboard Aqua, TMI onboard TRMM, AMSR-2 onboard GCOM-W) that contribute information on sea-surface temperature, near-surface wind speed, integrated atmospheric moisture, clouds, and precipitation (see “*Microwave Radiometers*”).

A major step forward has been the development of infrared spectrometers (grating spectrometer AIRS onboard EOS Aqua in 2002, interferometer IASI onboard METOP-A/B in 2006/2012 and CrIS onboard Suomi NPP in 2011) that provide unprecedented vertical resolution and measurement accuracy by making available thousands of channels with very high spectral resolution covering the 4–15 μm range. These instruments have produced substantial impact on NWP (Collard and McNally, 2009) and will complement microwave sounding radiometers for the next 20 years. Due to their superior spectral resolution, these instruments are also crucial for atmospheric chemistry and air quality applications (Clerbaux et al., 2009).

Further, the utilization of information on atmospheric temperature and moisture structures obtained from the bending of rays of actively transmitted radio waves by the GNSS has vastly increased over the past 5 years (Eyre, 1994; Healy and Thépaut, 2006; see “*Limb Sounding, Atmospheric*”; “*GPS, Occultation Systems*”). Currently, the assimilation of GPS signals in occultation mode by dedicated receivers (onboard CHAMP, GRAS onboard METOP, COSMIC Formosat-3 constellation) provides radiosonde-equivalent measurement accuracy, mainly in the upper atmosphere where NWP models tend to exhibit significant errors.

Apart from temperature structures in the upper atmosphere, trace gas observations (mainly ozone) can provide valuable contributions to weather prediction since ozone has a strong impact on radiative heating (see “*Stratospheric Ozone*”). Solar backscattered ultraviolet instruments (e.g., SBUV, OMI, and GOME-1/2) provide

the bulk of the observations when sunlight is available, while infrared spectrometers complement the observations at nighttime.

Apart from clear-sky satellite data, efforts toward cloud-affected data assimilation have been successful in recent years (Bauer et al. 2010; Geer et al. 2010; Bauer et al. 2011. Bauer et al., 2006a, b). This was mainly achieved by the greatly improved global model moist physical parameterizations and the enhanced computational capabilities that allow the operational employment of multiple scattering radiative transfer models (Greenwald et al., 2002; Bauer et al., 2006c). The explicit treatment of clouds and precipitation in operational analysis systems is accompanied by a large set of uncertainties, for example, greater model nonlinearity, potential dynamic instabilities, large and unknown error structures, as well as unknown model biases (Errico et al., 2007).

Atmospheric modeling requires accurate constraints of energy and water fluxes at the interface with land and ocean surfaces. Over oceans, the interaction between wind and waves is treated by wave models. Here, near-surface wind observations from passive (microwave radiometers) or active (scatterometers; see “*Radar, Scatterometers*”) satellite data and direct observations of wave height from altimeters (see “*Radar, Altimeters*”) and directional wave spectra from synthetic aperture radars (see “*Radar, Synthetic Aperture*”) are part of the operational set of assimilated data.

Over land surfaces, a recent development in NWP is the use of microwave radiometer observations to constrain soil moisture analysis (see “*Soil Moisture*”). This can be accomplished by fixed aperture radiometer observations at 6–10 GHz from TMI and AMSR-E (Reichle et al., 2007) and moderate resolution observations at 1.4 GHz from synthetic aperture imagery by SMOS (Merlin et al., 2006). Note that over land surfaces, RFI can impose serious limitations on data quality and usefulness for NWP (see “*Radio-Frequency Interference (RFI) in Passive Microwave Sensing*”). Also scatterometer is used to extract information on soil properties.

Snow and sea-ice products, mostly obtained from passive and active microwave instruments, provide important information for NWP systems on how to define surface albedo and heat fluxes.

Figure 1 illustrates the dramatic increase of satellite data diversity and volume since 1996 as well as a prediction until 2017 at ECMWF. The historic evolution of used data does not necessarily reflect the sequential launch of individual satellites but rather the ability of NWP data assimilation systems and computers to digest the available information. Today, data from about 50 different instruments is used constraining geophysical parameters in the atmosphere and at both land and ocean surfaces. The gap between data volume contributed by conventional (i.e., nonsatellite) and satellite data has largely widened. More

Weather Prediction, Figure 1 History and prediction of satellite data usage in data assimilation at ECMWF in terms of instruments (*top*) and data volume per day for conventional and satellite observations (*bottom*).

Weather Prediction, Figure 2 Evolution of ECMWF 500 hPa height forecast skill score, expressed as anomaly correlation. *Top panel* shows day 3 (blue), day 5 (red), day 7 (green) scores between Northern (thick lines) and Southern (thin lines) Hemispheres. *Bottom panel* shows corresponding scores from ECMWF reanalysis, namely, ERA-40 (gray) and ERA-Interim (colors).

than 40 million satellite observations are monitored per day, 95 % of which are assimilated directly as radiances while the remainder is composed of retrieved products.

Impact of satellite data on prediction skill

Data impact in NWP systems can be quantified in various ways and by assessing the impact on both analyses and forecasts. It is assumed that better analyses will provide better initial conditions for forecasts. Analysis quality is usually quantified by the comparison of NWP model fields to all available observations before and after they have been assimilated. A better system is expected to produce a consistently better fit of the analysis to the

observations and should maintain this advantage up to the next short-range forecast that has been initialized with this analysis. Forecast skill can be quantified by comparing forecasts to both observations and analyses.

Figure 2 shows the evolution of the ECMWF forecast model skill over the period 1980–2010 for the 3, 5, and 7 day forecasts over the Northern and Southern Hemispheres from the operational system (Figure 2a) and from the ECMWF reanalyses ERA-40 (gray, Uppala et al., 2005) and ERA-Interim (in colors, Uppala et al., 2008). Figure 2a illustrates the substantial increase of skill over three decades and the strong reduction of the difference between skill over the Northern and Southern

Hemispheres. While the former is the result of the combined evolution of model physics, data assimilation, and observing systems, the latter is only explained by the contribution of satellite data due to the sparseness of conventional data over Southern Hemispheric oceans. [Figure 2b](#) provides another angle at disentangling the individual contributions to the time series of NWP forecast skill: The reanalyses have been produced with a model version that has been frozen in 2001 (ERA-40) and 2006 (ERA-Interim), respectively. The small increase of skill over the ERA period is mostly due to the advancement of satellite observations, while the difference between ERA-40 and ERA-Interim is mainly due to the improvement of model and data assimilation system between 2001 and 2006. The larger gap of Northern and Southern Hemisphere forecast skill of ERA-40 compared to ERA-Interim in the overlap period between 1989 and 2001 illustrates the fact that the data assimilation system of ERA-Interim exploits the same satellite observations more effectively than ERA-40.

If the impact of individual observing systems (satellites or instruments) is evaluated, the most prominent assessment tool is the so-called Observing System Experiment (OSE), in which new data is added to an existing system and the relative difference to a control system is evaluated. Similarly, individual data sources can be withdrawn from a full system to assess the impact of the withdrawn data.

More sophisticated methods involve the model operators that are used in the data assimilation system. Based on forecast error estimates from the difference between forecasts and verifying analysis, the model and observation operator adjoints employed in 4D-Var can be used to deduce the dependence of this forecast error on individual observation types that were used in the initializing analysis (Zhu and Gelaro, 2008). An alternative is the use of ensemble-based analysis and forecasting techniques that evaluate forecast impact from ensemble spread (that represents model error) with or without specific observation types. Finally, Observing System Simulation Experiments (OSSE) provide a framework for evaluating the potential impact of observations that do not yet exist and therefore require an observation simulation from independent NWP models (Arnold and Dey, 1986; Tan et al., 2007).

A major OSE impact study was conducted in 2006–2007 to evaluate the impact of the satellite observing system in global NWP at ECMWF (Kelly and Thépaut, 2007). The experiments demonstrated that (a) infrared spectrometers (AIRS, IASI) produce the largest impact per single instrument on geopotential height and temperature forecast skill and (b) that the currently available constellation of 4–5 microwave sounders (AMSU-A/B/MHS) produces a very similar relative impact compared to one advanced infrared sounder. The results are similar for the Northern Hemisphere but with a smaller dynamic range due to the stronger constraint from denser conventional observations obtained over the continents. Further studies

suggest that, apart from infrared and microwave sounders, GPS radio-occultation and scatterometer data produce significant contributions to forecast accuracy since they are most directly related to temperature and surface wind (pressure) with good global coverage.

In terms of atmospheric moisture, Kelly and Thépaut (2007) confirmed previous investigations showing that SSM/I data has the strongest impact in the lower troposphere over oceans complemented by AMSU-B data in the mid and upper troposphere (Andersson et al., 2007). The impact of clear-sky microwave imager data is about as strong as that of cloud-affected data (Kelly et al., 2008).

[Figure 3](#) shows a different measure of global forecast impact from selected observation types that is obtained from the 24 h forecast error sensitivity to the accumulated sensitivity to all observation types (Cardinali, 2009). The methodology is able to estimate observational impact without having to add/withdraw them but only applies to short-range forecast impact estimation. In [Figure 3a](#), the total impact of the most prominent satellite and conventional observations for a 4 month period (September–December 2008) is shown, while [Figure 3b](#) shows the impact per individual observation.

It is evident that infrared spectrometers and microwave sounders produce the strongest impact followed by radio-occultation observations. [Figure 3b](#) shows that surface observations of pressure over the oceans from drifting buoys but also all types of direct wind observations have a strong impact, which suggests the importance of accurate wind observations from satellites as expected from ADM/Aeolus in the future (see “[Lidar Systems](#)”).

It is important to note that the impact of individual observations depends on the NWP system and the weight assigned to the observations in the analysis. It is therefore crucial to evaluate the NWP model, the data assimilation system, and the entire set of used observations together to characterize the importance of existing satellite data for NWP and to estimate the potential impact of future systems.

Summary

Current weather forecast skill is strongly driven by the sophistication of the physical processes represented in numerical models and advanced data assimilation schemes allowing vast amounts of data from conventional sources and satellites to be used. Globally, more than 40 million observations per day are used from about 50 different satellite instruments to produce atmospheric analyses with which the forecast models are initialized. The most important instruments are passive radiometers that measure infrared and microwave radiation emitted by the surface-atmosphere system and that are mostly exploited to derive information on temperature and moisture structures. Increasingly, observations of clouds and rain, surface waves, land surface characteristics, and atmospheric trace gases are added. In parallel, numerical models become increasingly capable of representing more

Weather Prediction, Figure 3 Relative contribution of different observing systems to 24 h forecast error reduction for September–December 2008 (Cardinali, 2009). *Top panel* shows contribution per observing system; *bottom panel* shows contribution per single observation.

complex physical and chemical processes at smaller scales. Ensemble analysis and forecasting systems allow the estimation of analysis and forecasting uncertainties – a crucial information in forecasting highly nonlinear atmospheric phenomena. Future satellite observing systems will develop toward more hyper-spectral instruments covering wider spectral ranges with fine spectral resolution as well as active instruments that sample vertical structures and wind very accurately.

WETLANDS

John Melack

Department of Ecology, Evolution and Marine Biology,
University of California, Santa Barbara, CA, USA

Definitions

Passive microwave radiation is emitted from the Earth's land, seas, and atmosphere at wavelengths generally between 0.15 and 30 cm or, if expressed as frequencies, between 1 and 200 GHz.

Emissivity is the ratio of energy radiated by a material to energy radiated by a blackbody at the same temperature.

Introduction

Wetlands cover extensive areas worldwide (Lehner and Döll, 2004), have important ecological and biogeochemical functions, and play critical roles in improving water quality, mitigating floods, and providing habitat for fish and wildlife. For many wetlands, remote sensing is the preferred approach to obtain a synoptic view of inundation and vegetative cover, and a suite of optical and microwave sensing systems and analysis algorithms are being applied to wetlands (Sahagian and Melack, 1998; Melack, 2004). In the case of the large, temporally varying wetlands found throughout the world, a remote sensing system with frequent, near-global coverage and sensitivity to wetness is necessary. These requirements are met by passive microwave sensors.

Passive microwave systems and analyses

A global record of *passive microwave radiation* measured from satellites is available from 1979 to the present. The Scanning Multichannel Microwave Radiometer (SMMR) was operated on board the Nimbus-7 satellite from 1979 to

1987, with global coverage every 6 days. The Special Sensor Microwave/Imager (SSM/I) replaced SMMR in 1987 and operates today with 3 day global coverage from a satellite in the US Defense Meteorological Satellite Program. The Tropical Rainfall Measuring Mission (TRMM), launched in 1997, included a microwave radiometer similar to that on SSM/I but providing higher spatial resolution because it flies at lower altitude than the SSM/I. The Advanced Microwave Scanning Radiometer (AMSR), launched in 2002 on the Aqua satellite, offers additional capabilities.

Measurements of passive microwave radiation are expressed as brightness temperatures ($^{\circ}\text{K}$) and are recorded as vertical and horizontal polarizations at several frequencies (Choudhury, 1989). To reduce effects of atmospheric water vapor and temperature on the measurements, the difference between the two polarizations, referred to as ΔT , is often used. However, surface roughness, exposed soil and rock, seasonal vegetation changes, and other atmospheric conditions can affect the ΔT . Prigent et al. (1998) have developed an approach to calculate microwave *emissivities* of land surfaces after removing the contributions from the atmosphere, clouds, and rain and modulation by surface temperatures by using ancillary remotely sensed information and meteorological reanalyses. In general, flooded regions have low microwave emissivities and high polarization differences relative to non-flooded areas. Spatial resolutions of approximately 10–50 km limit the application of the technique to large wetlands or to regions where the cumulative area of smaller wetlands comprises a significant proportion of the landscape.

Calm water surfaces result in a strongly polarized emission at 37 GHz (e.g., SMMR ΔT ca. 60°K), although this is attenuated to varying degrees by overlying vegetation. In the absence of flooding, the dense vegetation and relatively level terrain typical of large wetlands present a stable background of depolarized microwave emission (e.g., SMMR ΔT averaging ca. 4°K). Fluctuations in the extent of inundation can be quantified if the ΔT is raised sufficiently above background. Inundation area can be estimated from the ΔT by mixing models that incorporate the microwave emission characteristics of the major landscape units (Sippel et al., 1994). The results have been validated against independent measures of flooding, such as river-stage records in areas of floodplain where inundation is known to be controlled by a large river.

Passive microwave applications

Inundation

A global monthly time series of inundation during the 1990s was produced by Prigent et al. (2007) based on a combination of passive microwave surface emissivities, scatterometer responses, and visible and near-infrared reflectances for ca. 0.25° grid cells. The detection of inundation relied primarily on SSM/I data. In forested regions it appears that the results do not indicate inundation if standing water occupies less than 10 % of the pixel.

In comparison to inundation determined under low and high water levels at 100 m resolution with synthetic aperture radar for the central Amazon (Hess et al., 2003), Prigent et al.'s results do fairly well, underestimating low water area by 11 % and high water area by 30 %. Variations in wetland area match well with variations in water level derived from TOPEX-Poseidon altimetry in the Niger, Ganges, Pantanal, and Amazon basins on a 4° grid.

In tropical areas, passive microwave remote sensing studies have focused on analysis of the inundation patterns in seasonally flooded forests and savannas and on comparative analyses of hydrological patterns in the major wetlands in South America (Hamilton et al., 2002). Observations with SMMR at the 37 GHz have been analyzed to determine spatial and temporal patterns of inundation on floodplains of the Amazon, Tocantins and Orinoco basins, and the Pantanal wetlands of South America.

Ecological and biogeochemical studies

Information about inundation and wetland vegetation are essential for the understanding of carbon dynamics in the Amazon basin. By combining field measurements of carbon dioxide concentrations in surface waters with passive and active remote sensing of inundation, Richey et al. (2002) calculated the evasion (outgassing) of CO₂ from water to the atmosphere in the central Amazon basin. Similarly, by combining measurements of methane emission from a variety of habitats and sites with inundation and vegetation variations derived from microwave and optical remote sensing analyses, Melack et al. (2004) estimated methane emissions from the Amazon basin.

Variations in the distribution and inundation of floodplain habitats play a key role in the ecology and production of many commercially important freshwater fish. In a comparison of flooded areas estimated from a monthly series of passive microwave data (Sippel et al., 1998) with the annual fish yield aggregated from the Brazilian Amazon, Melack et al. (2009) found significant relationships for small species at lower trophic levels generally at short lag times (0–1 years), while those for large species at higher trophic levels had considerably longer lag times (3–5 years).

Summary

The principal advantages of the passive microwave observations are their frequent global coverage and their ability to reveal characteristics, such as inundation, of the land surface beneath cloud cover and vegetation.

Subject Index

- A**
- Absolute calibration, 47
 - Absorption, 492–495
 - atmospheric scatterers, 492
 - molecular absorption, 493–495
 - propagating electromagnetic wave, 492
 - Absorption bands, 692
 - Acoustic Doppler Current Profiler (ADCP), 1, 434
 - Acoustic radiation
 - dipoles, 2–4
 - echo sounders, 1
 - energy propagation and rays, 2
 - frequency audio spectrum, 1
 - monopoles, 2–4
 - pulsing sphere, 3
 - sound amplitude, 1
 - sound propagating, 1
 - wave equation, 2
 - Acoustic sounders, 719
 - Acoustic thermometry, 8–9
 - Acoustic tomography, ocean, 4–10
 - Acoustic Thermometry of Ocean Climate (ATOC), 8
 - Acoustic turbulent scattering, 15–16
 - Acoustic waves, 11–16
 - Doppler shift propagation, 12
 - reflection and refraction, 12–13
 - Lambert scattering, 14–15
 - rigid sphere, 14
 - turbulent scattering, 15–16
 - wave absorption, 12
 - Acousto-optical tunable filter (AOTF), 695
 - Active electro-optical instruments, 697–698
 - Active Microwave Instrument (AMI), 419, 699–701
 - Active remote sensing techniques, 574
 - Active sensors, 197
 - Advanced Baseline Imager (ABI), 809
 - Advanced Microwave Scanning Radiometer (AMSR), 63
 - Advanced Microwave Scanning Radiometer on NASA's Earth Observing System (AMSR-E), 282–283, 634, 736, 737, 823
 - Advanced Microwave Sounding Unit (AMSU), 69–70
 - Advanced Scatterometer (ASCAT), 534, 535
 - Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER)
 - Kliuchevskoi volcano, 892
 - land surface topography, 324
 - Mediterranean Sea, 436
 - Advanced Very High Resolution Radiometer (AVHRR)
 - aerosols, 17
 - land surface phenology (LSP), 886–887
 - Madden-Julian Oscillation (MJO), 356
 - surface radiative fluxes, 808
 - vegetation indices, 883
 - Advisory Committee on Commercial Remote Sensing (ACCRES), 81
 - Aerial photogrammetric techniques, 321
 - Aeronomy of Ice in the Mesosphere (AIM), 418
 - Aerosol Polarimetry Sensor (APS)
 - instrument, 666
 - Aerosol RObotic NETwork (AERONET), 18
 - Aerosols, 16–20, 660
 - Advanced Very High Resolution Radiometer (AVHRR), 17
 - Aerosol RObotic NETwork (AERONET), 18
 - Along Track Scanning Radiometer (ATSR), 17
 - climate and health impact, 16
 - elastic scattering, 498–501
 - environmental effects, 19
 - French Space Agency (CNES), 18
 - health and direct sampling applications, 18
 - human activities, 16
 - Moderate resolution Imaging Spectroradiometer (MODIS), 18
 - Multi-angle Imaging Spectroradiometer (MISR), 18
 - physical and chemical properties, 17
 - POLarization and Directionality of Earth's Reflectance (POLDER), 18
 - satellite observations, 18
 - solid/liquid particles, 16
 - Stratospheric Aerosol and Gas Experiment (SAGE) instruments, 17
 - surface-based sun photometry, 17
 - surface lidar networks, 18
 - Total Ozone Mapping Spectrometers (TOMS), 17
 - Agricultural expansion and abandonment, 20–22
 - Agriculture and remote sensing, 22–30
 - crop biomass, 27
 - crop ground cover, 27–28
 - crop nutrient status, 29
 - crop surfaces, 23
 - crop yield, 28
 - intercepted solar radiation, 27
 - leaf chlorophyll content, 26–27
 - leaf reflectance, 23
 - pests and potential stresses, 29–30
 - spectrophotometers, 23
 - Stefan-Boltzmann relationship, 23
 - thermal radiation, 28–29
 - vegetative indices (VIs), 23–26
 - Agulhas Current, 466–468
 - Airborne Multiangle SpectroPolarimetric Imager (AirMSPI), 665
 - Airborne Multi-Spectral Sunphoto-and Polarimeter (AMSSP), 664–665
 - Airborne observational platforms, 409–411
 - airborne radar platforms, 411
 - air sampling platforms, 411
 - cloud cover, 409
 - data systems, 411
 - manned aircraft, 409–410
 - mechanical vibration, 411
 - remote sensing aircraft, 410–411
 - thermal infrared channels, 411
 - unmanned aerial vehicles (UAVs), 410
 - Airborne Optical Spotlight System-Multispectral Polarimeter (AROSS-MSP), 665
 - Airborne Polarization and Directionality of Earth's Reflectances (AirPOLDER)
 - instrument, 664
 - Airborne radar platforms, 411
 - Airborne SAR system (AIRSAR), 52
 - Airborne sensors, 831–832
 - Air pollution, 32–34
 - Earth's atmosphere, 32
 - gases/particles concentration, 32
 - Interferometric Monitoring of Greenhouse Gases (IMG), 32
 - Measurement of Air Pollution from Satellites (MAPS) experiment, 32
 - Measurements of Pollution in the Troposphere (MOPITT) instrument, 32
 - NO₂, 33
 - SO₂, 33–34
 - Total Ozone Mapping Spectrometer (TOMS), 33
 - tropospheric CO, 33
 - tropospheric ozone, 33
 - Air sampling platforms, 411
 - Alaska Volcano Observatory (AVO), 890, 891
 - Albedo, 225, 226, 788, 806
 - Along-track interferometry (ATI), 426–428
 - Along-Track Scanning Radiometer (ATSR)–1, 659

- Alpha-derived emissivity (ADE) method, 309
 Alpha-residual method, 307–308
 Altimeters, 525–530, 700
 flight systems, 528
 ice-sheet radar altimetry, 528–529
 measurement precision, 527, 528
 mesoscale features, 526
 near-polar ice, 527
 oceanographic vs. geodetic orbits, 526–527
 orbit considerations, 529–530
 propagation delay corrections, 527
 pulse-limited geometry, 527, 528, 530
 satellite-based radar altimeter, 530–531
 sea-surface corrections, 527
 sea-surface height (SSH), 526
 significant wave height (SWH), 526
 Skylab, 525
 wind speed (WS), 526
 Amplified spontaneous emission (ASE), 168
 Amundsen Sea, 272
 Angular dependent model (ADM), 146
 Angular reflectances, 661
 Antarctica ice sheet
 Arctic-wide glacier recession, 269
 Circumpolar Current, 270
 Drake's Passage, 270, 271
 East and West Antarctica, 270
 Geoscience Laser Altimeter System (GLAS), 275
 global sea level, 269
 Gravity Recovery and Climate Experiment (GRACE), 275–276
 grounding line, 270
 ICESat, 275
 ice shelves, 270, 272
 Last Glacial Maximum, 270
 mass balance, 277–280
 passive-microwave radiometer, 274, 275
 radar altimeter, 274–275
 scatterometer, 274
 snowfall, 278
 surface elevation, 275, 276
 synthetic aperture radar (SAR), 274
 Transantarctic Mountains, 270
 West Antarctica ice sheet (WAIS), 272
 Antarctic ozone hole, 834
 Antarctic sea ice, 728
 Antenna effects, 46
 Antenna temperature, 383
 Anvil cloud, 768, 769
 Aperture blockage, 679
 Aperture field (AF) method, 668
 Aperture synthesis radiometry, 391–394, 699
 calibration, 394
 collection of N antennas, 392
 Corbella equation, 391, 393
 field of view, 393
 flat target transformation, 393–394
 historical development, 391
 polarimetry, 394
 radiometric sensitivity, 393
 spatial frequency sampling and aliases zones, 393
 spatial resolution, 391–393
 spatial windowing, 392–393
 Van Cittert–Zernike theorem, 392
 Appleton-Hartree formula, 286, 287
 Appleton-Hartree magnetoionic theory, 286–287
 Aquaculture, 207
 Aquarius/SAC-D mission, 752
 Arago, 663
 Arakawa C-grid, 448, 449
 Arctic region, 727
 Arctic-wide glacier recession, 269
 1999 Arctic Climate Observations Using Underwater Sound (ACOUS) experiments, 8
 Argo Project, 744
 ARGOS, 430, 432
 Asia-Pacific Satellite Data Exchange and Utilization Group (APSDEU), 263
 Atmospheric correction, 17
 Atmospheric Dynamics Mission (ADM)
 top-of-the-atmosphere radiation, 146
 tropospheric winds, 418
 Atmospheric general circulation models, 35–37
 climate prediction models, 36
 fluid dynamics and thermodynamics equations, 35
 model dynamics, 36
 model physics, 36–37
 weather prediction, 36
 Atmospheric motion vectors (AMVs), 849–850
 Atmospheric opacity, 558
 Atmospheric scattering, 854
 Atmospheric UV absorbers, 853–854
 Atmospheric water vapor, 755
 Austin Post aerial photograph, 104
 Autocorrelation spectrometers, 389–390
 Averaging kernel, 250
 AVHRR NDVI, 656
 Ayles Ice Shelf, on Ellesmere Island, Canada, 112, 281
 Azimuth processing, 537–538
 Azimuth resolution, 538, 544, 555
B
 Babinet, 663
 Backscatter calibration, 55–56
 Backscatter lidar, 697
 Backscatter ultraviolet (BUV) instrument, 861, 862
 Bare earth model, 323
 Baseline decorrelation, 540
 Basic Plan for Space Policy, 81
 Basic Space Law in 2008, 81
 Bathymetry Assessment System (BAS), 721
 Bayh-Dole Act of 1980, 490–491
 Beaufort gyre, 732
 Beijing case study, 869–876
 Bidirectional reflectance, 403–405
 Bidirectional reflectance distribution function (BRDF), 317, 619, 658, 789
 albedo, 788
 Lambert surface, 497
 reflected radiance, 497
 sea ice albedo, 722–723
 soil optical properties, 788
 Biomass, 214
 Bi-spectral methods, 641
 Blue Planet, 896
 Bookend vortices, 775
 Bootstrap algorithm, 109, 730–731
 Born approximation, 15
 Boundary conditions, 151
 Bow echo morphology, 771
 Bragg scattering, 15, 551
 Bragg's law, 224
 Brewer-Dobson circulation, 797
 Brewster, 663
 Brightness temperature, 730
 British Antarctic Survey, 112
 Bruggeman–Hanai–Sen mixing model, 399
C
Calanus finmarchicus, 207
 Calibration
 lidars, 698
 microwave radiometers, 46–47, 699
 optical/infrared passive sensors, 47–51
 scatterometers, 54–56
 synthetic aperture radars (SAR), 51–53
 Calibration and validation, 39–43
 climatic temporal context, 42
 Committee on Earth Observation Satellites (CEOS), 40
 geophysical products, 41
 international cooperation, 40
 NASA's Nimbus-7 satellite in 1978, 40
 prelaunch phase, 42
 remote sensing products, 39–40
 satellite remote sensing era, 40
 sensor products, 40–41
 spatial scaling, 41–42
 validation stage, 42–43
 CALIOP lidar, 72
 Canadian Space Agency Act of 1990, 81
 Canopy fuels, 213, 215
 Cassegrain reflector system, 677, 679
 Cassiopeia A, 582
 Catch per unit effort (CPUE), 202
 CHALLENGING Minisatellite Payload (CHAMP), 419
 Chimney clouds, 646
 Chlorophyll-a (Chl-a), 438–441
 Circular horn, 375, 376
 Circularly polarized wave, 579
 Circumpolar Current, 270
 Climate data records (CDR), 58
 Climate monitoring and prediction, 58–66
 CPC temperature probability product, 66
 ozone, 60–61
 precipitation, 61
 reanalysis data, 63–65
 remotely sensed observations, 59
 sea ice, 62–63
 seasonal climate forecasts, 65
 sea surface temperature, 63, 64
 statistical and dynamical prediction models, 65–66
 top of the atmosphere (TOA) radiation budget, 59–60
 vegetation, 61–62
 weather scales, 59
 Climate Prediction Center Merged Analysis of Precipitation (CMAP), 61, 647–649
 Clay soils, 802
 Cloud Absorption Radiometer (CAR), 659
 Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation (CALIPSO), 18, 336, 415, 416, 418, 689, 809
 Cloud condensation nuclei (CCN), 19
 Cloud Imaging and Particle Size Experiment (CIPS), 660
 Cloud indexing methods, 640–641
 Cloud liquid water, 68–70
